"Tempering" Notes. Presuming that the pupil is musically inclined, it may surprise him to be told that the foundation of the tuning of all our keyboard instruments is intentionally inaccurate. Let him look at the piano for a moment. Enharmonically, every white and every black note has two names, if not three. C natural serves also for B sharp and D double flat; C sharp is also D flat; D natural likewise is C double sharp or E double flat, and so on. Therefore, if we have twelve keys within an octave, we have to make them serve for upwards of twenty-four notes indicated in music. A very clever violinist with a sensitive ear, or a trombone player, because the tone of such instruments is not fixed, will play in what is called "just" intonation. On a pianoforte or church organ, the only intervals *absolutely* perfect with the pitch note are the octaves. The rest of the notes are "tempered." For the purposes of practical harmony, the notes within each octave have been so modified that the acoustical divisions between them have been made as equal as possible.

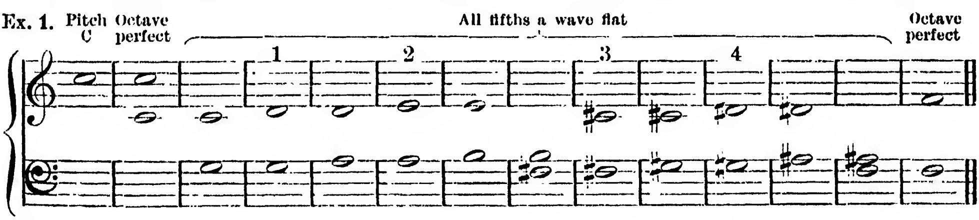
The ear of the musical student may at first rebel against the mutilation of any interval, but the system of modifying the notes within the centre octave internationally adopted is based on common-sense, and has been found the only possible solution of a problem which perplexed musicians for many years. Mathematicians, acousticians, musicians, and manufacturers have written libraries full of books on this subject. It is, therefore, a difficult one to deal with succinctly, and the reader is referred to Example 1.

After tuning the octave C, it will be seen that the student must proceed to G below. Tune the fourth perfect. Then from this G get the fifth above, D, "tempering" it by leaving it a beat flat. From the D tune the A below a perfect fourth. Then get the second fifth by tempering the E above a shade flat. Tune the B below a perfect fourth. From the B go down to the F sharp, and make that also a perfect fourth. Now get the third fifth by tuning C sharp a wave flat. Follow with the fourth below G sharp in just intonation, and then, from the G sharp, get the fourth fifth, or D sharp, a shade flat. Proceed to A sharp, a perfect fourth, and then get a fourth below the A sharp, technically E sharp but actually F natural, and, finally, tune the octave F above perfect.

Unless the "shading" has been distributed equally, the octave will not come out perfect, and to proceed any further with the tuning will only magnify the shortcomings of the bearings. Before equal temperament (advocated by the great composer Bach) was adopted, it was disagreeable, on account of the "howlings," to play the piano or organ in the "black keys"—now the most beautiful. As accurate "tempering" is an art which a beginner cannot learn immediately, his first attempt, when proved by the final octave, has, no doubt, revealed that his modifications of the fifths have been overdone. Let him, in going over the work again, therefore, check it in a different manner [Ex. 2].

Here the scheme includes all the keys on the piano between F natural (fourth space bass clef) and C (third space treble clef). But instead of four fifths presenting themselves, the student can check his work by eleven of them. After the low C, tune the G above a little flatter than perfect. Then prove this with the octave G below,

Ex. 1.



Ex. 2.

Ex. 3.

already tuned. From that G, get the second tempered fifth, or D above, and then the third, or A above the D. Now prove this note, which should be a perfect octave with the A below, already tuned. Go over the fourth fifth that now occurs, by checking the E already tuned under the first scheme. Now, get the B above, tempering this fifth fifth a wave flat, and from it prove the octave B below, already tuned.

Next get the sixth fifth, or F sharp above, and from that prove the F sharp below, already tuned. Check again the fifth above low F sharp, with the C sharp tuned according to Ex. **1**. Continue to get the eight fifth, or G sharp above, proving it with the octave note below, already tuned. Having arrived at the eight fifth of the series, the student must return to C. Tune the remaining fifths "backwards," first making the bottom note, F natural, a perfect fifth with the C, and then slightly sharpening it in the same degree that the upper notes were flattened when tuning the other fifths "forwards." By this means, the necessary tempering is done correctly, but the lower note is affected rather than the upper. Then, get the octave F above perfect. Treat the B flat below in the same way, so as to modify the lower note, and keep the upper one just. Get the octave B flat above, and, finally, tune the eleventh fifth, tempering the lower E flat. Of course, as we have first seen, it is not necessary to tune all these fifths in laying a scale, and there are other ways of checking correct equalisation than the scheme last referred to. As soon as the fifth marked "4" in Ex. **2** is reached, the C below gives the major third, and if this third is slightly sharper than perfect, it is an indication that, so far, the tuning is correct. In like manner, test each subsequent fifth by means of the triad [Ex. **3**].

Extending Operations. Upon the bearings laid the rest of the tuning is built up. The unisons, or two other strings, of each first one already tuned must be made to accord (altering the position of the wedge) until each group of three strings blends properly together in sound. This done, proceed to the octaves. Begin on C sharp (first ledger line beneath treble clef) and tune in succession one string of every octave note above until the extreme treble of the keyboard is reached.

All octaves must be "perfect." Then take the E below middle C, and tune each successive note in octaves down to the extreme bass. This done, go over the treble octaves again, as they are apt to fall in pitch as the tension increases on the lower part of the frame. Finally, try together double octaves, to see that all are accurate. Having adjusted all these notes on one string of each group of three, proceed to tune in unison the second and third string of every note. Taking these separately, adjusting the wedges as explained, get all unisons correctly above and below the central octave. To get increased brilliancy and fullness, some tuners pull the high notes a shade sharp, and leave the extreme bass a trifle flat. On completion of the work, clean the keys with a soft cloth slightly moistened with warm water, and replace the front.

Apprenticeship. In every large piano factory labour is much systematised, so that one instrument passes through many hands, each man being a specialist in his own branch. Particular attention is always given to the tuning department, because the best made piano in the world badly tuned will sound at a disadvantage beside one of inferior make finely tuned. But to take off experienced tuners to teach beginners deprives a factory of skilled labour, which has a definite value. Therefore, considering how difficult it is to find remunerative employment for many young men nowadays, the privilege of being taught the art of tuning is gladly paid for by parents when their sons are indentured as apprentices. To acquire the necessary flexibility of finger and perception of wave beats for good tuning, it is essential to begin in early youth when a lad is still growing. When the wrist is once set, it is seldom possible to make what is known as a fine tuner. The usual age for beginning is sixteen. Obtain an introduction to the manager of some well-known factory. If of good physique and character, the candidate's name is put down in the "waiting" list. Notice will be sent when a vacancy occurs. Preference is generally given to the sons of valued employes or good customers. Premiums vary from £5 upwards. Apprenticeship is usually for seven years.

Entering the Factory. The first work is to assist with odd jobs the qualified tuner who acts as instructor, when not employed in "chipping up." By keeping his eyes open, the young apprentice can learn much in a factory in many departments, as his work will not always be in the same shop. "Rough" tuning is generally done in the noisier departments where, in case-making, or marking off, there may be a good deal of hammering, and a subtropical atmosphere. As the lad improves in his work, he will be promoted to quieter regions, giving him an insight into hammer-covering, and ideas as to the latest method of polishing. After a certain length of useful service the beginner will receive a small weekly salary. According to ability to tune, this will rise gradually from 5s. to £1 a week.

When the term of apprenticeship expires, an ambitious young tuner will endeavour to get a few years outside experience. Vacant situations are announced in the various musical papers. Consult the foreman tuner, or factory manager, regarding the status of advertisers before accepting any offer. After an apprentice has done well, the manufacturer will usually be agreeable that he should seek to improve himself practically in some music shop, where he will come into contact with instruments by other makers, and learn to repair harmoniums, American organs, or piano-players in a way seldom possible in any one factory.

Concert Piano Tuning. The laudable ambition of many a young tuner is to do concert work. This, of course, demands the most artistic skill. Having gained outside experience and, subsequently, been received back on the staff of the firm where he was apprenticed, he will find, if the opportunity is given him, that concert tuning entails considerable responsibilities. It involves, during a tour, the constant packing and unpacking of a heavy iron grand, placing it in and removing it from various provincial halls, besides attending each performance after smoothing over the tuning of the instrument. At the concert it is the duty of the tuner to open and shut the piano before and after each solo, and turn over the music in concerted pieces. Yet it brings him into personal contact with some musician of distinction whose good word may be of considerable value. The weekly wage will probably be £2 2s., with an allowance for travelling and hotel expenses. A report should be made on each concert and sent by postcard to headquarters.

GERMANY

The Thirty Years War had a very bad effect both on the population and on the commerce of Germany—the population was much diminished, and the commerce destroyed for the time. The country was burdened with taxes, and the empire became divided into a number of small states whose rulers held tyrannical sway over their subjects. Leopold I., who succeeded in 1658, might have done much to restore peace and order in his empire, but he allowed himself to be drawn into a coalition against France. In his reign Strasbourg was added to the dominions of France. In 1705 he died, and was followed by Joseph I. and then by Charles VI., whose successive reigns lasted until 1740. These two kings were the last of the male sovereigns of the House of Hapsburg. During their reigns occurred the War of the Spanish Succession, which was ended by the Treaty of Utrecht.

Maria Theresa. On the death of Charles VI., in 1740, the succession was contested by his daughter, Maria Theresa, and her husband, Francis I. of Lorraine. Maria Theresa claimed the crown by right of the Pragmatic Sanction drawn up by her father in 1713. Charles VII., Elector of Bavaria, was, by the help of Prussia, elected to the Imperial throne in 1742, but was compelled to resign the crown three years later. Francis I. reigned from 1745 to 1765. The Seven Years War, which began in 1756, aggravated the troubles of his reign. His son, Joseph II., succeeded him, but was little more than a nominal ruler during the lifetime of his mother, Maria Theresa. Leopold II. reigned two years and was succeeded by his son, Francis II., who, after the Rheinish Confederation was formed under the protectorate of Napoleon the Great, resigned the German crown, and became Emperor of Austria in 1804.

The Struggle for German States. The history of Germany after the first Napoleon's career began to resolve itself mainly into a rivalry and a struggle between Prussia and Austria for the rulership of all the Germanic states and peoples. Prussia may be described as the rising power, and Austria as the power which had reached its zenith and was already beginning to show signs of decay. The interests of Prussia were entirely Germanic, but Austria exercised imperial sway over nations and states which were foreign to her, and were continually rising in revolt against her rule.

Prussia began to form alliances with the minor states of Germany, and against these alliances Austria issued more than one indignant protest. On January 2nd, 1861, the Prussian king, Frederick William IV., was succeeded by his brother, King William I., whose coronation was celebrated with great pomp at Konigsberg. Before this several attempts had been made to form a Germanic Confederation of which Austria, Prussia and all the minor states should form component parts, but nothing effective or enduring had come of these attempts, most of the smaller states feeling inclined to rank themselves on the side of Prussia, and to be distrustful of Austrian leadership.

Bismarck and Moltke. The Prussian king had as his leading Minister one of the greatest statesmen the modern world has seen—Count Otto von Bismarck, afterwards Prince Bismarck; he also had, as the commander of his armies, one of the greatest soldiers that the modern world has seen—Count von Moltke.

Bismarck was born in 1815. His long struggle with the Vatican, the "Kufturkampf," was a failure. He was known as the "Iron Chancellor" and "The Man of Blood and Iron," the latter phrase taken from a speech of his own.

The struggle between the two rival Powers kept growing, and all attempts to mediate between them or to settle the differences in any satisfactory and lasting form ended in failure. It at last became evident that only war could decide the question. Austria and Prussia had co-operated for the capture of the German Duchies of Schleswig and Holstein from Denmark, but this combined success only led to new disputes between the Powers thus in temporary alliance. On June 15th, 1866, Prussia declared war against Austria, and on July 3rd, 1866, was fought the great battle of Sadowa, which may be said to have marked the close of the contest, a contest in which Austria had suffered nothing but losses, resulting in her absolute exclusion from Germany.

Prussia's Development. One immediate effect of Prussia's victories was to create in her a military power which seemed seriously to threaten the domination of the French Empire under Napoleon III., and in consequence, on July 15th, 1870, Louis Napoleon, acting, it is believed under the advice of unwise counsellors and contrary to his own personal inclinations, declared war against Prussia. The result of this policy was the complete overthrow of the French armies in that memorable struggle, which, when the French had suffered defeat after defeat, and the crowning defeat at Sedan, ended in the capture of Paris itself on January 28th, 1871, and the proclamation at Versailles of King William as German Emperor. From that time the Kingdom of Prussia has lived as the German Empire, including under its sway, or as its allies and fellow-workers, most of the other Germanic

states, Austria being entirely excluded from cohesion with Germany. Since that time Prussia has engaged in no war, and, although she has had to undergo many grave political and religious struggles within her own sphere, she has been occupied only with the interests of the German Empire. William I. died on March 9th, 1888, and was succeeded by his son, Frederick III., who died June 15th, 1888, and was followed by the present Emperor, William II.

NORWAY AND SWEDEN

As Charles XII. of Norway left no heir, the crown went to his sister Ulrica and her consort, Frederick of Hesse, who was crowned in 1720. Next came Adolphus Frederick, who reigned until 1770. In his reign the nobles were divided into two parties—the "Caps," who were the peace party, and the "Hats," the war party.

Gustavus came to the throne in 1771, and abolished the Council of State and restored the Constitution. He was assassinated, and his successor, Gustavus IV., was dethroned, and during some of the wonderful changes caused in Europe by the career of Napoleon, Bernadotte, one of his generals, was elected to the throne of Sweden as Charles XIV. He had to resist the efforts of his old commander, Napoleon, to obtain complete power over Sweden, and he won for himself the character of a sagacious ruler animated by the best intentions for the good of the country over which he had so unexpectedly come to reign. Sweden joined the Grand Alliance against Napoleon in 1813.

It is not necessary to give a list of the sovereigns who governed Sweden and Norway under the new constitutional arrangements; the kingdoms were prosperous and for the most part peaceful. There were many Arctic expeditions, and many institutions were formed for the preservation of Sweden's older literature and for the promotion of culture. These systems were successful in causing the spread of popular education. Continual difficulties and troubles arose, however, from the efforts of the Norwegians to obtain a satisfactory constitution of their own, and these ended at last in a friendly separation which gave to Norway a separate government and even a separate king, while the two kingdoms still remained in friendly and peaceful association.

Separation of the Kingdoms. On June 7th, 1905, the Norwegian Parliament decided on a final separation from Sweden. It was felt that this resolve of the Parliament should be submitted to a popular vote, so on August 13th the voters endorsed the resolve by a plebiscite, giving a majority of 368,208 for the separation against only 184 votes for the retention of the existing union. On September 23rd the Swedish and Norwegian delegates met in conference and agreed to the terms of the separation. Amongst the conditions were a neutral zone on both sides of the southern border between the two kingdoms, and the dismantling of certain fortresses. On November 18th Prince Charles of Denmark was elected King of Norway, and assumed the title of Haakon II.

DENMARK

The later history of Denmark tells of many struggles and yet of much substantial progress. In 1665 the sovereign was made absolute and hereditary, and early in the following century Frederick IV. added to his dominions the Duchies of Holstein and Schleswig. Denmark became engaged in war with England during the convulsive period following the French Revolution, and its capital, Copenhagen, was bombarded by Lord Nelson in 1801 and by Admiral Gambier and Lord Cathcart in 1807, when the whole Danish fleet was compelled to surrender. Frederick VII., who succeeded in 1848, proclaimed a new constitution, by virtue of which he endeavoured to unite Schleswig and Holstein more closely with Denmark, and thus to absorb or extinguish their nationality. The immediate result was an insurrection in the Duchies and the formation of a provisional government. The forces of the Duchies were defeated, although the Prussians lent them some assistance. The European Powers recommended the making of peace, but hostilities went on, with success now on this side and now on that, but with nothing decisive either way. A new and somewhat liberal constitution for Denmark was sanctioned by the King and Parliament in 1849, and peace was made in 1850. On March 10th, 1863, the Princess Alexandra of Denmark was married to the Prince of Wales, the present King of England.

The Fate of Schleswig-Holstein. The Schleswig-Holstein question was now coming to a crisis. Schleswig, Holstein, and Lauenberg were entirely German in their populations, and were held by the King of Denmark as Duke of Lauenberg in the old Germanic Federation, while Schleswig was more directly attached to the Danish Sovereignty, though there was a large German population, especially in the Southern districts. The whole German people were concerned in the question, and could not endure that their countrymen should be under the rule of a Danish sovereign. Frederick VII. of Denmark had no direct heir, so the succession had already been arranged by the great European Powers by the Treaty of London in 1852, which declared Prince Christian of Schleswig-Holstein heir to the crown, with the title of King Christian IX. His claim, however, was disputed on the death of King Frederick VII. in 1863, by the Duke of Augustenburg, who took the title of Duke Frederick VIII. of Schleswig-Holstein. Count Bismarck, who was then the ruling statesman in Prussia, determined that the Duchies should be annexed to Prussia, and the dispute about the succession gave him his opportunity.

The War with Austria and Prussia. The Germanic Federation entrusted the conduct of the dispute to the combined powers of Austria and Prussia, and the Danish Government had a strong hope that England would come to their aid. Lord John Russell, then Prime Minister, had often told the Danish Government that they must, if only for their own interests, deal justly with their German subjects. He

had never sanctioned the policy which strove to bring the Germanic peoples into absolute subjection to Denmark, and he had made it clear that if Denmark did not take England's advice, England would not come to her aid in the event of war. In the war which ensued Denmark had to fight against Austria and Prussia. The Danes fought bravely, but they were utterly outnumbered, and their old-fashioned weapons were of little use against the needle-gun, the new weapon of their opponents. The Danes gained one victory over some Austrian warships in the German Ocean, but they lost all their fortresses, and their defeat soon became certain, even to themselves. Denmark, after some futile negotiations, had to accept terms of peace and to give up the Duchies to Austria and Prussia. By the Peace of Vienna in 1864 the King of Denmark resigned the Duchies to the Allies, consented to a rectification of his frontier, and agreed to pay a large sum of money towards the cost of the war.

The remainder of Denmark's history has few international interests. The Danes are a people of great intelligence and culture, and have given many famous names to literature, the arts, and sciences, among whom we can only mention Hans Christian Andersen, the famous writer, and Thorwaldsen, the great sculptor.

TURKEY

The advance of the Mongols to Khorasan drove the inhabitants, called the clan of the Oghuz, to Armenia, where they helped the ruler to repel the Mongol invasion, and, in return, he gave them land in Asia Minor near the Province of Bithynia. The Ottoman Empire began in Sugut, the city where their leader settled in the thirteenth century. Ertughrul—this was the name of the leader—has been followed by thirty-five descendants, Sultans of the Ottoman Empire. Sugut was the birthplace of Osman, from whom comes the name Osmanlis, now generally called in Europe, Ottoman. Osman and his son added much territory by conquest to their dominions.

In the time of peace which followed some of these wars of conquest, the Ottoman ruler organised the state and formed a standing army—the first, it is said, in modern history—the corps called the Janizaries, which became so powerful later on as to be an important element in the state. Murad I., the first "Amurath," who came to the throne in 1359, added Adrianople and Philippopolis to the dominions of Turkey, and in 1364 defeated the Servians and the Hungarians. He had many wars with the Christians, who tried in vain to resist him. In 1389, the Turks won a great victory, in the Battle of Kosovo, over a large army led by Lazerus the Servian, but Murad I. was assassinated in the same year.

The next important event in the history of the Ottoman Power was the invasion of the famous Tamerlane, which stayed for a time the wave of Ottoman success. The Tartars defeated the Turks, and took the Sultan prisoner in 1402, and the conquering days of the Ottomans seemed to have come to an end, but, under Mohammed I., called "the Restorer," its greatness revived. He transferred the capital of his country from Asia to Adrianople in Europe. In the reign of Murad II., the great Hungarian General, Hunyady, known as the "White Knight of Wallachia," was the most formidable opponent of the Turks; he defeated them in two battles, in 1442 and 1443, and compelled them to make a treaty of peace for ten years, to free Servia, and to cede Wallachia to Hungary. Notwithstanding the treaty, Hunyady invaded Turkey soon after, but the Christians were defeated by the Turks at Varna in 1444, and the King of Poland was killed.

The Siege of Constantinople. Mohammed "the Conqueror" reigned for thirty years, and in his reign occurred the siege and capture of Constantinople, one of the most important events in Turkish history. This was in 1453. Another event was the defence of Belgrade, three years later, by Hunyady and John Capistran. The Ottoman Power annexed Greece and most of the Isles of Greece, and also the Crimea in 1475, and Otranto in Italy in 1480. In 1481, Mohammed died whilst about to start on fresh conquests, and was succeeded by his son, whose reign was uneventful. With Selim I. began another epoch of Turkish conquests; he defeated the Shah of Persia in a great battle, and captured much of his territory. He also annexed Syria, and took Egypt from the Mameluks in 1517. But the reign of his son, Suliman, "the Magnificent," is perhaps the greatest epoch in Turkish history. In the forty-six years of his rule he conquered Belgrade and the Island of Rhodes. He defeated the Hungarians in a great battle, in which their king and most of his army were killed, and made Hungary part of the Ottoman dominions for 150 years. He also laid siege to Vienna, but was unsuccessful, and in 1533 made a truce with the Emperor, Charles V.

Battle of Lepanto. Suliman died in 1566. The next reign saw the famous Battle of Lepanto, in 1571, and also the first war between the Turks and the Russians, in which the Turks were unsuccessful.

It is not necessary to give a list of all the Ottoman sovereigns who followed; their reigns saw many wars with Persia, with Austria, with the Venetians, and with other European powers, in which Turkey was sometimes victorious. But her greatest days were over. In 1686, the Turks, undeterred by previous failure, again laid siege to Vienna, and were utterly defeated by Duke Charles of Lorraine and John Sobieski, the King of Poland. The Austrians afterwards took Hungary. Ahmed III., who succeeded in 1703, was the Sultan who refused to hand over Charles XII. of Sweden to the Russians after the Battle of Poltowa, in consequence of which Peter the Great invaded Moldavia; but he was so unsuccessful that he would have become a prisoner of the Turks but for the intervention of his Queen, afterwards Catherine I.

Later on in the century, however, Russia began to be successful in her wars with Turkey, and after many wars, in which the

Russians were generally victorious, the Treaty of Kuchuk Kainarji was made in 1774. But notwithstanding this treaty, the Russians, nine years later, took possession of the Crimea and the country to the east as far as the Caspian Sea. The wars continued through some years of the reign of Selim III., but occurrences in Western Europe soon made the Russians wish to end the war, and a treaty of peace between the two countries was signed at Yassy in January, 1792, which confirmed the former treaty of Kainarji. By the peace which was now secured the Sultan was able to turn his attention to reforms in his own dominions. But, like many reformers who are in advance of the popular opinions of their time, his projected improvements were too much for his subjects, and brought about his dethronement and his death. After the short reign of his successor, Mahmud II. came to the throne, and in his reign occurred the War of Greek Independence. At that epoch began again the history of Greece, of which there is nothing to relate from the time when she came under the dominion of the Ottoman power until she regained her freedom in the year 1821—a year made for ever famous by that event.

GREECE

Greece had for many centuries ceased to be known as a distinct nationality. During the later of these centuries she was entirely under the barbaric rule of the Turks. Yet throughout that long period of subjection, and of what often seemed to be utter national extinction, the Greeks never became absorbed into the dominion, the kinship, or the ambitions of the ruling race. The Greek, when he had to make a living, took service wherever he could get it, but he still remained a Greek. The Turks had made themselves odious to the civilised world, and early in the last century it became evident that Greece would take advantage of Turkey's troubles with foreign states to strive for her national independence.

The Greek War of Independence. In March, 1821, Prince Alexander uplifted the national standard, and soon after that the War of Independence actually began. The Greeks won many victories, and captured the famous town of Missolonghi in November, 1821, after a long siege. On January 27th, 1822, their independence was proclaimed. The Greeks also won a great victory on July 13th, 1823, at Thermopylæ, a fitting scene indeed for the patriotism and the warlike genius of Greece once again to assert themselves. Lord Byron arrived in Greece in the August following, devoting his life to the cause of her freedom. He died of fever, however, not very long after, at Missolonghi. On October 12th, 1824, Greece set up her Provisional Government. The Turks meanwhile won several victories, chiefly under the leadership of Ibrahim Pasha, who for a time recaptured Missolonghi. One of the most brilliant of the Greek soldier patriots was Marcos Bozaris, who won several victories for the Greeks, and died on the field in an attack on the Turkish army.

Intervention of the Powers. The sympathy of Europe was almost universally with Greece, and a treaty was signed at London on July 6th, 1827, between Great Britain, France, and Russia for the defence of Greece. The result of this united movement was the complete defeat of the Turks, and by the Treaty of Adrianople, signed on September 14th, 1829, the Ottoman power acknowledged the independence of Greece. Greece became a kingdom under the protection of Great Britain, France, and Russia.

The crown of the new kingdom was offered to Prince Leopold of Saxe-Coburg, but was refused by him on the ground that the boundaries of the new kingdom did not include the whole Greek nationality, and especially excluded the Island of Crete. The crown was then offered to, and accepted by, King Otto of Bavaria, who was made King by a Convention signed May 7th, 1832, and he assumed government on June 1st, 1833. He proved a despotic ruler, and had to leave Greece in 1861, and a son of the King of Denmark was made King with the title of King George I. The new king was born in 1845, and at the time of his becoming king the Ionian Islands were restored to Greece. King George I. was unpopular for a time because of his unwillingness to go to war with Turkey, which the Greeks, as a whole, wished to do. But during his reign the condition of Greece was prosperous, notwithstanding political and financial troubles, until the time of the disastrous war with Turkey in 1896.

The Greece of the Present Day. The constitution of Greece places the executive power in the hands of the King and his Ministers, and entrusts the legislative power to a single representative chamber elected by manhood suffrage for a period of four years. Greece has since been on the whole a prosperous and progressive country, although the fact that so much of Greek soil and so many Greek populations were still cut off from her became the occasion of many struggles against Turkey. The Island of Crete was by the protecting Powers released from the baneful control of Turkish rule and placed under the control of a High Commissioner, at present Prince George of Greece, assisted by his councillors and a representative assembly. There is a strong demand among the Greeks of the Kingdom and of the island alike that Crete shall be allowed to became an integral part of the kingdom, and there cannot be much doubt that this national demand will before long have to receive complete satisfaction. Greece is a country in which education is widely spread. The intelligence of the people displays itself in agriculture, in trade and commerce, in literature, in arts, and in political life.

Continued

SAW DETAILS

Varieties of Saw Teeth. Drunken Saws. Tension of Saws. Saw Guards. Planing, Jointing, and Thicknessing Machines

Continued from page 6360

By FRED HORNER

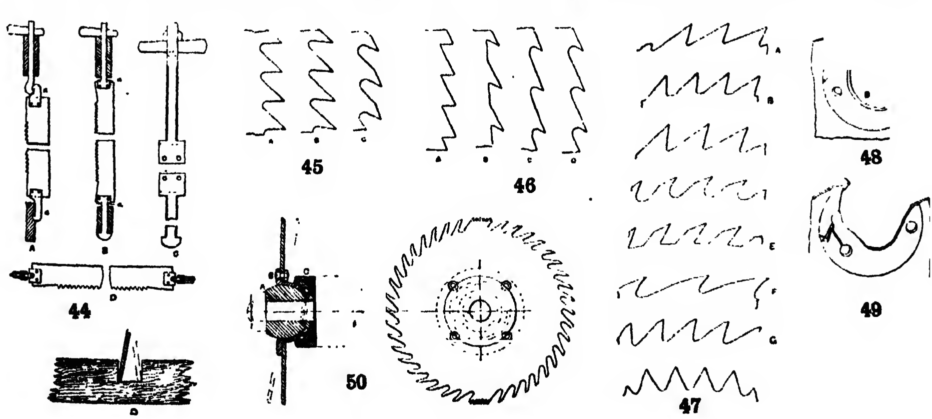
DEVOTING now a brief space to the consideration of the saws which are used in the various machines hitherto described, we begin with the frame-saws. The types employed in the log and deal frames [**44**, A and B] are long flat blades, or *webs*, to which are riveted *buckles* [*a*] held at the bottom end of the swing frame by a hooked portion, or by a head, and strained up in the top by *tillers* and cotters. Enlarged views of the buckles and cotter are given in C. The horizontal board-cutting machines have saws like D, attached and strained with buckles and screws tightened up with nuts.

The shapes of the teeth for such saws are shown in **45**, A and B being triangular, with a moderate amount of radius at the roots, C, with a *gullet* tooth, while the horizontal machines use webs with double sets of teeth, placed in reverse fashion, D, to cut in both directions alternately.

Band-saws. Band-saws are necessarily very flexible, to lap around the pulleys, and endure the constant bendings and straightenings which go on, and the temper must be uniform throughout the blade, in order to avoid cracks and breakages. The sizes range from ⅛ in. to 16 in. wide. The most common shape of tooth is that at A in **46**, while other shapes are shown at B, C, and D, with a greater amount of radius at the roots. The pitch or distance apart of the tooth-points is greatly varied, according to the size of the saw and the class of work which it has to do. Thus an ⅛-in. blade will have nine teeth to the inch, ¼-in. six, 1-in. three, and so on. The blades are made in lengths from which bands of suitable size are prepared, by brazing the ends together. A *scarf* joint is formed by filing down each end for a little distance, so that when the ends are lapped over each other the combined thickness is equal to that of the rest of the blade. Brass or silver solder is used, in the form of sheet, wire, or filings. The silver solder has the advantage of melting at a lower temperature than brass, although its cost is greater. After scarfing, the ends of the saw are placed in special screw clamps, which retain the blade in correct position, with the back in line. Powdered borax paste is applied to the joint, and the solder put in place. On the application of heat the solder fuses, and the joint being pressed together, a union results. Iron wire is usually bound round the ends to keep them together until set. The method of applying heat varies. Sometimes a special pair of thick tongs is made hot and pressed over the joint, or an oil-flame is used in conjunction with a blowpipe. There are also brazing machines, constructed with a hearth beneath the clamps, so that a charcoal fire can be lit to play around the joint. The superfluous solder is subsequently cleaned off with a file, to make the blade thickness uniform.

Tension of a Band-saw. The *tension* of a band-saw blade relates to a certain slackness of the centre, produced by a hammer, or by rolls, the effect of which is to cause the blade to bear on the pulleys with its outer edges, and not in the middle plane. The tension is produced by working about the central plane, or reduced by working along near the edges. The amount of tension varies for different saws, and the makers provide tension gauges, of certain set curvatures, by which to test the tension. Twists and lumps in the blade are tested by applying a short straightedge, while the saw lies on a levelling-table, and are eradicated by light blows with hammers.

Another point is that, to run properly, the back of the saw must be perfectly straight. A long straightedge is applied to test the accuracy or otherwise, and the matter put right by hammering or by rolling. Should the back be concave, the surface is worked over near the back with a series of blows extending to the central portion; if convex, the



SAW TEETH

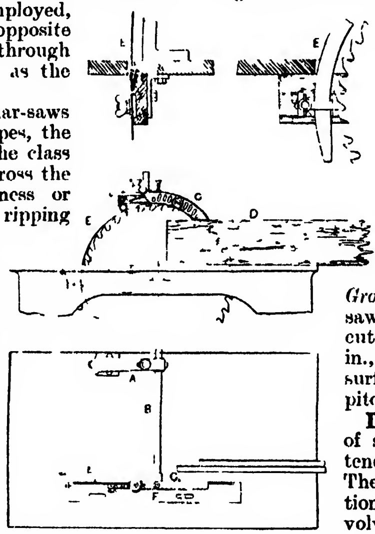
hammering must be done near the toothed edge. The necessary side clearance of a band-saw blade in the timber is obtained either by forcibly setting over each tooth alternately to right and left, so that the resulting cut is wider than the blade itself, this being termed *spring set*, or by *swaging* the points of the teeth—that is, applying pressure to the front of the teeth, so spreading them sufficiently to clear the blade in the cut. This is the *swage set*. The latter is not quite so smooth cutting as the spring set, but operates quickly. Swaging is effected by an appliance fitting over the blade and forcing hardened dies against the tooth faces. Spring setting is performed by side pressure, or by blows, which force the teeth over to an exactly uniform extent all along. The simplest sets comprise a block and a punch, which is struck with a hammer, to drive the teeth into a recess in the block. Other hand sets are constructed something like pliers, with an anvil, against which the teeth are forced by a plunger, brought into action by squeezing the handles of the tool together. Where a sufficient run of work is certain, a machine of automatic character is employed, having steel hammers on opposite sides of the saw, which is fed through by a ratchet or other device as the teeth are set.

Circular Saws. Circular-saws have teeth of very diverse types, the shapes of which depend upon the class of cutting, whether with or across the grain, and the relative hardness or softness of the timber. For ripping soft woods, the teeth are spaced widely, and are formed more acutely than for the harder varieties. Figure **47** illustrates some of the commoner shapes of circular-saw teeth in use. A, B and C are triangular teeth, with more or less rake, for softer woods; D has gulleted teeth, which afford great freedom for the sawdust. Two other shapes for ripping are shown at E and F. G is for ripping hard wood, the rake being lessened accordingly. Cross-cutting requires a different form of teeth, because, instead of passing down and forcing the fibres asunder, as with ripping, the saw has to sever the fibres at right angles, which imposes much more resistance. The shape of tooth is that of an equilateral triangle, called a *peg* tooth, H, and it is bevelled to produce a keen edge, each tooth having the bevel facing in an opposite direction to that of the adjacent tooth. There is no hard and fast rule for the use of the peg-tooth, since some of the other previous shapes of teeth, notably D, are used freely for cross-cutting in the soft woods, but they are limited to these woods.

Inserted Teeth. The Americans have developed a class of circular-saws with *inserted* teeth, which are used largely for diameters above about twelve inches. The advantages claimed are that a better class of tooth can be produced, as regards temper and clearance, than when the teeth are formed out of the solid plate, and also that in the event of nails or spikes being encountered in the timber, the damage to the saw is far less, because at the worst a few teeth are broken off or torn out without damaging the plate, and can be quickly replaced with new ones. But a solid-tooth saw under the same circumstances may have several teeth broken out, necessitating the reduction of the entire diameter to bring it down sufficiently to make a new set of teeth all around. The fitting in of the tooth is effected by vee edges, which prevent lateral movement, and the actual cutting portion or *bit* [A, **48**] is secured by a *shank*, B, the two wedging together firmly when slipped into place by the help of a special wrench, having a pin fitting in the hole in B. The shank is split in some cases to produce a decided spring, to retain the parts in place [**49**].

Special Saws. *Ground-off*, or *bevelled*, or *swaged* saws are tapered off in thickness from the centre to the edge, which may be very thin, while still leaving the body stiff. The grinding-off is done only on one side. The result of thinning the saw thus is to save wood in the kerf, and to enable fine sawing to be done, so that these ground-offs are very suitable for fine cabinet and box-work. The teeth of swaged saws are pitched rather closely together, and are smaller than those of ordinary, or *plate* circular saws.

Hollow-ground saws are a class which work without set, the clearance being provided by grinding each face tapering from the teeth to near the centre, where a parallel portion is left for the spindle collars to grip. As the teeth are wider than the blade behind them, there is no side friction. These saws make a very smooth cut, and are used for the finer classes of work, including mitre cutting. *Grooving* saws are hollow-ground saws, made of definite thicknesses to cut grooves, ranging from ⅛ in. to 1 in., or more. They leave a very smooth surface. The teeth are coarsely pitched for good clearance.

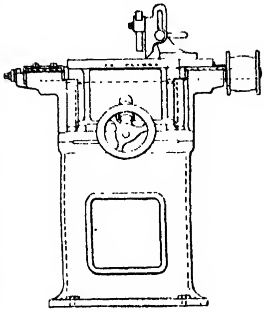


51. CIRCULAR SAW GUARD

Drunken Saws. Another class of saw employed to cut grooves or tenons is the *drunken* or *wobble* saw. The blade is held in an oblique position, so that it wobbles while revolving, or alternately travels from one side to another, so that when fed into the wood a slot is cut out. Bevelled washers are employed in some fittings to cant the saw. Figure **50** illustrates a saw by Carron Company, Carron, Stirlingshire, which has a ball centre, A, upon which the saw, bolted to a socket, B, embracing the ball, may be moved to give any required inclination within its range. B has a stud fitting in an inclined groove cut inside in the surface of a washer, C. The whole arrangement is firmly clamped by the nut, shown dotted, at the end of the spindle, and the saw cannot alter its angle until this nut is slackened. The saw-blade, shown in place, is a type much used for grooving, differing from ordinary ones in having a couple of sets of *cleaning* teeth which ensure a smooth surface. The diagram at D shows the action of the drunken blade in a groove. The saws are usually made in a range of sizes from 7 in. to 16 in. diameter, cutting slots of from ⅛ in. to 1¼ in., and from $\frac{3}{16}$ in. to 4 in. respectively. By putting oval or elliptical blades on, round bottomed grooves may be cut.

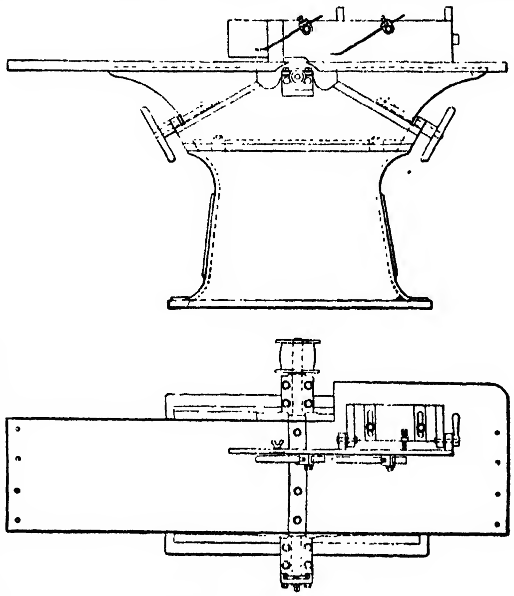
A few other special saws may be mentioned, such as the *segmental* types, which have their blades

built up of radial segments mounted on a central boss, by which device a thinner edge can be obtained than by using a solid plate. These are used for thin re-sawing work, and for veneers. *Concave* saws are dished to form the envelope of a sphere, and are employed in cutting curved pieces, such as for wheel felloes and barrel parts. *Cylinder* saws, which are in the form of a large tube, with teeth on one end, saw out barrel staves to the correct curvature on one side.



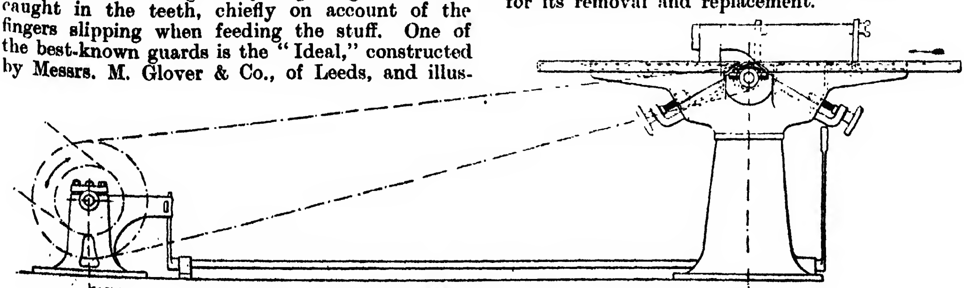
Tension and Packing. The *hammering* of a circular saw is done to bring it into a proper condition for true running; there may be tightness or *tension* at the rim, or near the centre, according to the manner in which the hammering is done. The apparent rigidity of a saw plate disappears as it attains a high speed, and it becomes limp and pliable and is very susceptible to lateral pressure. There is a certain critical speed for every saw, at which it will run true, if hammered accordingly, but if the speed is altered, or the saw becomes reduced in diameter through repeated sharpenings, in the course of time, re-hammering is required. Another feature of great importance is the *packing*, which usually consists of hemp, plaited, and packed in on each side of the plate, being supported by boxes or strips underneath the table. The object is to support the saw laterally and enable it to stand up to the work without running out of truth, which it would do on encountering variations in the timber. There is another effect, that of imparting a certain amount of warmth to the saw plate, regulating the tension, and preventing buckling. The running of the saw can be controlled by packing harder or softer. Thus a saw that is "loose" on the rim may be made to run properly by packing rather tighter near the centre than towards the periphery, so that the central area is warmed up, and so the metal expands more, pressing on the rim portion, and checking the unsteadiness. The packing is lubricated by some class of rather thin oil.

Saw Guards. The question of a provision of a *guard* to a circular saw has to be considered; it is a very dangerous tool, and many accidents have occurred through sawyers getting their hands caught in the teeth, chiefly on account of the fingers slipping when feeding the stuff. One of the best-known guards is the "Ideal," constructed by Messrs. M. Glover & Co., of Leeds, and illustrated in **51**. It is so made that the saw is completely protected, no matter what the height of the wood being sawn. The device comprises a bracket, A, bolted at the back of the saw-bench, and supporting a steel shaft, B, centrally above the saw spindle, by means of another vertical shaft, in order that the guard may be altered to suit differing



52. HAND PLANER

diameters of saws. The actual guard or hood, C, cast in brass, and perforated to let the sawyer see the line of teeth, is hinged, so that it falls automatically down on to the timber, D, and leaves no portion of the teeth exposed. The rear portion of the saw is guarded by a *back knife*, E, slightly thinner than the saw, and attached by a sliding clamp beneath the bench [see the enlarged detail], and above to the hood-holder. This back, or *riving* knife prevents the sawyer from getting his fingers into contact with the teeth, and also obviates the danger of stray pieces of wood touching the back, and being thrown up by the teeth with great force into his face. E is the loose *finger-plate* (not previously referred to) with which saw-benches are provided, to enable the saw to be removed, and to the underside of which one of the packing-strips is attached. A couple of slots in the finger-plate enable the operators' fingers to be inserted for its removal and replacement.



53. HAND PLANER, SHOWING COUNTERSHAFT DRIVE

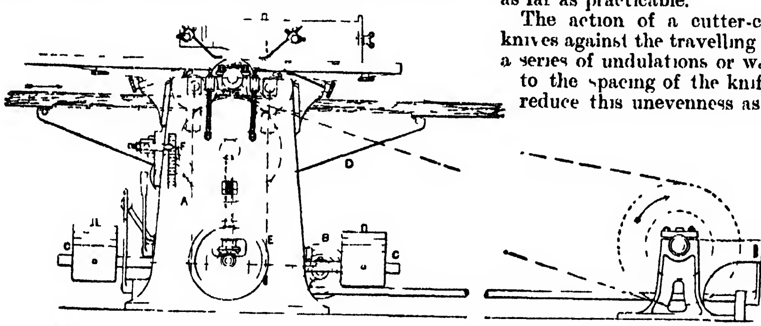
Planing Machines. The *planing* machines constitute a large group, which operate by *cutters* or *knives*, either revolving or fixed. They true up narrow or broad surfaces, cutting on one or on several sides of the timber, and have hand or power feeds. The simplest class of planer is that represented in **52** (Messrs. John Sutcliffe & Son, Ltd., Halifax), termed a *hand* or *overhand*, or in America a *buzz*-planer. The frame carries bearings for a revolving spindle, which holds two or three long cutters revolving at a high speed, the spindle being driven from the belt pulley at one end. The timber is passed over the two tables projecting out at each end, and adjustable vertically upon sloping ways by screws and hand wheels. The fence on the right-hand table guides the wood in a straight line, and can be canted over for angular work. The two curved springs passing down the front keep the timber upon the table. In operation, the right-hand table is set lower than the left-hand one by the amount necessary for the cut, and the workman, standing alongside this right hand table, passes the wood over it and the cutter spindle until the other table receives it. The machine is often termed a *jointer*, because one of its principal functions is that of preparing edges for gluing together. Planing out-of-wind, surfacing, chamfering, rebating, etc., can be done also, or by putting in special cutter-blocks, mouldings and tongues and grooves can be produced. The machine shown will plane to width of 16 in., the spindle makes 800 revolutions a minute, and about 3 B.H.P. is required for driving.

The illustration [**53**], showing a similar class of hand planer and jointer, by Messrs. John McDowall & Sons, Johnstone, includes also the driving arrangements. A countershaft is placed on the floor, and carries one pulley which is driven from the line shaft and another belted to the planer-pulley. The belt is shifted from the one fixed pulley on the countershaft to another loose one adjacent, the striking gear being connected by a long rod to a handle at the end of the planer, so that the operator has complete control without moving away. The tables in both of these machines are fitted with adjustable upper slides, which can be drawn back sufficiently to allow of extra overhang of grooving or other cutters.

These planers are sometimes adapted to the requirements of wheelwrights by fitting curved guides at the front, to pass felloes over an extension of the cutter-block, and so to plane the inside to a regular curve. A boring and mortising attachment is also included when desired; it is fitted similarly to that mentioned previously in connection with circular-saw benches.

The hand planer is one of the most dangerous machines to operate, because the knives revolve between the lips of the tables, and the attendant's fingers are very liable to slip into the opening and become mangled. The safest class of work is that of shooting the edges of boards, in which case the hands are raised up to a considerable height from the knives. A safety guard, as applied to such planers, comprises a bridge spanning over the opening, its height being variable to suit the thickness of wood being planed, so that there is no chance of the workman's hands touching the cutters. If thin boards, etc., are being surfaced, the guard reaches across to the fence; but if edges are being planed, the guard is drawn away from the fence sufficiently to let the stuff pass, leaving the rest of the gap covered. The opening between the tables is made as narrow as possible in most machines by screwing thin tapered steel lips on to the table edges, projecting over the cutter-block as far as practicable.

The action of a cutter-cylinder, revolving the knives against the travelling wood, tends to produce a series of undulations or waves, which correspond to the spacing of the knife strokes. In order to reduce this unevenness as much as possible, the diameter of the cutting circle must be small, and the speed of rotation high, while steadiness of running is essential also. The last-named feature can only be secured by accurate balancing of the cutters and well-fitting bearings. The latter are made very long, and have adjustments for taking up wear.



54. 15 IN. × 7½ IN. SURFACE PLANING AND THICKNESSING MACHINE

Surfacing and Thicknessing Machine. An advance on these machines is the combined surface planer and *thicknessing* machine [**54**], which has a power-feed by rollers, passing the timber through between the rollers and the cutters, and reducing it to an even thickness. One side of the stuff is previously trued upon the surfacer. The upper portion of the machine in **54** (also by Messrs. McDowall) is formed like the preceding one; the arrangements for thicknessing include four serrated rollers, lying to right and left of the spindle, and passing the stuff between them, the upper rollers being positively driven by spur gears (the dotted circles of which are indicated), deriving various rates of speed from cone pulleys at A and B. Heavy adjustable weights at CC press upon levers which pull down the top rollers and enable them to get a bite on the wood. The table, D, supporting the latter, is raised or lowered by a vertical screw, operated by the hand wheel, E, and an index scale at F shows the thickness being planed. The arrows show the directions in which hand and power feed are given, these necessarily being in opposite directions, on account of working above and below the cutter-block respectively.

WELDING AND SOLDERING

Continued from page 6314

Welding Various Metals. Autogenous Welding. Air-hydrogen, Oxy-hydrogen, and Oxy-acetylene Blowpipes. The Use of Thermit. Hard and Soft Solders

In the manipulation of metals it is essential that there should be simple and efficient methods of uniting two pieces of the same or different metals, and there are many processes for making such unions. The ideal method is by *welding*—that is, by fusing, or almost fusing, the edges of the metals to be united, usually by the heat of a coke fire, and by hammering the edges until the opposing surfaces become merged into each other, making a homogeneous and strong union. In making a weld—with two pieces of wrought iron, for instance—the finished work may be as strong as if it had originally been rolled in one piece; and if a subsequent rupture takes place, it is as likely to be at some other spot as at the weld. But many metals—such as cast iron, many steels, zinc, brass, etc.—cannot be welded by the simple process described, and some cannot be welded at all. In cases where the temperature of the coal or coke fire cannot raise the metal to a temperature sufficiently high to permit welding by the time-honoured method of heating in the fire or blowpipe, the process of electric welding may be employed, and is extensively employed in welding steel. The air-hydrogen blowpipe—that is, a blowpipe the gas of whose flame is a mixture of air and hydrogen—is also used in the process known as "burning" or autogenous soldering or welding. Now the oxy-hydrogen and the oxy-acetylene blowpipes are employed for the same purpose. The wonderful *thermit* process introduced a few years ago is also of great industrial importance, and by its agency welds in difficult positions are easily and economically made. It takes advantage of the great affinity of aluminium in the form of powder for oxygen and the very high temperature attained during the process of chemical union. All these processes we shall consider at some length.

Soldering. But in addition to the various welding processes there are the processes of soldering, which may be divided into two classes—hard soldering and soft soldering. The value of soft soldering compared with welding is that it may be used without necessarily spoiling the appearance of the surfaces being united. In soldering, the two surfaces to be joined are not raised to the point of fusion. Union is attained by the use of a third substance—the *solder*—an alloy with a lower melting point than the metal being joined, which, by the help of a *flux*, is made to flow over the surfaces to be placed into contact, so effecting union. Soft soldering does not give such an intimate union as welding, but it is sufficiently strong for very many purposes. Ordinary tinware is invariably soft soldered. The process is the only one that would permit the tin-coated iron surface to retain its finished appearance.

Hard soldering, on the other hand, uses alloys of a much higher melting point than the soft solders, and the unions are therefore stronger. These hard solders are usually termed in the trade "spelter" or "brazing spelter." The name should not be confounded with the word "spelter" used as a synonym for ingot zinc.

We do not include in the processes of uniting metals the mechanical one of riveting, which scarcely falls into the classes of work we set out to consider.

Welding. Welding is possible with those metals which, as they are raised under the influence of heat from cold to the fused or molten state, pass through a pasty or plastic stage. This plastic stage is the welding heat. The ends of two bars of iron may be heated to this welding heat, placed in contact and hammered, and the result is a weld. The ends may be sloped or upset; or one may be split and the other pointed, so as to give greater chance of a good weld. The process has been described on page 2988. The necessary conditions for a good weld are that the welding surfaces should be as large as possible—hence the sloping, upsetting, or splitting—that there should be no scale or oxide, and that the heat should be sufficiently high. To remove any scale that may exist, welding powders, so-called, are frequently thrown upon the surfaces to be united. The most frequently used powders are boric or boracic acid and silica or sand. The effect of these powders is to form with the scale a slag, which fuses readily, and does not therefore interfere with the process of welding.

No weld is possible with cast iron or steel, the carbon content of which exceeds 2 per cent., as these metals pass quickly from the solid to the molten state and have no plastic stage to give them a possible "welding heat."

Welding Steel. Iron is welded at white heat or a high red heat, but steel must be welded at a lower heat—in fact, the heat of the latter should never be raised higher than the degree necessary to effect a weld, or the quality of the metal is impaired. At the beginning of a steel weld the pieces should be struck lightly, and only after the weld has gone a little way should the sledge-hammer or the power-hammer be used. Steel must be worked quickly on account of the low heat at which the work must be done, and even then it may be necessary to give it more than one heating. The article welded must be annealed after welding—that is, it must be heated slowly to welding heat, and allowed to cool gradually. After being heated, the article may be covered with dry, warm sand, or may be left in the forge until the fire is cold, either method giving the necessary time for cooling; but, of course, the latter is impracticable if the fire is in constant use.

The fuel in heating cast steel for welding purposes should be coke or breeze, and not coal. The steel should be heated quickly, being meantime covered from the air. The welding heat is low, and the metal should not be overheated. Before putting it into the fire, a flux composed of equal parts of borax and washing soda and a little white glass which has been fused together and afterwards ground, should be sprinkled over it, which will dissipate the oxide that may form. Many other fluxes besides that mentioned may be used. One authority recommends a mixture of sulphur,

sal ammoniac, and borax in the proportions of 1, 2, and 10 respectively; while another uses powdered white marble.

In welding cast steel to iron the latter must be raised to a much higher heat than the former. Usually a flux different from that mentioned above is employed. It generally contains a percentage of prussiate of potash with borax and sal-ammoniac. An extensively used French process of welding—the Lafitte—uses plates made of wire gauze covered with the fluxing powder.

Welding Copper and Platinum. Copper for welding is usually heated under the blowpipe instead of in a fire, for the carbon of the fuel would unite with the metal and form copper phosphide, making a solid weld impossible. Copper, particularly at its welding heat, is very soft, and requires careful manipulation, as it does not offer the resistance to blows that iron does. The flux should be applied before the metal is at the proper cherry-red welding heat. It usually consists of soda phosphate and boracic acid in the proportions of 1 and 2.

It is possible, but difficult, to weld platinum, because this metal gives off its heat so rapidly that the heated edges scarcely remain at a welding temperature long enough for the operation. To make an efficient platinum weld it is necessary to have the hydrogen blowpipe playing upon the surfaces during the entire operation. No welding powders are used for platinum.

Autogenous Soldering, or Burning. The process of autogenous soldering, or *burning*, as it is commonly termed, consists in uniting two pieces of the same metal or of different metals by fusing the edges to be joined, and thereby causing them to run together so as to form a strong union. It is more akin to welding than to soldering proper, hence we give it consideration before passing on to discuss the subject of soldering. It makes a much stronger and more intimate union than soldering. No interposing metal is used, hence the expansion and contraction of the finished joint is uniform, and rupture is not likely to take place under any strain insufficient to rupture the solid metal. In soldering, also, the interposed solder is apt to oxidise more or less than the joint, thereby causing weakness; autogenous soldering is free from this objection.

The heat used in autogenous soldering must be intense enough to fuse the metals being operated on. Hence, until recently it has been only the metals with comparatively low melting points that have been "burned" with the help of the blowpipe. But during recent years the oxy-hydrogen blowpipe and the oxy-acetylene blowpipe have been pressed into service for autogenous soldering, so that now even iron, steel and nickel can be successfully joined by burning. We shall consider these improvements in the process when we have discussed its older applications.

We must recognise two classes of autogenous soldering. In one, molten metal the same as that being joined is poured over the edges desired to be joined. It unites with these edges and forms, if thoroughly successful, a homogeneous mass with the work upon which it has been poured. We have seen this process already in the treatment of brass castings which are required in one piece, but are, for foundry convenience, or because of the limited sizes of moulding boxes, cast in two or more pieces [see page 6313]. The process is also used for iron castings, small pieces that have broken off a large casting being renewed by this means, or faulty parts of a large casting being intentionally removed and renewed by pouring molten cast iron around the part, placed in a suitable mould. In these cases the essentials to good work are a properly prepared mould, in which the work is placed, and into which the molten metal may be poured, a high degree of fluidity in the pouring metal, and provision that the first part of the pouring may run out by suitable gates after passing over and heating the surface. Thus, the cold surface is thoroughly heated before the later part of the pouring reaches it; the union by this means is more certain, and stronger. To attempt to use the first part of the pouring before the cold surface had been raised to the point of fusion or semi-fusion would result in a chill.

Pewter and Lead Burning. Pewter work is usually united at the corners by autogenous soldering, especially if the piece be of such a shape as to make soldering from the inside impossible. A small piece of pewter of suitable shape is laid upon the part where the union is to be, and heat is applied with a copper soldering bolt, which is passed over the work until the joint is properly made. The work is then filed and polished. If it has been properly done no joint is visible, and the corner looks as if it had been made from the solid. The heat may be applied by means of a blowpipe instead of with the soldering bolt.

Lead burning is the most common application of autogenous soldering. For lead tanks and lead vessels used in chemical works "burning" is the only proper method of making a joint. The lead to be burned must be scraped clean. For some work, such as lead roofing [see page 5032], it is sufficient that the two edges to be joined overlap a little; but for strong seams, such as are required in the bottom of acid tanks, strips of clean lead are placed above the two butted edges it is desired to join, and the heat, when applied, causes the new piece to fuse on to the top of the other two above the butt. The heat may be applied with a plumber's lamp, or by a blowpipe burning service gas, but the best and usually most convenient method is by a "burning machine" or hydrogen gas generator. This is an apparatus consisting of a lead cistern, into which zinc cuttings are put with diluted sulphuric acid so that hydrogen is evolved, and after passing through a water chamber to be purified is led into an air vessel, which is merely a barrel containing an inverted circular tank of zinc floating on water. A suitable pipe is led from this tank, and by applying a weight to the top of the floating tank or gas bell, the hydrogen is given pressure to send it with the required force through the blowpipe, which is connected to the end of the pipe.

Lead burning may have to be done in work in a horizontal position, working from the top. It may have to be done upon lead in a vertical position, which is much more difficult. It may, finally, have to be done overhead, and this is naturally the most difficult of all. The method pursued may be divided into two classes: surface fusion, which is comparatively simple, and through and through fusion. Lead oxidises rapidly, especially when hot, and oxidised edges cannot be joined so as to give a perfect seam. The outside flame of the blowpipe is an oxidising flame, and the point of the inner flame, which is the point of greatest heat, should be applied to the spot it is desired to fuse. The blowpipe should be brought sharply into position and withdrawn sharply, so that the external flame may not linger upon the lead that is fused or in process of fusion. Some lead burners claim to be able to run down a seam without

withdrawing the flame, but this is neither the usual nor the safest practice. Intermittent fusion is better. Select a point of the work and apply the flame to it until a circle of semi-fusion is made. Then withdraw the flame for a moment and select another point a quarter of an inch along the seam on which to operate. With heavy lead—say over 6 lb.—the seam must be attacked on both sides to make first-class work. When the position of the work makes this impossible, the two edges to be joined should be butted and the edges should be scraped so as to form a V-shaped joint, with the apex of the V where the edges touch. A strip of lead should now be burned on to the recess, the surfaces meanwhile being kept clean by scraping with a shave-hook.

Care should be taken to get a flame of the proper shape. It should be regular, each side of it being the shape of a true arc drawn from the point of issue from the blowpipe to the tip. An irregular flame splutters out in the shape of a horse's tail and has no true point. The proper shape of flame can be got only with practice, and by making the pressure and quantity of both gas and blast proportionate, so as to give the best results.

The Blowpipe. We may consider the blowpipe. It is essentially, in the case we have been considering, an apparatus consisting of an inner or central brass tube, and an outer brass tube encompassing the inner one. The inner tube is connected to the gas supply, in this case the hydrogen generator. The outer tube is connected to an air blast, usually either a fan or foot bellows. The gas coming from the inner tube is ignited, and by causing a blast to issue from the larger and surrounding orifice the flame is directed upon any piece of work to which it is desired to apply heat. The principle is the same whether the fuel be hydrogen, coal gas, oxy-hydrogen gas, or oxy-acetylene gas, the gases in the case of the two last-mentioned being mixed in the blowpipe. The hottest part of the flame is the point of the inner or blue flame, and for work to which it is desired to apply the greatest possible heat the blowpipe is held so that the part of the flame mentioned may impinge upon the work. Most blowpipes have a spring device by which the blast passing up the blowpipe may be regulated in accordance with the requirements of the work.

For small work an ordinary mouth blowpipe is used, and jewellers invariably use such a blowpipe. The heat is the flame of a spirit lamp, and the tip of the blowpipe is inserted into this flame, and the workman, with cheeks distended, blows through the blowpipe, meantime holding the article to which he is applying the heat in the proper position that the flame may be blown upon it. In such cases the article is usually put upon a block of charcoal. An efficient blowpipe device may be made by anyone with a penny candle and the stem of a clay pipe.

Oxy-hydrogen Blowpipe Welding. One difficulty long stood in the way of oxy-hydrogen blowpipe welding—the lack of any known method of producing the gases at economical cost. This difficulty has been overcome by a process recently introduced by Messrs. Braby & Co., of London and Glasgow. The advantages of the oxy-hydrogen flame over the electric arc for welding purposes are that it is under complete control, and that it is not liable to alter the carbon proportion of the steel being welded. The decomposition of water by electrolysis is obviously the most simple manner of securing the two gases, and the apparatus used does this effectively at low cost. Two problems had to be solved in designing the apparatus—the selection of the best material for the electrode plates and some manner of collecting the gases apart. The tank used is 6 ft. long and 18 in. deep, its sides being only $1\frac{1}{2}$ in. apart. A vertical plate of iron is placed the whole length of the thin tank so as to keep the gases apart as they are generated; this plate has a rectangular aperture so as to permit the flow of the electrolyte. The opening at top of the tank is closed with two rubber blocks, which rest between the centre plate and the sides. The sides of the tank are of iron and form the anode and cathode. To the water in the tank is added soda, which liberates sodium and hydrogen at the cathode side and oxygen at the anode side. The sodium, as soon as liberated, decomposes the water in its vicinity, thereby increasing the delivery of hydrogen at the cathode. Water is added continuously by means of a pipe at the bottom of the tank and the gases are led off separately from the top, passing through a 3-ft. water seal, into the gas holders, where they are stored. In each gas-pipe a piece of platinum is kept red hot by electric current, and this provision removes any traces of oxygen from the hydrogen and any hydrogen from the oxygen. At Messrs. Braby's works the current is 200 amperes at 70 volts, and passes through thirty vats in series. The blowpipe, where the gases are burned, is a conical mixed jet pipe with a small brass nozzle. The work done with the oxy-hydrogen blowpipe includes the autogenous soldering of all kinds of sheet-iron work and general repair work of all kinds. The process is used for iron, steel, brass, copper and other metals. One metal may be fused to another by its means. Oxygen and hydrogen are used in the apparatus in the proportion of one to six respectively, and as the decomposition process yields the two gases in the proportion of one to two, there is excess of oxygen, which is compressed into cylinders and sold for medical and other purposes.

In autogenous soldering of iron and steel by the oxy-hydrogen or oxy-coal-gas, difficulty is experienced owing to the oxidation of the iron by the steam produced in the flame. A French precaution to avoid this oxidation consists in the addition to the coal-gas or hydrogen of a hydrocarbon rich in carbon, substances such as acetylene or the vapour of light petroleum being used. It is claimed that by this means the products of combustion contain less steam and more carbon dioxide; also that the latter is partly dissociated with formation of carbon monoxide, which has a reducing action, and thus prevents oxidation of the iron.

Oxy-acetylene Welding. The use of oxygen and acetylene in a special blowpipe for supplying the heat necessary in autogenous welding is a recent development and has many advantages. Pioneers in the manufacture of apparatus for this work are the Thorn and Hoddle Acetylene Company, of London. The oxygen is contained in a cylinder, where it has been compressed to 120 atmospheres. The acetylene is generated in an "incanto" generator, and after passing through a purifying apparatus is led into a gas-holder, where it is retained under a pressure of 6 in. of water. With the oxy-acetylene blowpipe it is found, in practice, that the best welding results are obtained by a mixture of 1 volume of acetylene with 1·7 volumes of oxygen. The flame produced has in its centre a small white cone, at the apex of which the temperature is about 6,300° F. This flame consists almost entirely of carbon monoxide,

which is being converted at its extremity into carbon dioxide. Round the flame is a relatively cool jacket of hydrogen, which, not being able to combine with oxygen at the very high temperature in the immediate neighbourhood of the flame, remains temporarily in the free state, and thus protects the inner zone from loss of heat while excluding the possibility of oxidation, which is a difficulty other methods of welding have to contend with.

The heat, in addition to being greater than that obtained by any other blowpipe system, is also more concentrated. The gases are mixed in the injector chamber before they issue from the nozzle of the blowpipe. Work with this blowpipe is rapid. A good workman can make a weld of 15 ft. per hour, working on a $\frac{1}{4}$-in. steel plate, or of 6 in. per hour on a $\frac{1}{2}$-in. steel plate. Oxy-acetylene autogenous welding has been successfully applied to a wide variety of work, such as cycle parts, welded boilers, steel safes, tanks, tubes, and all classes of copper work.

Aluminothermy. The introduction of aluminothermy in the process of welding or autogenous soldering a few years ago attracted more attention than any other process in the same department of industry for many decades. It ranks in importance with electric welding, and is much wider in its application. A brief introduction is necessary to enable the basic principle of the process to be understood. All chemical reactions are accompanied by the absorption or the liberation of heat. Mix sulphuric acid and water and observe that considerable heat is evolved; indeed, the heat may be so great as to cause an explosion, and it is much safer to add the sulphuric acid gradually to the water. The manufacture of aluminium from the oxide demands great heat and the commercially successful process of making aluminium is by the electric furnace [see page 5989]. This heat, or a great part of it, is absorbed by the metal, and becomes latent heat, which may be given off again if the proper method of causing this liberation of heat is known. It was the discovery of the method of achieving this end that brought aluminothermy into the realm of everyday industrial processes.

Oxide of aluminium is formed with very great heat, but the oxidation of aluminium at ordinary temperatures is negligible. If, however, the oxidation is started at a sufficiently high temperature, it will proceed rapidly until the whole mass of metal is reached. This reaction depends upon the fact that aluminium gives out very great heat as it combines with oxygen, for which its affinity is very great. So great is this affinity that the metal will reduce all other metallic oxides to their metals.

Thermit. In practice, the material used in aluminothermy is a compound sold under the proprietary name of *thermit*, and is made and sold by Thermit, Ltd., of London.

It is a compound of finely divided aluminium and a metallic oxide, usually oxide of iron. The heat evolved is so great—it exceeds even that of the electric arc—that special crucibles and special methods are necessary in the practice of aluminothermy. The crucible usually has the shape of an inverted cone, and is made of iron sheet with a magnesia lining, and a sheet-iron hood, which prevents sputtering during the reaction. The bottom—that is, the apex of the inverted cone—has a round hole into which is fitted a tapping bar, which is merely a short iron rod. Above this tapping bar is placed a sheet-iron disc made to fit the bottom of the crucible, and above the disc is placed a piece of asbestos with some fireproof material tamped in above it.

The thermit is placed in the crucible, into which the tapping bar has been fitted as described, and the mass is ignited by the use of a special ignition powder. Then the reaction begins, and proceeds rapidly until the aluminium is burned to aluminium oxide, and the iron remains in the pure state, being in reality a very low carbon steel, usually with about ·1 per cent. of carbon. Then the reaction subsides, and with a rod the tapping bar is dislodged upwards and pushed into the intensely hot body of molten iron, where it is instantly reduced and incorporated. The mass flows out through the tapping hole into the mould prepared for it, where it settles upon the surfaces it is desired to weld or unite.

Uses of Thermit. The most frequent use to which thermit has been put is in the welding of tramway rails. It welds rail end to rail end so that the whole rail system of a tramway service may be welded into one entire length of rail. It is possible to follow this practice for tramway rails where the rails are bound into position by paving blocks, but for the permanent way of our railways, where the rails have no such binding, welding is impracticable on account of the bending that would ensue when the rails were elongated by heat.

There are many other uses for thermit. They lie chiefly in foundry practice, for burning castings together or for renewing faulty parts of castings. In marine repair work the process has saved many thousands of pounds, as by its means a shaft or other piece of marine engine mechanism may be repaired at once, and so enable the vessel to put to sea, or proceed without the delay that would be caused by the older method of making a duplicate part.

Crucibles and Moulds. Several other considerations may be mentioned before we leave the subject of thermit welding. The crucible we have described is tapped from the bottom by the method described. The use of such a crucible is imperative, because lip pouring is impossible. The slag which forms upon the top adheres to anything which it may touch, and if a little slag entered with the poured metal it would prevent proper adhesion and spoil the work. The mould must be made so that the first part of the metal will run to waste, heating the parts to be united before it does so. Also the moulds must be made as for high-grade steel castings, and the faces finished with a wash of silica, or of silica and plumbago. They must be thoroughly dried, and slowly heated to red heat so as to make them quite free from moisture. The thermit must not be poured at too high a temperature. It is usual to allow the heat to subside a little after the reaction has ceased, and it is also customary to throw into the crucible some soft steel punchings and to permit these to melt before tapping.

We have described only a small part of the field in which thermit is used. For the rest we must be content with mentioning a few of its applications without detailed description. In steel castings, thermit may be placed in the riser, the heat of the molten steel being sufficient to ignite it. It raises the temperature of the pouring, enabling smaller risers to be used, and keeping them open longer. The same process is sometimes used for cast iron, but as the heat of cast iron is not high enough to start the reaction, some ignition powder

must be placed along with the thermit. It is also introduced into steel castings to prevent "piping"—that is, the formation of a large shrink hole near the top of the casting. In such a case the thermit is introduced just before the casting becomes solid; it makes the steel more fluid again, and permits the gas to escape before final solidification.

Electric Welding. The process of electric welding permits welding to be applied to the union of many metals which could not be united by the ordinary process of welding as already described. Given the proper appliances, the operation of electric welding does not require the high skill born of long practice that ordinary welding demands. The intelligence has been put into the machine, and man's part becomes to an equivalent extent mechanical. The work is secured in clamps, through which the current passes, the surfaces to be joined being opposed to each other. As at the point of contact there is more resistance than there is through the solid metal, heating takes place, and as the metal becomes soft the clamps are made to exert pressure towards each other, and the weld is made by this pressure. The Thomson process of electric welding is that usually followed, and the makers of the machines for this process are the Electric Welding Company, Ltd., of London.

In electric welding it is desirable that there should be a good deal of work of one class, because the machines are limited in the scope for which they are fitted. The power required to raise the metal to welding heat is very great during the time it is called into action, and the machines are graded by the cross sectional areas they can undertake and the horse-power of the generator. Thus only work of approximately the same sectional area is suitable for one machine. Angle iron could not be welded on a machine for wire, for instance.

Sometimes the electric currents used are as high as 50,000 amperes; but the electromotive force is only half a volt, so that little danger attaches to their use. Alternating-current generators are used, and if a direct current only be available a motor alternator must be installed.

The weld begins in the centre and extends towards the surface as the temperature rises. The resistance of the hot metal, being higher than that of the cold metal, draws the heat to the desired parts. When the welding heat has been reached, the ends are pressed together as already stated. The pressure is given either by manual or hydraulic power. The machines have been developed very much in the direction of making them automatic.

Value of Electric Welding. The quality of the work done by electric welding is more likely to be excellent than work performed by hand welding. From the point of view of economy, the former has everything in its favour when output is large. Its sphere, however, does not lie in small or in general work, but in repetition work. The economy secured by electric welding is caused largely by the absence of special preparation of the work—such as sloping, upsetting, and splitting—which often make a union demanding a somewhat lengthy drawing out and finishing. Work for which electric welding is specially suited includes chain manufacture, cycle components, carriage work, and tools such as axes, where the poll of mild steel is electrically welded to a tool steel edge. The speed with which the work can be carried out is surprising. Tests made show that iron and steel pieces of 4-in. sectional area can be welded in 90 seconds with a horse-power expenditure of 83·8, and a copper weld of 1-in. sectional area takes 23 seconds, with almost the same horse-power expenditure. An additional value of the process lies in the fact that dissimilar metals can be united by its agency. Iron, wrought or cast, can be welded to zinc or copper, for instance.

Soft Soldering. Soft solders melt at comparatively low temperatures. It is possible to use them with nearly all metals. In the operation of soldering there are three necessities: the means of applying the heat sufficient to fuse the solder, the solder itself, and the flux, which enables the solder to associate itself intimately with the metal or metals to which it is applied. The further apart the melting points, the hardness, and the malleability of the solder and of the metals being soldered are, the weaker is the union. Thus, a soft soldered joint in iron, brass and copper is always comparatively weak. It may have some strength if the metals joined by soldering are comparatively thin, so that they can bend under any stress to which the joint may be subjected, thereby relieving the solder of the duty of resistance; but if the metals be heavy and inflexible a blow or other act of violence may cause disruption of the union. Soft solder, again, having properties not far removed from those of tin and lead, makes a strong union with these metals, which, when soft soldered, may be hammered and worked with comparative freedom. This point has much to do with deciding the method of soldering to be adopted in any particular case.

In soft soldering the usual way of applying the heat is by means of the tool known as the *soldering iron, soldering bolt* or *soldering bit* [see page 5030]. This tool is a short, square bar of solid copper drawn to a point and mounted on an iron rod, which is provided with a handle. Its point must be covered with tin before being used. To tin it, it is heated in a stove or fire of any sort until it is dull red; it is then filed slightly so as to clean the point, and is rubbed first against a piece of sal ammoniac and then upon some solder placed upon a copper or tin plate. It is then ready for use. In the actual operation of soft soldering the surfaces to be united are first cleaned if necessary—diluted hydrochloric acid applied with a brush or cloth is usually employed—then the flux is applied to the surfaces, and finally, the hot soldering bit, after being rubbed against the solder so as to take on a small quantity, is rubbed over the flux and the joint is made. The flux and the solder may vary in composition and depend upon the nature of the metals being soldered. We shall consider them presently.

Soft soldering is often done by means of a blowpipe instead of a soldering bolt, particularly by gasfitters and pewterers. A plumber's soldering lamp may be used, or expert workmen may burn some rushes or wood chips around where the joint is to be made, directing the flame by means of a blowpipe. The flux is, of course, used as with the soldering bolt. Gasfitters use a solder rich in tin and a flux made of oil and resin mixed in equal proportions. Pewterers use a solder containing bismuth, which is more easily fused than most soft solders, and as flux they employ Gallipoli oil, which is a green olive oil.

Soft Solders. The most commonly used soft solder consists of one part of lead to two parts of tin. "Plumbers' sealed solder," so-called, is two parts of lead to one part of tin, and is fusible at a considerably lower melting point [see page 5987]. The solder consisting only of lead and tin, and

COMPOSITION OF SOLDERS

Purpose.	Composition.								Flux.
	Tin.	Lead.	Copper.	Brass.	Zinc.	Silver.	Gold.	Bismuth.

In this table the solders of which borax is given as the flux are hard solders, and those of which resin or chloride of zinc is the flux are soft solders.

Manufacturing Soft Solder. Soft solder should be made in a porcelain or stone vessel, because in an iron pot the solder may absorb some of the iron. First melt the tin and then add the lead gradually in small pieces, stirring with a wooden stick. When the whole is fused and thoroughly mixed the alloy is poured into moulds, usually short bars about 8 in. long, from $\frac{1}{2}$ in. to 1 in. broad, and from $\frac{1}{4}$ in. to $\frac{1}{2}$ in. thick. Suitable moulds may be made by taking a mass of clay, beating its top flat and pressing into it in various places a stick of solder, thus making depressions into which the new solder may be run.

Fluxes. Soldering fluxes are numerous. The plumber uses both resin and chloride of zinc. For electrical work chloride of zinc is frequently forbidden, but is still used to a fair extent. For the meat canning industries, also, chloride of zinc is supposed to be harmful but is still greatly used, sometimes unknown to those who use it and who purchase chloride of zinc solution under a proprietary name. To make chloride of zinc solution, or *killed spirits*, as it is called, dissolve zinc in hydrochloric acid, or spirit of salt, as it is commonly termed, putting in more zinc than the acid will dissolve, so that the solution may be saturated. The ebullition may be too violent with pure hydrochloric acid, and water up to two parts to one part of acid may be added. The zinc should lie in the acid for at least twenty-four hours, when any excess of zinc may be removed, and the soldering liquid is ready. It is bad to use scrap zinc as it may contain iron, which is deleterious, and scrap zinc is always dirty. The solution may be filtered with advantage. Sometimes other substances, such as sal ammoniac or glycerin, are added in small proportions and are held to improve the fluid. This flux will suit nearly every purpose. For iron it requires to be stronger and may be used without water. For soldering galvanised iron—an extremely difficult operation and not a pleasant one—this flux would cause adhesion only to the zinc coating, and, therefore, raw spirit—that is, pure hydrochloric acid—is used to remove the zinc, after which the above mentioned solution may be used to solder to the iron. Tallow and other oils and fats are used to a fair extent as fluxes. Lard oil is used to solder aluminium with fair success, but the soldering of aluminium is a difficult matter, which we shall consider separately. Gallipoli oil is used by pewterers, as already mentioned.

For copper and sheet iron a flux frequently employed is powdered sal-ammoniac or an aqueous solution of it, followed by resin. Sometimes the powdered sal-ammoniac and resin are mixed before application. It is extremely difficult to solder zinc as it removes the tin from the soldering bit very quickly, making frequent retinning necessary.

Before passing from the subject of fluxes we may notice a few that are put forward as having specific merit, although they give no promise of deposing chloride of zinc as the all but universal flux. The proprietary fluxes sold under fancy names we leave alone; they are almost without exception solution of chloride of zinc prepared as we have described above.

A soldering paste is made by mixing chloride of tin with starch paste. A soldering fat is prepared by heating two parts each of olive oil and tallow and by adding one part of powdered colophony: then, after the mixture has been stirred and has boiled up and cooled, one part of a saturated aqueous solution of sal ammoniac is added. Phosphoric acid in solution with water or spirit is also used.

Soldering Without a Bit. By careful manipulation the operation of soft soldering may be performed without a soldering bit. A lamp or gas jet may be used to make the surfaces hot, the flux is then applied, followed by the solder, and with skill a successful joint is achieved. If two pieces of brass or copper be filed to fit each other, covered with a soldering fluid, and have a piece of tinfoil interposed, thereafter being heated over a gas jet or fire, a union will result, the tinfoil fusing and joining the two surfaces.

Hard Soldering. Hard soldering is the process of joining two metals or two pieces of the same metal by a solder that has almost as high a

melting point as the metals joined. The term *brazing* is generally applied to this kind of soldering. The heat of the copper soldering bit used in soft soldering is not sufficient for hard soldering. The work is sometimes done in an open fire such as a smith's forge, but the usual process is to raise the heat by a blowpipe, using gas as a fuel and applying the blast either by a power-driven fan or by hand or foot bellows. The most usual and convenient way, especially in small shops, is by the use of a brazing forge with pedal bellows. The workman can then use both hands in controlling the application of the heat. Sometimes the bellows are replaced by a rotary fan for supplying the air blast, and either method is satisfactory.

Sometimes, again, a plumber's lamp may be used, but this is not so satisfactory, as the heat cannot be raised so high as with gas, and good work is not so certain. Some large firms—such as cycle manufacturers—who have much and constant brazing work of one class, have the hard solder in a molten bath and dip the work into this bath. This process is unsurpassed for the quality of work produced, but it necessitates more finishing than is required by the blowpipe method, as the molten solder adheres to a larger area of the work than is necessary to make the brazed or hard-soldered joint.

Hard Solders. In the table already given appear some recipes for hard solders. Such solders are, for convenience, divided into three classes—brass solders, which are used with steel, iron, and copper; argentan solder, used for German silver; and gold and silver solders used for these metals. The common composition of solders of the first class is 8 parts of brass to 1 part of zinc. Refractoriness is increased by lowering the proportion of brass and adding tin. Thus, a composition with 6 parts of brass and 1 part each of tin and zinc is much used where a more refractory solder is desired, and this may be made still more refractory by adding 1 part of copper. By increasing the tin, the ductility decreases and the colour tends to grey. For work where the joint has to withstand bending stress, a high percentage of tin is to be avoided, as it causes brittleness.

Making Hard Solders. In making hard solders it is advisable to use brass instead of its constituent metals—zinc and copper—because the loss of zinc when fusing the metals separately is uncertain, and because by using brass already made this loss is minimised very much. Sheet brass is better than cast brass as an ingredient in hard solder, because the rolling has imparted to it a higher degree of homogeneity than is possessed by cast brass.

First melt the brass at a strong heat, and in another crucible melt the zinc that is being added as such, also at a strong heat. Pour the molten zinc into the molten brass and stir the mixture well. Then the solder is ready to be poured, and there are several ways of doing this, the object of all being to obtain a fine granular product suitable for soldering. Sometimes the molten alloy is poured through a wet broom into cold water, this separating the metal into the granular particles desired. A better method requires a cistern placed so as to give a good head of water, and an orifice that projects a stream of water horizontally over a water-tank. The molten alloy is poured on to this horizontal jet of water, which divides it, and the grains fall to the bottom of the tank, whence they must be taken and dried before they have time to oxidise. By varying the strength of the water-jet and of the metal-pouring, it is possible by this method to make grains approximately of any desired size.

Argentan solder is used for German silver, and also for steel and other work, the joints of which are required to be very solid. A readily fusible argentan solder is made of copper 35 parts, zinc 57 parts, and nickel 8 parts. A more refractory composition contains copper 38 parts, zinc 50 parts, and nickel 12 parts (Brannt). A general rule is that the higher the percentage of nickel in the German silver to be soldered, the higher is the proportion of nickel in the solder. The composition is cast in thin plates, which are broken and beaten in a heated iron mortar, so as to make them into a powder. If it is found to powder easily, it has too much zinc, and if the operation is too difficult, it is deficient in that metal; if it shows either fault, it must be remelted and the fault remedied.

Gold and silver solders are used chiefly for soldering these metals, but are also used for articles to be enamelled, for bronze, cast-iron, etc., but on account of their expense their use is naturally limited to work of a high-class nature. A few recipes for these have been given [see also page 5857].

Fluxes for Hard Solders. The most generally used flux for hard solders is borax. The purpose of the flux is to remove the layer of oxide upon the surfaces it is desired to solder, and borax is the best all-round agent for this. It effects its purpose by reason of the excess of boracic acid which it contains dissolving the layer of oxide. For higher temperatures, finely powdered glass of a fusible nature may be used. For soldering copper, phosphate of soda or phosphate of ammonia may be employed. Quartz sand mixed with decomposed soda, or, for very high temperatures quartz sand alone, is satisfactory. For coarse work, turpentine or olive oil mixed with sal ammoniac is a good flux. A solution of carbonate of ammonia (saturated) is used for brass. A liquid flux, known as *hard-soldering fluid*, is made by dissolving phosphoric acid in alcohol. Many other fluxes are employed with satisfactory results, preference attaching universally to no particular agent, even for the same metals. It is largely a matter of experience and individual liking.

Soldering Iron and Steel. All metals are not equally satisfactory under treatment by the ordinary processes of soldering, and special measures are often required. We shall review the best processes of treating such metals.

Cast iron is frequently considered unsatisfactory under any process of soldering, but it is not so. It is frequently desirable to solder cast iron, especially in altering cast-iron foundry patterns. For this purpose, soft soldering imparts all the strength necessary. The surfaces to be soldered must be polished bright. Then dip the surfaces into potash water, and upon withdrawal dip into clean water, after which apply quickly undiluted hydrochloric acid. Then sprinkle with powdered resin and solder with the bit in the usual way, using any soft solder, but for preference one made of equal parts of tin and lead. The operation must be performed quickly before the surfaces have time to dry. A more refractory soldered joint may be made with iron or steel, by using copper or brass as the soldering medium. The surfaces are first filed or polished bright, and are tied into position with wire. Then upon the joint place a thin strip of copper or brass. Cover the whole with a good layer of clay containing no sand, and place it near a fire that the clay may dry. Then put the part to be soldered under the blowpipe and raise it to white heat. This causes the clay to vitrify, thereby forming a flux. If the metal being soldered is iron, it is cooled in water,

but if steel, it is allowed to cool slowly. Then the clay is removed and the joint has only to be cleaned. When the soldering medium is a copper strip, it requires a stronger heat than a brass strip, and the latter is therefore more frequently used for soldering steel. For small pieces of iron, a silver solder—equal parts of silver and soft brass—may be used; it is used as foil, and, after annealing, is placed upon the surfaces to be soldered, borax being used as the flux, and the heat being applied with the blowpipe.

A short time ago some tests of hard solders on steel and iron were made at the National Physical Laboratory. Of five solders experimented with, the best was found to have the composition—copper, 63·19 per cent; zinc, 36·31 per cent.; and lead, ·65 per cent. A conclusion drawn from the tests was that the quality of solder improves with the copper percentage. The solder that stood the tests most satisfactorily had the highest proportion of copper, and was as stated above. At what point the improvement of quality ceases by increasing the copper—for, of course, there is such a point—was not determined.

A German patent (E. Herzog, 6th May, 1902) makes a soldering paste for cast iron by mixing pure steel or iron powder, free from oxides of iron, with stearin or paraffin oil, borax, and camphor. A suitable mixture is steel or iron powder 80—120; paraffin oil 10—30; borax 30—50; camphor 1—4. The parts to be joined are well cleaned, coated with the soldering paste, and after addition of borax and solder are heated to redness, usually under the blowpipe.

The work of soldering or brazing saws is a common operation with saw doctors, and it is essential with band-saws. File the two ends to be joined smooth and tapering, so that one overlaps the other some distance. Tie the ends together with wire, so that they will retain their proper position during the operation. Apply to the joint some borax, reduced to a cream by rubbing it with water on a slate. Now sprinkle some brazing spelter over the joint and apply the blowpipe heat, until it is seen that the spelter has run into the lap. Allow the work to cool gradually, and finish by filing.

Soldering Zinc, Brass, and Silver. In soldering zinc and galvanised iron, the soldering bit must be kept very hot, and the flux used is hydrochloric acid, undiluted, or diluted with only one third of its volume of water.

The soldering of brass is made more easy if the surface has been previously tinned. This is easily done. Clean the surface, apply borax paste, prepared as already indicated, and place upon this a piece of tinfoil. Heat until the tinfoil fuses and runs over the surface. The solder adheres uniformly and tenaciously to surfaces treated thus. A good solder for brass is a soft spelter—commonly called Bath metal solder—consisting of 21 parts of copper to 79 parts of zinc.

Brass and steel may be soldered together by first coating the steel with a solution of sulphate of copper, and then by soldering the two surfaces in the usual manner.

Silver is soldered with an alloy containing 19 parts of silver, 10 of brass, and 1 of copper. This is reduced to granular form by the process already described, or if for fine work is made into powders by filing it. The flux used is borax, which should be rubbed with water upon a slate or hard stone, so as to make a cream, which is applied to the two surfaces with a brush. The powdered solder is then applied between the pieces, and the work is laid upon a charcoal block, where the heat is applied with the blowpipe. When the union is made, an immersion in pickle removes the excess of borax, and the work is finished.

Soldering Aluminium. A fortune lies at the feet of any man who can find a simple and efficient method of soldering aluminium. Many attempts have been made, and workers in aluminium have had their hopes raised many times that the problem had been solved, only to be dashed again. No economical process of soldering aluminium has been proved to be permanently successful [see also page 5991]. The film that always lies on the surface of aluminium is an oxide that forms immediately the metal is exposed to the air. The oxide can, of course, be removed by filing, but a new film of oxide forms instantly upon the new surface created by the file. It has been found possible by ordinary soldering to make what appeared to be a satisfactory soldered joint with aluminium, but the lapse of a few months has always shown it to be otherwise, and the union has been found to be faulty. It is for this reason that commercial articles of aluminium are never, or almost never, sold with soldered joints. Usually the articles are cast or pressed and drawn from one piece of the metal, or if it is necessary to join one piece to another, or another metal to aluminium, riveting or screwing is the method employed. Still, we can indicate some of the solders used for aluminium when attempts are made to solder it. One solder is composed of 1 part of zinc to 4 parts of tin, and the flux recommended for it is made of 1 part each of tin chloride and zinc chloride, and 8 parts of stearic acid. Another worker professes to have achieved success with lard oil as a flux. The aluminium is usually heated with a blowpipe, and kept hot during the operation. The copper soldering bit is said to discolour the aluminium, and a nickel soldering bit is recommended. Other solders for aluminium contain that metal as a constituent. Horner, in the "Encyclopædia of Practical Engineering," gives the following recipes for aluminium solders:

1. Aluminium 2·38; zinc, 26·19; tin, 71·19; phosphorus, 0·24.
2. Aluminium, 6; copper, $4\frac{1}{2}$; zinc, $89\frac{1}{2}$.
3. Aluminium, 6; silver, 3; copper, 3; tin, 18; zinc, 9.
4. Bismuth, 6; tin, 94.

Soldering Metal to Glass. Glass may be soldered to metal by first coating the former with lead or with amalgam. The glass to be coated with lead is coated on one side with chalk and water, and after drying is placed clean side up, and fixed down in a special cast-iron tray, which is then placed in muffle surfaces and heated until the glass is at about 650° F., just above the melting point of lead. Then molten lead is poured over so as to cover the glass, and the tray is oscillated for some time. Then the lead is allowed to run off, and leaves a layer upon the exposed surface of the glass. This process is used in the manufacture of glass buttons, in order to allow the stems to be soldered to them.

UNDERGROUND WORK

Laying Telegraph and Telephone Lines Under the Streets. Conduits. Manholes. Pipelaying. Cabling and Jointing

By D. H. KENNEDY

AERIAL conductors have, broadly speaking, two principal advantages over the underground method of construction—namely, low cost and, owing to the small electrostatic capacity, high efficiency as electrical conductors; but these are frequently outweighed by other factors, which lead to the substitution of subterranean routes.

In large cities, overhead routes are generally unobtainable; moreover, when some degree of conducting efficiency can be sacrificed, and where the number of conductors is large, the underground system may be found to be cheaper, especially when the cost of subsequent maintenance is taken into account. Maintenance, which is heavy in the case of aerial wires, may, by good first construction, be reduced to insignificant dimensions in the case of underground work. Until about the end of the last century wires insulated by a covering of gutta-percha were almost invariably used. These were placed in iron pipes of 2 in. or 3 in. diameter, with joint boxes at suitable intervals. When telephone circuits were concerned, the wires were made up in fours twisted together to form a "quad" cable. A 2-in. pipe could take seven, and a 3-in. pipe nineteen of such quad cables, and as they could not be drawn in over each other it was necessary either to fill the pipe at one operation, or in cases where this had not been done, to draw out one lot before pulling in another.

These G.P. wires had conductors of 40 lb. copper insulated with 50 lb. of gutta-percha to a diameter of 174 mils (the mil is $\frac{1}{1000}$ in.), and not more than eighty wires were ever pulled into a 3-in. pipe.

Cables. The invention of the dry-core cable has, however, revolutionised affairs, and it is safe to say that the present highly developed underground telephone systems would have been impossible without it. In this form of cable the wires are wrapped in paper, but the real insulator is dry air. The electrostatic capacity is one-fourth that of gutta-percha cables. The paper-covered wires are enclosed in a tube of lead, but the economy of space is such that a 3-in. iron pipe will accommodate a lead-covered cable containing 182 40-lb. conductors, as compared with the eighty gutta-percha-covered wires already mentioned.

Post Office London Underground System. It is probable that a description of the methods adopted by the Post Office in laying down their huge underground system will best enable the student to comprehend this subject. Beginning at the exchange, we have first the main conduit routes. These are laid along the centre of the main thoroughfares, and contain ducts varying from six up to any required number.

Earthenware Ducts. The ducts are made of earthenware, 18 in. and 24 in. in length, with internal circular section 3¼ in. diameter, and external hexagonal section 4½ in. diameter. In building a duct route, the ground is first excavated, and, if necessary, shored up; a 6-in. concrete foundation is then laid, having embedded in it T-irons laid lengthwise under every alternate line of ducts. These are 2½ in. by 2½ in. by ¼ in. thick, and they are employed to resist the vertical displacement stress. When the concrete has set, the layers of ducts are put down, bedded in cement mortar. As in the case of succeeding lines of brickwork, the ducts are arranged so that the joints in one line do not coincide with those in adjacent lines.

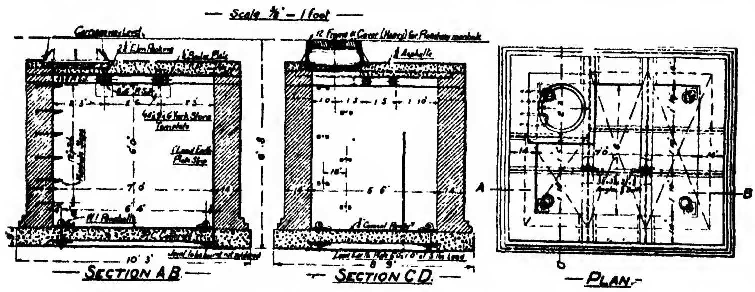
To facilitate jointing, wooden mandrels are used, 11 in. long and 3⅛ in. diameter. When a joint is being made, the mandrel is arranged so that one-half of it is in each of the abutting ducts. A strip of prepared calico, which has been soaked in ozokerit, to make it adhesive, and which is 20 in. long by 4½ in. wide, is then wrapped tightly round the joint. The mandrel is then drawn forward. Such joints can be made rapidly, and a train of a dozen mandrels is usually employed. Of course, it is absolutely essential that the ducts shall not be deflected during the subsequent operations, and once the cement mortar has set the permanence of the whole system is assured. When all the ducts required are in position, concrete is added to the sides and top, and the roadway filled in and reinstated.

Manholes. At intervals of 150 yd. to 180 yd. manholes are provided to house the joints. If possible, the junction of thoroughfares is chosen as the position. These roadway manholes [33] have to be of substantial construction, a need which is emphasised in these days of heavy motor traffic. The minimum dimensions are: length 4 ft., width 4 ft., height 4ft. 6 in., and these are increased as required, a very common type being 8 ft. by 7 ft. by 5 ft. 6 in. The method of construction may be briefly described as follows. The trench is widened and deepened, and a 6-in. floor of concrete laid down, but with the thickness at the sides extended downwards to 9 in. to form footings for the walls, which are of 14-in. brickwork. An earthplate of 5-lb. lead, 6 ft. long by 1 ft. broad, is laid under the concrete, to be subsequently connected to every cable sheath by a 1-in. strip of lead, which is taken up the inner wall of the manhole. Provision is also made for the subsequent drawing in operations by embedding in the concrete in each corner heavy wrought-iron ring-bolts, with large anchor plates bolted on below the concrete. When the concrete has set, the walls are built. Galvanised iron footsteps are built into the corner, above which the entrance is to be placed, and when nearing the roof-line, the stone templates which form the supports for the roof joists are carefully set in position. The roof is as simple in construction as it is strong. The width of the manhole is bridged by rolled steel joists of 8 in. by 6 in. section. These, in turn, are connected together, and to the walls at each side, by smaller rolled steel joists (4 in. by 3 in.). Resting on these is placed a roofing of ½-in. boiler plate. Above this comes 6 in. of concrete, and then a layer of asphalt. Above this the road is made up in the ordinary way, except at the entrance corner. Here a heavy cast-iron frame, 12 in. deep, is provided, into which fits a similar lid, having its upper surface filled in with wood blocks set in pitch. The

inner walls of the manholes are carefully pointed, and the floor covered with a ¾-in. rendering of Portland cement. Figure 33 gives details of a typical manhole.

Distribution Pipes. While it is necessary to have the main routes in the roadway, the distribution pipes must be as near to the shops and houses as possible, and they are, therefore, run along the footpaths. For this purpose, cast iron pipes are used. These are classified according to their internal diameters, as 2-in., 3-in., or 4-in. The first-named are made in 6-ft. lengths, the others in 9-ft. lengths, and the respective weights are 42 lb., 98 lb., and 154 lb. A 3-in. pipe placed on supports 5 ft. apart will support a ton and a half, and a jointed pipe similarly tested will support a load exceeding a ton. They are coated with Dr. Angus Smith's composition, which prevents rusting, and gives a glazed surface. Figure 34 illustrates such a pipe. The left end is called the spigot end, and the right end the socket end. Bends of convenient dimensions are also provided. In laying a line of distribution pipes great care has to be exercised in the choice of the route. Allowance must be made for existing gas, sewer, electricity, hydraulic, and other mains, and in many cases the existence of under-footway coal-cellars makes special difficulties. Very often the line nearest the house-line is found to be the best, because not only is it most economical for distribution, but, owing to the fall of the paving to the roadway, the distance from cellar top to paving is here at a maximum. Ten men form a convenient gang, and when the foreman has chalked out the route, the paving is taken up, great care being exercised to avoid breakages, and the stones (where York or artificial stone is concerned) being laid so as to enable them to be returned to their original positions. While the first dozen yards of trench is being excavated the jointing of three lengths of pipe is in progress. For this purpose four blocks of wood, with V-slots in them, are set up at (for 3-in. pipes) distances of about 9 ft. The spigot end of the second pipe is fitted into the socket of the first, and so on with the third, but before being brought together, they are carefully gauged and examined to see that their interior surfaces are in order.

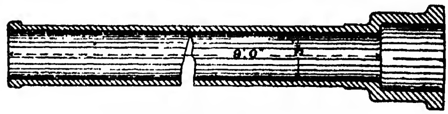
Into the annular space between the spigot and socket a length of spun yarn is inserted, being first wrapped round the spigot and then driven home by a caulking iron. Meantime, a roll of clay has been prepared by wetting and rolling on a board, and this is placed under the pipe and round the mouth of the socket, the ends being brought up above and curved outwards, so as to leave an opening into which molten lead may be poured. The space between the yarn and the clay is in this way filled with lead, which efficiently joints the two lengths of pipe.



33. GENERAL CONSTRUCTION OF CARRIAGEWAY MANHOLES

The clay is then removed, to be used again, and the cooled lead tightly caulked. A level bed having been prepared in the trench, small holes are made to receive the sockets, and the pipes are lowered into position. One joint in every four has to be made in the trench. A No. 8 iron wire is threaded through the pipes length by length as they are laid to be used in the drawing-in of the cable.

Under fair average conditions, a good gang can lay 100 yd. in a day of 9½ hours. Footway jointing chambers of various sizes are provided at intervals not exceeding 100 yd., but they are usually required at more frequent intervals for distribution purposes. Six sizes are in use, varying from "double junction" boxes 4 ft. 2 in. by 1 ft. 11 in. down to "distribution" boxes, 1 ft. 2 in. by 8 in. A concrete floor with Portland cement rendering is provided, and the sides built up of brick, the box proper being merely an iron frame designed to hold the iron lid, the top of which is filled in with stone. The connection between the footway boxes and the subscribers' premises is made by a length of 1 in. pipe. The connection between the roadway manhole and each of the adjacent footway junction boxes is in all cases made by three lengths of pipe.



34. DISTRIBUTION PIPE

Cable System. Having disposed of the pipes, we may now consider the cables more fully. It has already been mentioned that a short length of silk and cotton insulated cable connects the street cable to the main frame. This is for convenience of handling. The joint between the silk and cotton cable and the paper insulated cable is made solid by filling up the lead sleeve with molten insulating compound and allowing it to solidify.

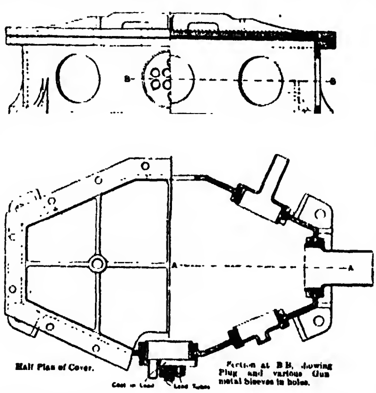
The main distribution cables are varied in type according to the purpose in view.

For serving subscribers near at hand, cables containing 1,212 wires of 10-lb. conductor are used. For the next ring, 750 or 606 wires of 12½-lb. conductor, while for the general case the standard cable is one of 434 wires of 20-lb. conductor. All these go into 3-in. or 3¼-in. pipes, so that the first-named enables us to imagine 606 separate conversations taking place through a 2¾-in. diameter circular space.

From the exchange basement the main cable runs through the ducts to the point where it is interrupted or terminated in a cable distribution head [35]. This is a cast-iron box, octagonal in shape, fixed on a side wall of the manhole, and with eight holes for the insertion of gunmetal unions. Through one of these the cable is led, the lead tube of the cable being connected to the gunmetal by a "wiped" joint. From the other holes other cables are led away. Those to the distribution pipes are usually 7-pair cables, of half-inch diameter. One lining

accommodates eighteen 7-pair cables, so that a 217-pair cable can be distributed through two such linings. The further subdivision of the 7-pair cable is effected by *double solid* and *single solid* joints, referred to later.

Main Cabling. The drawing-in of the cables is known as *cabling*. In the case of main routes it is first necessary to *rod* the pipes. Sweeps' rods with patent trigger joints, which prevent unscrewing in the pipes, are jointed length by length and pushed through the ducts. They are then used to pull through (*a*) a spun yarn mop, (*b*) a circular brush, (*c*) a test piece of cable one yard in length, and (*d*) a 3-in. rope. *a* and *b* are used to clean the duct, *c* is examined to see if any obstruction may be anticipated, and *d* is to be used for drawing in the cable. The cable, which is mounted on a big wooden drum, may weigh from two to three tons, and is brought to the manhole on a low float. To enable the drum to be revolved a steel axle is passed through its centre, and it is elevated on a pair of screw jacks. At the other manhole a winch has meanwhile been got into position, and the pulley rope brought round a pulley block anchored so as to be opposite the proper duct when the strain is applied. When all is in readiness four men turn the winch handles and the cable is fed in, turning off the drum and through a large arc of a circle into the duct. A liberal dressing of petroleum jelly is applied in order to facilitate its progress.



35. DISTRIBUTING BOX FOR 217-PAIR CABLE

Seven-pair Cabling. Similar operations, but on a smaller scale, are carried out in connection with the distribution cables. There is, however, one special feature which in London has been extremely valuable. Seven-pair cables can be introduced into pipes as required, the rods being introduced over the cables already in place. When the pipe is nearly full the ordinary 1-in. rods cannot be used, and a ½-in. steel-core rod is employed. Sometimes in long lengths it is desirable to use a few lengths of ½-in. rod, and then, to obtain the necessary rigidity, a special reducing length is used to connect on the ordinary 1-in. rods. In this way as many as 20 7-pair cables can be placed in a 3-in. pipe, and in cases where the distance between boxes is small, 23 can be inserted.

Cable Jointing. Proceeding from the less to the greater, we will first describe the making of a joint between two lengths of 7-pair cable. The materials required are a lead sleeve 6 in. by ½ in., 14 small paper sleeves for covering the conductor joints, some solder, some mixed resin and Russian tallow, lamp cotton, thread, and wrapping paper. Everything must be kept properly clean and dry, and to this end a Gothic tent is usually mounted over the joint box. The paper sleeves and wrapping paper are kept warm over a spirit lamp. The lead sleeve is threaded on to one of the cables.

From each cable end a 6-in. length of lead is removed, exposing the outer paper wrapping, which is cut off back to the lead. The seven pairs of wires, each with its identifying coloured thread, are separated; in each case the thread being carefully looped round its proper pair. The arrangements for identification are so complete that when the jointing has been done properly, a cable can be cut into at any point and any required wire picked out. To achieve this the two wires forming a pair are wrapped one in red and one in white paper; these are the A and B wires respectively of the telephone pair. Round the centre pair of wires there is a white thread. This is No. 1 of the seven pairs. No. 2 has a black thread, No. 3 blue, No. 4 green, No. 5 two threads, one red and one black, No. 6 red and blue, and No. 7 red and green. Without unrolling the paper the whites of No. 1 pair are laid across each other at a point 1½ in. from the ends, the white thread from one side being included. A few twists are made, and then the remainder of the paper is stripped off and the copper conductors twisted together for a length of an inch. The twisted joint is then laid parallel with the wires, and a paper sleeve, which has previously been threaded on to one side, is brought over the copper joint. The other pairs are similarly treated, an expert jointer arranging that the joints are "staggered" so as to reduce the maximum diameter.

A wrapping of paper is then put over all and tied down tightly with thread. The lead sleeve is now pulled over the conductors and set up vertically so that one end may be soldered. A little wad of lamp cotton is first pushed in between the cable and the sleeve, some tallow and resin comes above this, and by means of a small spirit blow lamp the opening is neatly closed with solder. The other side is similarly dealt with. It should be stated that before making such a joint the lengths of cable are adjusted so that when completed the cable joint may be neatly trained round the box and fastened up along the side on a supporting bracket. Single solid joints are used to connect a 7-pair cable to seven separate 1-pair cables. A special sleeve and a solid lead plug containing seven lengths of 1-pair cable are used. The method of jointing is similar to that described above, with the addition that the conductors are tipped with solder at the joint and that melted insulating compound is run into the sleeve, which is provided with a screw cap inlet. Double solid plugs connected by seven lengths of 1-pair cable are provided for connecting 1-pair cables to 7-pair cables at intermediate points.

Cable Codes. To facilitate reference and identification every cable has code letters allotted to it. Junction cables have four letters; main distribution cables, three letters; and 7-pair cables bear the three-letter code of the main cable they spring from, plus one or more letters. Thus, the circuits on Nos. 1 to 7 in main cable QBX become in the 7-pair cable QBX+A, Nos. 8 to 14 are in QBX+B, and so on round the alphabet.

The connecting up of subscribers takes place from the box outwards, and in a properly managed system plans are kept up to date, showing the position of every wire both working and spare, and new subscribers are added without the slightest disturbance to those in existing cables, everything being planned out in the drawing office and complete detailed instructions issued to the workmen.

IS THE WORLD REAL?

The Failure of Materialism to Explain Life. How Prof. Hæckel's Foundations Slipped Away. Is Mind Matter or Matter Mind? Idealism and the Problem

By Dr. C. W. SALEEBY

THE word "monism" is derived from the Greek *monos*, one, and therefore literally means simply one-ism.

Now it is, of course, evident that the word as such makes no assertion as to the nature of the one; it merely crystallises in a modern term the idea expressed in Indian philosophy thousands of years ago that "the Real is one." The word, however, has somewhat ingeniously been appropriated by those who believe not merely that the Real is one, but that this one is essentially physical and not psychical. Armed with this word, they are in the habit of describing all their opponents as "dualists" or "pluralists"—persons who believe that the real is not one, but two or many. This is, of course, a quite unwarrantable assumption.

Monism is Oneism. The truth, indeed, is that all honest and serious thinkers of all ages have admitted the monistic principle—have indeed been monists. The demand for some unifying principle is an imperative necessity of the mind of man directly he begins to think. In his heart of hearts every thinker believes that the Real is one, and this central principle of what now calls itself monism, so far from being in any sense new, is quite the oldest doctrine in philosophy. Indeed, we may safely say that there could be no philosophy until the human mind had advanced far enough to entertain this very idea. Properly speaking, then, when we use the word "monism" we should always employ a qualifying adjective. The monism which has succeeded the materialism of last century should properly be called materialistic or physical monism. Beside it, for the sake of order, we may place in our minds two other kinds of monism which have absolutely equal claims to the use of that word. One is *pantheistic monism*, which asserts that everything is God. This great conception is the central tenet of what has lately been called the "new theology," and is probably about three thousand years old. Lastly, there is *idealistic monism*, or idealism, which asserts that everything is mind. To those who especially call themselves monists to-day pantheism is pure superstition, and idealism is pure nonsense.

A Ridiculous Riddle. The supporters of these doctrines have every whit as good a title to the use of the word "monism." We have yet to hear more of it, of course; meanwhile, let us note that the battle has always been, and still is, not between monism and pluralism—for no one believes that the Real is many—but between monism and dualism, the doctrine which asserts that the real is two, what we call mind and what we call matter. Our business, then, in tracing the materialistic school of philosophy, is to address ourselves to that particular doctrine to which, of late, the great name of "monism" has been especially attached.

This new doctrine is the legitimate successor of the materialism of last century. It is the doctrine that everything that exists is really a form of what the physicists call "energy," and plainly the best and simplest and most accurate title for it would be *energism*. This new doctrine is at present in need of a proper philosophic statement, and so we ourselves must do our best to fill the gap. The nearest approach to such a statement will be found in Professor Hæckel's "Riddle of the Universe." That volume, recent though it is, already contains a great deal of very ludicrous reading, and if there be any competent person who believes in the philosophy which it contains, he is really called upon to provide a successor to that book, less easily contradicted by the admitted facts of physical science. It is in the absence of any such successor that we are compelled, curiously enough, to outline the newest form of this doctrine without having any author to whom to refer.

The Lost Foundations of Professor Hæckel. Omitting any inquiry into the nature and conditions of our knowledge, and taking it for granted that the crude realism of common-sense is open to no question, Hæckel turns to the physical sciences for foundations upon which to build. For this purpose he takes from physics the law of the conservation of energy and from chemistry the law of the conservation of matter, and upon these as co-equal and co-relative, he builds. Nowadays, however, chemists have been compelled to abandon utterly the law of the conservation of matter, as we have seen in another course, and with the disappearance of matter as in any sense an entity Hæckel's pages can no longer be regarded as relevant to the philosophic problem as it presents itself to the mind of the twentieth century. The following is a recent and very acute criticism of Hæckel's position:

"He believes that mind and soul are inherent attributes of all bodies. Curiously enough, he supposes that by making mind a universal attribute of matter he has made his philosophy not materialism, but monism. It is really both: monistic, because it reduces substance to one kind; materialistic, because it identifies that one kind of substance with body or matter, and reduces mind to an attribute of matter. It makes no difference to attribute mind to all matter, so long as it is attributed as an attribute. It is at least as materialistic to say that unconscious mind is an attribute of brain; and this is the position of Hæckel." [Encyclopædia Britannica. Tenth Edition. Article on "Metaphysics."]

But, as the reader is surely aware, this word "matter," which fills so large a place in the pages of Haeckel and his predecessors—and also, indeed, in the pages of philosophy generally—has lately suffered many strange experiences, and the upshot of them is no less than that the word "matter" has henceforth no reason or business to occur at all in any philosophic controversy. We are compelled to believe, nowadays, that matter is merely a more or less transient manifestation of that wider something which physicists now know as energy, and the really important and vital thing is the new aspect which the old doctrine bears when it has been restated, as it must be.

The Sad Betrayal of Materialism. From the very first, materialism has had a magnificent advantage over all other philosophic systems. As the mind of man is constituted, there is nothing that breeds such conviction in it as the palpable and the tangible. The abstract, the invisible, the impalpable, is for most minds more or less of a fiction. It does not "really" exist in the sense that a marble or a grain of sand exists. There, at any rate, is something which you can touch, something that you can feel the very resistance of. It is real. Now, materialism is simply the doctrine which asserts, or used to assert, that this good, hard, palpable, tangible stuff which we call matter is the real real. It asks us to conceive, as we think we can so readily conceive, of everything in terms of tiny bricks or grains of sand moving about in one direction or another. The picture is simple and intelligible, and it makes an appeal to that particular sense which, humble though it really be, has the privilege of endowing its information with a peculiar certainty—the sense of touch.

Now the real value of the recent scientific study of matter lies in the curious transformation it has wrought in the plausibility of materialism. That poor doctrine has been cruelly betrayed in the house of its friend. Uncritically examined, the conclusions of science seemed not so long ago to afford some sort of surface ground, at any rate, for this doctrine, which declares in effect that atoms are the only real thing and that mind is a myth. Upon that imperfect scientific conception materialism was built—any inquiry as to the nature of our knowledge of atoms being ignored.

Materialism a Philosophy Without Foundations. But now, quite apart from any criticism of knowledge, materialism finds itself in the difficulty of feeling its very foundations slip from under it—not into nothing, but into the intangible. There is, of course, something to which atoms correspond, something of which they are a manifestation; but that something is intangible, and there's the rub for materialism. Its age-long advantage of appealing to the sense of touch, in which we are apt to believe so heartily, has been taken away. However real a marble may feel to us, that peculiar sense of reality can no longer be appealed to or utilised by the materialist. His theory is now on a level with other theories, and can make no special appeal to this biassed judge. For the marble, despite its convincing air of solidity, must yet be conceived by us, if we are to accept the verdict of science at all—as materialism constantly asserts that we must—in terms not of hard atoms as resistant as itself, but in terms of electrons which, we are now taught, have no mass that is not electrical inertia. Now, materialism, as it has lasted throughout the ages, has really been built upon this notion of mass. There, at any rate, in whatever had stuff in it—good massy, solid stuff in it—there, at any rate, was something real; but it is rather a different task to persuade mankind that the only ultimate reality is electrical inertia.

The Real is Unknowable. But let us give the doctrine a fair chance, and employ a word which is more familiar, and which, at first sight, we may seem more easily to grasp. It is to the something called "energy" that physical science would now reduce the external world. All matter has to be regarded as simply a mode of energy, and we have to try and conceive of this something as the only physical reality. We may remark in passing that this physical conclusion is by no means as secure as some would have us suppose. There is, for instance, the little problem of the universal ether, about which no one has yet said anything that he can persuade anyone else to believe. But still, we may take it, for the sake of argument, that all external things are simply transient modes of this one thing—energy, and we may then address ourselves to the very necessary question, What is energy *itself*?

The plain fact is that we cannot get any "clear and distinct notion," as Descartes would say, of the nature or inmost reality of energy. We know of it nothing but what it accomplishes; it is a something that has power, and this power seems to be incapable of creation or destruction; but in what it inheres, what is the *substance* of it? These questions we cannot answer at all. This is a strange conclusion to be reached in the order of time by those simple, dogmatic, and so plausible propositions which materialism with its hard, round, massy atoms, used to afford us. All criticism of the nature and quality of our knowledge apart, we are now ordered to brush aside tangible matter as a mere transient accident, and to endeavour to conceive what is indeed utterly beyond conception. The inner nature of the external world we find to be unknowable, inconceivable, ineffable.

And the most significant thing is this—that our conclusions are not based upon "metaphysical" considerations; we are not forced to them in deference to the criticism of professional philosophers, nor psychologists, nor logicians. On the contrary, they are the conclusions directly reached by physicists as a direct consequence of their continuance in those very studies upon the immature stages of which the old materialism was built.

What is Mind? But there is now growing out of modern physics a new and very plausible theory which constitutes a further attack upon the supremacy of mind, and which seeks to clinch once and for all the case for energism. The older materialism did not attempt to include mind within its system. Mind was simply an accident that could be ignored; it had

a physical basis and origin, but it could not be thought of as having any real existence at all; not even a physical existence. Remembering that the older materialism was based upon the idea of atoms, we can understand how it was that no one ventured actually to count mind amongst the material things. The old speculation of Democritus, which made the mind consist of a particular kind of atom, was evidently too naïve for modern use. But the reader will readily understand that, just as the new form of materialism loses in plausibility by no longer having the tangible atom to appeal to, so it greatly gains in plausibility in another direction, for it finds possible the argument that this impalpable, inaccessible, but nevertheless physical something, which is called energy, may display mind as one of its forms.

Is "Mental Energy" Physical? We all speak at times of mental energy—a somewhat vague phrase, which nevertheless stands for an intelligible idea; and the passage is easy from regarding this phrase as a metaphor to regarding it as the literal truth. Electrical energy, kinetic energy, thermal energy—why not mental energy? Everything except mind has been more or less clearly resolved into what the physicists call energy. This is capable of infinite transformation—sometimes into gross forms, such as ponderable matter; sometimes into utterly impalpable forms, such as chemical energy and other forms of potential energy or energy of position. Now, we know that mind is intimately correlated with physical energy, for we know its correlation with the brain, which, physically considered, is only a gross manifestation of physical energy. Why, then, should not mind be one of the subtler modes in which physical energy may display itself?

Up to a point, the argument becomes more powerful the more it is studied. If we approach it systematically from the inorganic to the organic we find that the problem of life itself affords what seems to be a convenient link, hinting at the real identity of physical energy and psychical energy. The more complete is our study of the physical sciences, the more thoroughly we blend physics, chemistry, and biology into a consistent and coherent body of knowledge, the more strongly are we convinced that this something which we call energy is the one universal reality, uncreateable, indestructible.

Is Mind a Form of Matter? Thus convinced and strongly urged to the view that the Real is One, the student proceeds to consider *mind.* We can readily understand how it seems to him, thus prepared, to be almost a necessary truth that, just as motion, sound, light, heat, electricity, magnetism, the chemical forces, the vital forces, were found each in turn to be forms of energy, so, of course, this next entity that he has come to study is just another form of energy—a form somewhat more subtle, perhaps, somewhat more ethereal, somewhat further removed from matter, which may be conceived as the grossest form of energy, but, nevertheless, necessary to be identified with all, these in the last analysis. Space is too precious for us to repeat anything already said on page 2115, but the argument is so important, and especially so important to-day in the absence of refutation of it from the scientific side, that we must add something to what has there been said. The following considerations are new, and the reader is asked to study them in association with the page referred to.

The Physical and Psychical. It is a wholly gratuitous assumption, and is doubtless untrue, that in the course of an hour's consciousness the brains of two men consume equal amounts of food material. But let us grant it for the sake of argument. The facts are these. If you oxidise a gramme of phosphorus, whether in a brain or in a test-tube, you will obtain the same amount of heat. Meanwhile, however, one such brain is yielding, in addition to the heat, Macbeth's speech beginning: "To-morrow and to-morrow and to-morrow." Another such brain is producing imbecile doggerel; and the test-tube is producing nothing besides the heat. Those who maintain that mind is a form of energy have it incumbent upon them to demonstrate the strict quantitative equality of (1) Macbeth's speech; (2) imbecile doggerel; and (3) nothing.

In truth, there is no quantitative relation between the psychical activities and the physical activities of the brain. The present writer has yet to meet with any recognition of the philosophic significance of a fact well known to dieticians, that there is no correlation between mental work and the amount of food required. It is recorded by Professor Atwater, one of the most distinguished American students of dietetics, that "a man was confined in a respiration calorimeter for a number of days, and on certain of them he engaged in the severe mental work of reading a German treatise on physics." The subject purposely worked very hard at the book, since he well understood what it was desired to ascertain by the experiment. All the other conditions were kept carefully constant, but it was found that *on the working days the bodily waste was no greater than on the days when no mental work was done at all.* All the exact experiments that have been made agree that mental work, whether productive or receptive, has no quantitative relation whatever to the transformation of physical energy.

Eating and Thinking. This absolute want of any quantitative relation between psychical and physical energy is of significance not only because such a relation must be demonstrated before any physical theory of mind becomes plausible; it is of practical interest in relation to dietetics. If we consider the effortlessness of the highest genius, and the frequent sparseness of diet of intellectual workers of the highest order, we find it impossible to doubt that the most potent and complex psychical activities may be correlated in one brain with the oxidation of much less food material—that is to say, with the transformation of much less physical energy—than may be required by another brain, the psychical activities correlated with which signify nothing. It is very commonly observed that men of consummate genius have been sparse eaters.

Amongst recent instances are three great figures of the nineteenth century, Darwin, Huxley, and Spencer, all of whom suffered from chronic dyspepsia. For many years Spencer's diet cannot have been more than one-fourth or one-fifth part of the ordinary diet of a man of his weight. Yet his psychical activity was incessant, and since it kept him awake he was ever at a loss for fresh devices to make him "stop thinking." If we follow the argument out, and consider the case of the large eater, in whose body enormous quantities of physical energy daily undergo transformation, we shall see some meaning in the idea to which men in all ages have given utterance—the idea of the burden of the physical, and the load it imposes upon the psychical.

"When We Lie A-thinking." On the popular theory that mind is a form of physical energy, any such doctrine of the burden of the physical spells nonsense, for in proportion as mind is exhibited, its source—physical energy—must be supplied to the body. The facts, however, are notoriously otherwise, and, on the contrary, lend a somewhat novel support to the ascetic principle—the principle that the bodily or the physical must be kept under, lest it burden and clog too much the psychical. There is a fallacious reply to this argument which depends upon the confusion of physical with mental energy in the case of the individual man. Many men of action are, and have been, men of great physical energy. In the course of their enterprises they will actually utilise an amount of physical energy which is exceedingly large, and such men must inevitably be hearty eaters; but it is an utter confusion to confound this energy of the energetic man—which is obviously and measurably physical energy—with the psychical activity of pure thought. So far as all evidence and probability goes, there is absolutely no quantitative relation between the psychical and the physical when one lies a-thinking in the night. Physical changes are, of course, occurring in the brain, food material is being broken down, and potential chemical energy is being transformed into kinetic energy, such as energy of heat. But a complete equation could be written, demonstrating the truth of the law of the conservation of energy, *without the insertion on either side of it of any psychical term;* and, as we have already observed, if it were attempted to insert any such psychical term there is no conceivable unit of quantity which could be employed in the statement.

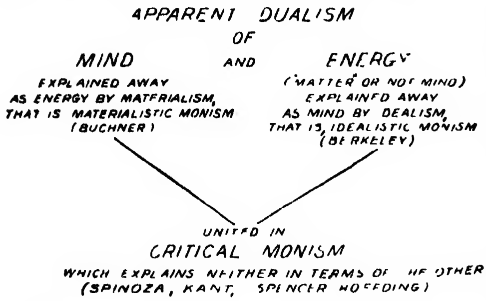
Mind and Not-Mind. We pass on to a new subject, and meanwhile let us take stock of our position. We have attempted a complete refutation of the doctrine that mind can be included within the physical, which latter, by general consent, has been reduced to a somewhat intangible One. Now, that seems to be something accomplished; but observe that our rejection of materialism or energism seems to involve the loss of our belief that the Real is One. We find ourselves asserting that the Real is not One, but two—mind and not-mind. We find ourselves rejecting monism—which is the goal sought by every philosopher—and accepting a dualism. We have yet to see whether this dualism is proximate or ultimate. Here, at least, we may note the historical fact that the greatest thinkers of the past have never yet rested content with this dualism of mind and not-mind—or mind and matter, as men used to say—as the final truth. On the contrary, they have always gone on to seek behind or within this proximate dualism an ultimate oneness or monism. To this we must return.

The Opposed Schools of Materialism and Idealism. Meanwhile, however, let us pursue our systematic course. In the face of this apparent dualism between mind and not-mind, two ever opposed schools of thought have sought two diametrically opposed solutions which at least agree in this, that they seek alike to dethrone one of the terms of the dualism and to explain it in terms of the other. Materialism in all its forms declares that the dualism is only apparent, since not-mind is the reality and mind may be explained in terms of it. That view we have discussed. Over against it, throughout the ages, another school of philosophers have placed the precisely opposite view. They also have sought to dethrone one of the terms of the dualism and to explain it in terms of the other. But it has seemed to them that it is not-mind which must be dethroned and explained in terms of mind. "The only reality is not-mind," says materialism; "the only reality is mind," says idealism.

Now, we are studying what is incomparably the most difficult subject to which the human mind can address itself, and we shall reach no goal at all if we do not take frequent bearings. For this purpose the writer has attempted to prepare a scheme which may be of some use. In it we shall definitely abandon the word matter, and we shall accept the great physical generalisation which includes, or attempts to include, under the unitary fact called energy everything that is not-mind.

A Third System of Thought. We contemplate, then, an apparent dualism of mind, on the one hand, and energy on the other, this last word being used in its technical scientific sense. We then proceed to discuss two great systems of thought which have one point and one only in agreement. This is, that one or other of these two terms, mind and energy, is *the* ultimate. Materialism attempts to describe mind as energy; idealism attempts to describe energy—that is, the external world—as mind or mental creation. It is incessantly asserted by thinkers of both these schools that there is no third choice—except to rest content with dualism, as no one can. Let us have it clearly stated, however, before we proceed to discuss idealism, that there *is* a third choice. This consists in examining afresh the two terms in our apparent dualism, and seeking a monistic solution, not by the sinking of the first in the second, nor the second in the first, but by rejecting both alike as ultimates, and by regarding them as the converse aspects of a *something beyond*, which is their common *substance*. Following Professor Höffding, we may call this third doctrine *critical monism*, since it is a monism based upon a criticism of our knowledge of mind on the one hand, and our

knowledge of energy on the other hand. Critical monism asserts that the idealists have not criticised their notion of mind, and that the materialists have not criticised their notion of energy. Here is the scheme, which may possibly crystallise what would otherwise be chaotic. Having thus seen the direction in which we are going, let us attempt to do justice to the great system of thought which is called idealism.



The Master Idealist. Many names of various greatness may be associated with idealism. The greatest of them all, George Berkeley, Bishop of Cloyne, was born in Ireland in 1684, and died in Oxford in 1753. Though he lived almost all his life in Ireland, he was an Englishman. He was not only one of the most illustrious philosophic thinkers of all time, not only by reason of his "New Theory of Vision" a master in science, but also one of the noblest and most beautiful characters of whom history has any record. Says one critical and cold-blooded contemporary, "So much learning, so much knowledge, so much innocence, and such humility, I did not think had been the portion of any but angels till I saw this gentleman." His wonderful book on "Optics" was published when he was twenty-five, and his "Principles of Human Knowledge"—one of the few greatest works of all times—when he was twenty-six. In some remote age, when "oblivion has spread her poppy" over the memory of the statesmen, falsely so-called, the warriors, the self-seekers, and the crowned fools and knaves whose ignoble names fill our history books and are thrust in all their pettiness into the memories of our children, the name of Bishop Berkeley will be remembered and honoured at its due worth.

Idealism and Common-sense. Now, let us enter into a preliminary warning before we proceed to discuss the philosophy of Berkeley. Pope has a line, "And coxcombs vanquish Berkeley with a grin." His views have been "laughed at, written at, taught at, shrieked at." Everyone is familiar with the story of Dr. Johnson, that incarnation of the limitations of common-sense, who thought he had disposed of Berkeley by kicking a stone. Let us try to recognise what every student of philosophy must know from his own experience—that there is a stage of mental development in which idealism appears to be the most monstrous of absurdities. Some of us may remember hearing at school the quaint notion that the world only exists in our minds or in some Higher Mind than ours; and probably, after the fashion of schoolboys, we characterised this notion as "rot." Now recent psychology has shown that a very large proportion of the population never develop at all beyond the stage which may conveniently be described as the twelve-year old mind, and to the twelve-year-old mind, certainly, the doctrine of idealism is the sheerest nonsense—"only that and nothing more." Whatever our conclusions may finally be, let us remember the great advice of Lord Acton—"to understand what we reject as thoroughly as what we accept."

Idealism and Matter. When we say that Berkeley denied the existence of matter—or, as he would now have to say, physical energy—we do not mean that he denied, or acted as if he denied, the phenomenal existence of phenomena. The difference between him and his opponents is that, while they postulate something behind phenomena, Berkeley says that this supposition is superfluous. He finds no need to suppose that there is an inaccessible *noumenon* or substance underneath all the properties by which we know the outside world. For him those properties are themselves the whole thing. There is nothing beyond the world of sense, *but*—this world of sense is no more than the phrase suggests—a world of *sense. Outside and beyond sense it has no existence.*

What we commonly do, however, is to group together in our minds certain of the properties or qualities from which we infer the external world, and then we declare that these inhere in something which we agree to call matter, or nowadays energy. According to Berkeley this is a creation of our minds, and has no existence outside them. It is our minds that have put together these qualities and properties, compared them, and then explained them in terms of something behind. But there is no such something behind; it is only our way of thinking. As Berkeley points out, once we admit its existence we find ourselves in all sorts of difficulties. The further we pursue it the more certainly we find ourselves in absurdities and contradictions; but, says Berkeley, "Upon the whole, I am inclined to think that the far greater part, if not all, the difficulties which have hitherto amused philosophers and blocked up the way to knowledge are entirely owing to themselves — that we have first raised a dust, and then complain that we cannot see." He boldly solves the difficulties in which realism finds itself, and especially the pre-eminent difficulty of explaining how it is that mind can know not-mind at all.

The Doctrine of Berkeley. Here is the famous passage in which, especially in its last sentence, his theory is stated: "That neither our thoughts, nor passions, nor the ideas formed by our imagination, exist without the mind is what everybody will allow; and to me it is no less evident that the various sensations or ideas imprinted on the sense, however blended or combined together, cannot exist otherwise than in a mind perceiving them. . . . The table I write on, I say, exists—*i.e.*, I see it and feel it—and if I were out of my study I should say it existed, meaning thereby that if I

was in my study I might perceive it, or that some other spirit actually *does* perceive it. As to what is said about the existence of unthinking things, without any relation to their being perceived, that is to me perfectly unintelligible. Their *esse* is *percipi*; nor is it possible they should have any existence out of the minds or thinking things which perceive them."

If we perceive nothing but our own ideas and sensations—which everyone admits—it is impossible to imagine that any one of these ideas, or any combination of them should exist *unperceived.* Their *esse* is *percipi*—their being is the being perceived. Furthermore, "When we do our utmost to conceive the existence of external bodies, we are all the while only contemplating our own ideas."

Followed out in its logical entirety, this theory leads Berkeley to the famous passage which it is a privilege to quote:

"In a word, all the choir of heaven and furniture of earth—all those bodies which compose the mighty frame of the world—have not any subsistence without a mind; their *esse* is to be perceived or known, and consequently, so long as they are not actually perceived by me, or do not exist in my mind, or that of any other created spirit, they must either have no existence at all, or else subsist *in the mind of some eternal spirit.* . . ."

The Crux of Idealism. The most obvious retort to the idealist, of course, is the question whether he believes that the round earth, and all that it contains, would vanish with his annihilation, and the reply he must make is that of Berkeley himself: "Whenever bodies are said to have no existence without the mind, I would not be understood to mean this or that particular mind, but all minds whatsoever." Then it might be replied that the whole human race may conceivably suffer destruction: would this involve the annihilation of the external world? Berkeley's doctrine, however, does not lead to the conclusion that the existence of dead matter depends upon the existence of living matter.

But now for a further objection to idealism—an objection which every consistent idealist recognises and which it seems impossible to answer. Let us freely grant Berkeley's position as regards the external world in general. But how does the idealist escape from the conclusion that he, as a perceiving entity, is the only thing that exists at all; that he is not merely the centre of his own universe, but *is* the whole universe—that is to say, that apart from him all other things, including his fellow men, have no being? Here and there a stray thinker has been found who thought himself compelled to accept this conclusion, which is sometimes known as *solipsism*, but evidently it is too monstrous for anything but ridicule. If idealism necessarily leads to the conclusion that he, the idealist, is *solus* and *totus*—alone, and the whole—then so much the worse for idealism. And, in any case, if he thinks so, why does he make a fool of himself by saying so, there being none to hear?

The Supreme Idea of the Divine Mind. Now we need not imagine anything so foolish as that so obvious a criticism as this did not present itself to the magnificent mind of Berkeley. His answer to it we may readily anticipate. It is that he and other men "subsist in the mind of some eternal spirit." Without this supreme idea of the divine mind, idealism cannot hope to stand at all. It might effectively criticise all other philosophies and reduce us to scepticism, but it could substitute nothing for them. None of us has any use for a doctrine which asserts that his best friend has no existence outside his own mind. This is the last and most ridiculous egoism.

But, completed as idealism may be by invocation of an all-embracing divine mind, in order to solve what would otherwise be insoluble difficulties—so completed, it may be incapable of rational proof, but it is equally insusceptible to the assaults of rational criticism. It is a consistent, self-consistent, complete, and noble hypothesis.

The Grandeur of Idealism. Starting with the one fact of which we are absolutely certain—the fact of the existence of spirit, mind, or something that thinks—it proceeds by processes of impeccable logic until it has constructed what is not only a great philosophy—whether or not it actually compels rational assent—but also the basis of a mighty religious conception. Technically and rationally, this idea of the divine mind is perhaps an assumption; it may be declared to be outside the proper range of philosophy—that we have no right either to assert or to deny regarding it. That is a question which it is impossible to follow up here. Berkeley would say that it is a necessary assumption, and that without it we find ourselves in greater difficulties—that is to say, rational difficulties—than with it. But this we may recall or anticipate—that the conception of a universal mind is by no means a last resort for puzzled idealism, by no means merely a *deus ex machinâ.* On the contrary, some such conclusion is reached by many other roads, and with what compels us to regard it as equal necessity.

Since the time of Plato, at least, there have been idealist philosophers, but it is frankly to be confessed that they feed the mind on very little more than wind and words. After you have long tried to get hold of them, and failed, you begin to suspect that there is really nothing there to grasp. When it is found, also, that they incessantly contradict themselves, that none of them has any difficulty in refuting all the others, that the disciples of their bosoms offer wholly contradictory accounts of what the master taught—your conviction is reasonably confirmed.

"We Live in the Creation." It is really unnecessary to discuss these other idealists at any length, though just the very briefest mention must be made of the name of Hegel (1770-1831), who founded a school—if school it can be called—which was dominant for many years in his native Germany, was exported to Oxford, and is only now beginning to evaporate there. Hegelianism is founded upon the doctrine that "to be and not to be are the same," and that the non-existence or the nothing *exists,* because

it is a thought. Thus beginning with the *identity of contraries*—the principle that everything is and at the same time and in the same sense is not—it may well be imagined that Hegelianism ends in the most amazing medley of verbal absurdities that the human mind has yet achieved.

At least, however, we cannot leave the name of Hegel without commenting upon the magnificent advance involved in his idea of creation. To Hegel, as indeed to many greater thinkers than he (but his statement of it was of historical importance) the "creation of the world" was not a thing once done by God, but a thing perpetually doing by Him "in whom we live and move and have our being." Creation is "God passing into activity; but neither suspended nor exhausted in the act." God did not make the world "one fine day," nor in seven, but sustains and creates and recreates it "from everlasting to everlasting."

The Newest of all Philosophies. Now, it is to be hoped that we have not lost our bearings. Let the reader glance again at the scheme which we made for him. We have discussed as best we may the two fundamentally opposed doctrines of materialism and idealism, and we have noted also the one point in which they agree. We must pass on now to the philosophy of the present day. Doubtless that embraces thinkers of many schools, but still it is fair to say that the systems which we have been discussing are scarcely representative of current philosophy, which has been so deeply affected by the criticism that was the chief part of the life work of Kant.

It is not necessary here to return to the philosophy of Kant, the substance of which we have previously endeavoured to state, but we may trace in the present day, and to him, the wide recognition of the necessity of examining even our most cherished notions before we venture to build great philosophic generalisations upon them. This demand that we shall beg no questions at all —and least of all the question, What is truth?—has generated in the present day, in England and America, what is indeed the very latest brand of philosophy; and before we pass on to greater themes we must spare a word for this new school, especially as its case is very interesting, and has lately become very popular.

What is Truth? The chief names that may be mentioned in connection with this most up-to-date of philosophies are those of Professor Dewey and Professor William James, of America, and Mr. Schiller, of Oxford. It is from the latter especially that we draw, as accurately as may be, the argument of this new school regarding the agelong and fundamental question, What is truth?

We must say, in a word, that according to this school we have no means of knowing or identifying the truth except in so far as we may agree to call the truth anything that "works." The name which has been given to this new philosophy is "pragmatism," from the Greek verb *prasso* (I work, accomplish, or achieve), and it is upon this conception that the philosophy is built. Its importance for us at this point lies in its rank as a critical philosophy, and its criticism is certainly directed to the very root of the matter.

An Old Test of Truth. Many are the thinkers who have addressed themselves to this question of the means by which we may identify truth. Probably on the whole this is the first preliminary question of all philosophy, for, if we are not agreed as to the answer, or if no answer is obtainable, it would seem hopeless to proceed further. The essence of the pragmatist position consists in examining and rejecting various tests which have been proposed for truth and substituting a new one.

It is not necessary here to examine the various ways in which truth has been defined, nor to discuss the issue between the absolute scepticism which denies that we can know any truth and the relative scepticism which declares that our knowledge, even if it be only symbolic, is yet valid so far as it goes. Suffice it that, by practically general consent in these days, philosophers are agreed that the test of truth is precisely that which each and all of us employs as the test of truth in daily life. It is *consistency with the rest of experience*. This is not to assert that the test is a final one or that it never errs. Obviously its value must depend upon the quality of the rest of experience. The immobility of the earth was for ages regarded as a truth just because all experience seemed to be consistent with it, and with nothing else. Yet with the widening of experience and the making of astronomical observations, which added new *data* to experience, the theory of the motion of the earth came to be the only one now consistent with the rest of experience, and it is accepted on that ground.

A New Test of Truth. Let the reader take this idea with him into his thoughts and life for a few days, and he will realise that it is by this means that we all of us judge of truth or fact. Let him reflect further that all human action and thought furnishes evidence of the value of this principle, and let him also ask what is assumed by everyone who uses it. The assumption that no fact can contradict, but on the contrary must be consistent with, any other fact involves the belief that the universe is a universe, and not a chaos. Though, like the rest of mankind, they use this test in their daily lives, pragmatists endeavour to show that it cannot at all be accepted as a test for truth. Instances such as that of the motion of the earth, however, in no way affect the validity of the principle. They merely show the results of its imperfect application. However, it is possible with a little skilful writing to make this test of truth, its consistency, seem absurd, though, of course, you are assuming its value in every word you write, and would be very much astonished if your readers took your argument to be a comic story about a dog and a tin kettle. Thereafter the pragmatists set up a new test of truth, as interesting and attractive as may be. This test is to be nothing else than human action. There is and can be no truth, say the pragmatists, except just what suits him who believes it. If it suits him, serves his life, and goes with his actions, then he may know it to be true—nor can he do so by any other means.

WHAT TO DO IN ACCIDENTS

How to act in Cases of Emergency. Treatment of Wounds and Bruises. How to Restore Respiration in Cases of Drowning

By Dr. A. T. SCHOFIELD

WHEN an accident occurs, let the patient lie or sit. If he is at all faint or insensible, keep him lying down flat, loosen the things round his neck, and do not let people crowd around, but keep them away so as to give him plenty of air.

Do not move him at all till you quite understand his injury, and be as quick as possible in finding out what is wrong.

Until the patient is removed to his home, or to a suitable place, let your aim be only to stop any bleeding for the time, and to prevent injury in moving.

Avoid needless questions and pulling about. Unless the case be plainly trivial, send for a doctor at once. Do not *drag* clothes off an injured part, but carefully rip them up or cut them off to examine it. When you have to remove the clothes, take them off the injured side last. Always begin on the sound side.

If the patient appears very low, give two teaspoonfuls of brandy, or a little water with a few drops of sal volatile.

Hæmorrhage Cases. We will now consider the most common emergencies one by one. In hæmorrhage, if the blood be bluish and dark, it is from a vein; if bright red, and comes in spurts, it is from an artery. The latter is far more profuse and dangerous than the former. In all cases one must act decidedly and quickly.

The first thing is to see where the blood is really coming from, and at once to fold up a bit of rag, handkerchief, or any other cloth, and press on the spot with your thumb steadily until you can get a bandage ready.

Pressure on the spot where the blood comes from is always the first thing to aim at. Do not stand and look at it, but make at once a determined effort to stop it.

In most cases, in a minute or two the blood will cease to flow, and will clot. The pressure must not be taken off, but another neat pad must be made by folding up a piece of rag, and then placed over the first, and a bandage put round the part.

If, however, the blood still flows round your thumb and from under the pad, look out for garters or tight strings above the wound, and cut them. Always raise the limb and expose the part freely to the air; by these means you lessen the flow of blood and make it clot more quickly. Should it continue to flow in jerks, at once press on the artery higher up than the place from which the blood comes.

If the blood comes from *the head*, firm pressure against the skull with a piece of cork in the pad is generally enough, if well secured.

If from *the face*, the blood-vessel should be held tight between one of the fingers (inside the mouth) and the thumb (outside).

If from *the neck*, as in cut throat, press the artery you feel beating below the cut firmly against the back of the neck.

If from *the arm*, press the artery above the wound with the fingers against the bone till the bleeding stops; or knot a handkerchief loosely round the limb, and then, with a stick, twist the handkerchief round and round till it squeezes the artery tight.

If from *the forearm*, press in the same way on the arm artery, or put a pad in front of the elbow, and bend the arm up firmly on it.

If from *the thigh*, press the artery in the centre of the groin firmly down with both thumbs on to the bone.

If from *the leg*, put a pad under the knee, and bend the leg forcibly on it.

An indiarubber band, tube, belt, or brace stretched firmly round the arm or leg above the wound stops the bleeding at once.

Bleeding may come on suddenly from the nose or mouth. If from the nose, and it is not excessive, it may relieve headache and congestion, and do good rather than harm. If, however, it continues and is severe, do not allow the person to hold his head over a basin, but make him sit up with his head erect, and hold his own nose firmly for five or ten minutes, while you slip a cold door-key down his back. This attitude and slight shock is often enough to stop it. Should bleeding continue, or blood run down the throat behind, soak a handkerchief in common turpentine and let the fumes be sniffed up. The arm raised above the head also stops it. It it still persists, send for the doctor without delay.

The blood may come from the mouth. If it comes in any quantity, its source is probably either the stomach or lungs.

If it is from the stomach it will be rather dark, mixed with food in large quantities, and vomited up after a severe pain. If from the lungs, it will be very light, mixed with froth; it will be coughed up, and come in lesser quantity.

In either case, lay the person down under an open window, loosen everything about his neck, keep him quite quiet; and to stop the bleeding—supposing the doctor is not at hand—give him a teaspoonful of turpentine in a little milk, and let him breathe in turpentine from a soaked handkerchief.

Bruises and Wounds. Bruises are injuries caused by falls or blows, which may result in internal lacerations, particularly of the smallest blood-vessels.

In slight cases, apply hot fomentations or spirit and water lotion to the bruise to prevent discoloration.

Wounds may be clean-cut, torn, bruised, stabbed, poisoned, or gunshot. They heal in two ways:

1. Quickly, by primary union (union by the first intention) without suppuration, leaving only a very fine scar. This mode of healing should always be tried for, but can be got only under the following conditions: when the sides of the wound can be accurately brought together; when they are not displaced by bleeding or exudation of matter; when the wound is left quiet and protected from outward injury; and when it is kept perfectly free from impurity.

2. The second mode of healing takes place slowly, with suppuration and the formation of granulations, leaving a large red scar.

It is the matter formed in the process of suppuration which separates the sides of the wounds. When the wound begins to heal, granulations form. These granulations, by degrees, and with constant suppuration, fill up the wound and are finally covered by a large scar, which remains red for a long time. Suppuration and putrefaction open the door to other dangerous surgical ailments, of which many people die after wounds and operations.

Modern surgery has made wonderful progress in the treatment of wounds, chiefly because a more accurate knowledge of the causes of suppuration and putrefaction has taught us how to prevent these processes, and how to guard against many of the dangers to which they give rise.

How to Treat Wounds. The first thing in the case of a wound is to stop the bleeding as already directed. The next is to cleanse it gently, as far as possible without disturbing any blood-clot that may have formed. After that, bring the edges of the wound as closely as possible together, and secure them there by little strips of plaster, the skin being well dried first. Apply the dressing of a pad and bandage, support and keep the injured part at perfect rest, and then attend to the person's general comfort.

Clean-cut wounds heal quickly and easily if all dirt is removed and the edges are brought close together. The pad should be dry, or soaked in a little olive or carbolic oil, and if the wound does not become unpleasant, the dressing may be left for three days.

Torn wounds cannot be closed up, but require cleansing, and the pad must be constantly soaked in plain cold water. Crushed wounds and stabs are to be treated in the same way.

Poisoned wounds are caused by the bites of mad dogs, poisonous snakes, and by poisoned weapons. The danger of these is that the poison from the wound may by means of the lymphatics be carried to the heart, and so poison the whole blood.

To prevent this diffusion of the poison one should, without loss of time, bind the limb round tightly above the wound; this is best done with an elastic belt or a strap or string, or a handkerchief made tight by means of a stick twisted round in it. When this has been done, try to get rid of the poison from the wound. This may be done by sucking it out (if the lips are not sore), by burning with hot coal, hot knife or knitting-needle, or by caustic (carbolic acid, nitric acid, etc.).

In gunshot, and all other *serious* wounds, all that can be done is at once to arrest the bleeding and send for a surgeon.

Bones are hard but brittle, and break like glass or porcelain by outward force—by a blow, fall, or jump—often with a snap or crack which may be heard and felt.

Fractures. Fractures are divided into two kinds—simple and compound. We call a fracture *simple* when the skin is not injured. We call it *compound* when it is accompanied by a wound, caused either by the same force which produced the fracture—a bullet, for instance—or by the ends of the broken bone protruding through the skin.

Compound fractures are much more dangerous than simple ones, because the skin and muscles are always much bruised at the same time, and because dirt may get into the wound and be with difficulty removed.

How do we know when a bone is broken? In four ways: (1) The limb is bent or shortened; (2) there is an unnatural degree of movement at the seat of the fracture; (3) there is violent pain; (4) when the limb is moved the broken ends of the bone may be felt grating against each other.

How does a fracture heal? New bone-substance (*callus*) is formed at the broken ends of the bone and knits them together. This new substance is at first soft, but hardens gradually into bone.

In all cases, therefore, when you have any reason to suspect broken bones, from the pain or the helplessness of the limb, be very gentle and make the person keep quite still. Cut the clothes off the part. See where the fracture is, but move the bones only so as to place the limb in a straight line in its natural position, and then put splints on the inside and outside and back of the limb, and secure them firmly round it by bandages above and below, so that the broken part is fixed and quite immovable. Splints can be formed out of umbrellas, boards, cardboards, sticks, rolls of newspapers, cricket stumps, rolls of rushes, bark of trees, and can be tied on with anything. Thus secured, the patient can be moved with safety on a board, stretcher, or even carried in the arms.

When a jaw is broken, tie it up firmly, by a bandage under it to the top of the head. When ribs are broken, put a broad roll of flannel or linen round the part, and let the patient sit up till the surgeon comes. When a collar-bone is broken, tie the arm to the side with a large pad in the arm-pit till the surgeon comes. In the case of any other fracture, apply splints as directed, and be sure that they are secured above and below the broken part.

Treat any case when you *think* the bone is broken like this; and even if you are wrong, you have done no harm, and have certainly made a mistake on the right side. A surgeon must, of course, be sent for at once.

Dislocation and Sprains. In the case of dislocation, some limb is suddenly put out of joint by over-use or by an accident. You may think it is a broken bone, because the limb is fixed and cannot be moved without pain. But then you remember that though when the bone is broken the limb is helpless, it is not fixed, but very movable at the broken place, and that it is your business to fix it up in splints.

If in doubt as to whether it is a broken bone or only a dislocation, always act as if it were broken and put on splints. Do not try to set the bone yourself.

A sprain is a wrench to a joint; a strain is over-exertion of a muscle. In a sprain, which happens most frequently to the ankle, if at all severe, always send for the surgeon. Neglect of this precaution may lead to serious results.

In the case of sprains, therefore, let the part have complete rest, laying it on a pillow. Elevate the leg (if it be the ankle), and apply cold, either in the form of ice (broken in pieces in a sponge-bag and resting on the joint), or sponge with cold water or with spirits and water. If the pain is still very bad, very hot fomentations may relieve it.

In a case of strain or cramp of the muscles, rub them steadily with warm oil.

Burns. Both burns and scalds arise from the same source, but the one kind is caused by dry heat, and the other by moist.

If a person's clothes are on fire, the one thing to do is to lay him flat down on the floor, roll him over on to the burning part of his clothes, and cover him as he lies with a thick rug; and lastly, if needed, drench him with cold water.

With regard to treatment in slight cases, a little flour dusted on the part at once, so as to form a crust, is very good. In more severe cases, any burnt

parts of dress, etc., should all be cut off first, and the wounds dressed with strips of rag soaked in sweet oil, and then covered with cotton-wool. The blisters that form so quickly should never be broken, but, if large, pricked at the lowest part, and the shrivelled skin not cut away, but left. The surgeon, of course, must be sent for at once. The person must be kept warm, and be given some hot drink.

Scalds require the same treatment, except that as much of the scalding liquid should be washed off as soon as possible.

Burns from strong acids or alkalies, such as vitriol, spirits of salts, or caustic soda, potash or lime, should be first drenched with water, and then, if from an acid, bathed with soda and water; if an alkali, with vinegar and water.

Burns of the face are best treated by painting with olive oil on a feather or brush.

Poisoning. In cases of poisoning, at once send for the doctor; but as he is sometimes a long time coming, and promptness of action is often a matter of life or death, a few very definite instructions are absolutely necessary.

Find out at once (if possible) what has been taken. If it is a strong acid, as vitriol, spirits of salts, etc., etc., give soapsuds, plaster from the wall or ceiling, chalk, or soda in water. If it is a strong alkali, soap lees, caustic soda, lime, or potash, give a glass of vinegar and water. Afterwards give, in either case, a tablespoonful of olive oil.

If it is any other form of poison, give two teaspoonfuls of mustard in a cup of warm water, or any other emetic that may be handy; or get half a teaspoonful of sulphate of zinc and give it in water. Carefully preserve all bottles and all vomited matter, as the case may be one for legal investigation.

When anyone is stung, apply ammonia (sal volatile) to the part, and extract the sting if left in.

Unconsciousness. The chief causes of loss of consciousness are: (1) injuries to the brain, with or without fracture of the skull; (2) diseases of the brain, apoplexy, epilepsy, etc.; (3) poisoning by narcotics, opium, morphia, alcohol, ether, and chloroform; and by retention of urine, the result of kidney disease; (4) fainting, paralysis of the heart through fright, pain, exhaustion, loss of blood, etc.

As it is often very difficult for the best medical man to determine at once with what form of unconsciousness he has to deal, it would be useless to attempt to tell how to distinguish between and recognise these conditions. What should be done, however, in all cases, is this:

1. Remove all tight clothing from about the neck—neck-tie, collar, shirt-studs, etc.—as these interfere with the flow of blood from the head.

2. Give free access to fresh air round the patient, and send all useless bystanders away.

3. Place the body on the back with the head low, if the face is pale, as in faintness after great loss of blood. If the face, however, is red, the head must be raised. If sickness sets in, the head should at once be turned on one side, so that the vomited matter should not be drawn into the lungs.

4. If the patient no longer breathes, which can be ascertained by holding a looking-glass or flat piece of metal, or a feather, before the mouth and nose, then we should at once have recourse to artificial respiration.

5. Send as quickly as possible for medical aid, or transport the patient without delay to the hospital.

Insensibility may occur without a fit. You may have to decide before the doctor can come whether a man is under the influence of drink or dying, and this is exceedingly difficult. Open the person's eyes, and if both pupils are very small, he is very likely asleep. Wet a towel, and gently slap his cheeks; you will suddenly see the pupils enlarge. This shows he is now awake, though possibly still insensible. If they dilate very much, and there are general signs of drink, he is probably drunk; if one pupil remains small, and the other large, it is probably an injury to the brain. If both remain small and cannot be altered, he is probably drugged.

Of course, these rules do not always hold good. Your duty is clear—send for a doctor in all cases at once.

In an apoplectic fit, the person falls down suddenly, and is always more or less paralysed. Send for the doctor at once. Give the person fresh air; let him lie quietly with his head a little raised; loosen all tight clothing, put hot bottles to his feet, keep the room quiet, and give him nothing by the mouth.

Fainting. Fainting is a common and an alarming occurrence. If you see a person turning deadly pale, and about to "go off," you may prevent his doing so by steadily pressing his head down between his knees till his face is quite red. If he has fainted, let him lie flat on the floor. On no account allow him to be raised. Loosen everything round the neck, and let him have plenty of fresh air, a little cold water in the face, and smelling salts. A teaspoonful of brandy and water may be given if the face is very pale.

Drowning. In drowning, the action must be very prompt, and you must have a clear idea of what to do at once. First turn the body over on the face, and let any water escape by the mouth. Then wipe the mouth and nose dry; apply ammonia to the nose, or put a feather down the throat; rub the chest with hot cloths, or beat it well with the end of a wet towel. If in a short time breathing does not begin, adopt immediately this method:

Place the patient on his back with a firm cushion under the shoulders. Draw the tongue out of the mouth and fix it with an elastic band over it and under the chin, or a piece of tape. Take off the braces and all tight clothing; kneel or stand behind the person, grasp his arms above the elbow, and draw both arms well back over the head, and keep them at full stretch so as to expand the chest while you count ten rapidly; then bring the arms forward and downwards, and press the elbows well into the sides of the chest, and hold them there, counting ten again. Then repeat this slowly about 15 times a minute, until a natural breath is drawn, when you at once proceed to warm the patient, and rub his legs and arms up towards his heart. Put him in blankets, if possible, during this treatment. When he can breathe, give him a little brandy.

Be sure the tongue is well stretched out during your efforts, and that people do not crowd round. As in every other serious case, this only "until the doctor comes."

If a person is choking, seize his nose at once with one hand, and push the finger of the other hand right down the throat, and try to hook up or push down the obstruction. If unsuccessful, slap the back vigorously, or tickle the throat and try to bring on vomiting.

TEACHERS & SECRETARIES

The School Teacher's Training, Salary, and Prospects. Public and Private Schools. Posts at the Universities. The Private Tutor. Secretaries

By W. H. STUART GARNETT

It will be well at the outset of this article to indicate in some degree its scope, and the meaning which we propose to assign to the term scholastic professions.

Strictly, the term should include all those concerned in imparting to others the education which they have themselves received, whether by writing, preaching, or personal instruction. It is not our intention to deal in this article with the literary professions: it is with the teacher proper that we are concerned—with the man or woman who gives direct oral instruction, or supervises the work of the pupil in school, gymnasium, or workshop. We shall endeavour to indicate briefly the course of training and the prospects to be enjoyed by the academic, the technical, or the physical teacher in every grade.

To the academic teachers three great careers are open—those of elementary, secondary, and university instruction, as well as the less satisfactory one of private coaching. Of these, by far the most important—at least, considering the number of persons engaged in it—is the profession of elementary school teaching.

Elementary School Teachers. In the past this profession has been divided by a marked line of cleavage between the teachers in Denominational and in Board schools, of whom the latter had—financially, at least—much the better position. Elementary school teachers are drawn almost entirely from elementary schools, and the supply is at present considerably less than the demand. Very few of these teachers have private means, and the local authorities have, therefore, found it necessary to take charge of their education from the earliest stage, setting them apart for their profession from youth up like the Catholic priests of the Middle Ages.

Pupil-teachers. In the old days the future teacher became a pupil-teacher at the age of thirteen or fourteen, when the compulsory school period ceased. In return for a hard day's work the child received a small wage and the privilege of being taught by the headmaster after school hours. This went on until the age of seventeen or eighteen, when the pupil-teacher took the King's Scholarship examination, and, if successful, entered a training college.

The Board of Education have now very properly decided that no teaching is to be done by children under sixteen. The local authorities have, therefore, to provide by scholarships for the education of children up to that age. Generally these scholarships are awarded on examination at the age of twelve [see Ladder of Learning, page 481], and carry free education at a secondary school up to the age of sixteen. In London the examination is taken at the age of eleven, and about 2,000 junior scholarships are awarded every year. Of the successful candidates, rather more than half become teachers. These scholarships include, in addition to free secondary education, a grant of £5 a year for the first three years, and £15 a year for the remaining two.

The London elementary school child has a second chance of becoming a teacher by winning a "probationer" scholarship at the age of fourteen. These are open to future teachers only, and admit them to the ranks of the junior scholars.

At the age of sixteen the child definitely takes up his or her profession, and becomes a pupil-teacher, remaining at the secondary school, or entering a pupil-teachers' centre, but teaching at the same time in a public elementary school. The salaries of pupil-teachers are given in the following table. The salaries in the great provincial municipalities are intermediate between the two.

PUPIL TEACHERS' SALARIES

	First Year.		Second Year.	
	London.	Country.	London.	Country.
Boys ..	£32 10s.	£17 10s.	£39	£20
Girls ..	£20 16s.	£17 10s.	£26	£20

The King's Scholarships. The most critical moment in the life of our future teacher comes at Easter, after he has been a pupil-teacher for a year and a half. At this stage he enters for the preliminary certificate examination, which entitles him, if successful, to a King's Scholarship. This scholarship is paid only to the student who gets into a training college. The grant is £53 a year to a man, and £38 to a woman, in a residential college; or £13 a year to a student of either sex in a day training college. As this grant is not quite sufficient to cover the cost of training, most residential colleges charge an "entrance fee" not exceeding £25. This fee is paid for London students by the County Council, who also pay a special grant of £20 to students in day training colleges. A full list of recognised training colleges, with fees, etc., is contained in the regulations for training published by the Board of Education.

The number of teachers required annually to supply all the elementary schools in England is about 10,000, of whom something like three-quarters must be women. Unfortunately, the whole available accommodation in training colleges is for 1,677 resident men, 3,537 resident women, and 3,751 day students. It follows that only about 5,000 students can be received in one year, and a number of people otherwise qualified must be rejected.

The great majority of these training colleges belong to the Church of England, though, of course, it does not follow that they are open only to Churchmen. The Board of Education are putting pressure on local authorities to increase the number of colleges provided by them; but it is not surprising the local authorities contend that the teachers they train may not remain in their service, and they urge, with reason, that the whole cost of training should be borne by the State.

The Untrained Teacher. The lack of accommodation has excluded, and still excludes, many future teachers from the training colleges,

and it is only natural that some preference has been shown to Churchmen in the Church colleges. This has in the past been a very serious hardship to Nonconformist teachers, though the Education Acts of 1902-3 did a great deal to improve their position in this respect.

The teacher shut out from the training college has practically no alternative but to begin work at eighteen as an untrained teacher, and to endeavour by private study to qualify for the Board of Education certificate. These "untrained, uncertificated" teachers are paid in London a fixed salary of £70 for men and £60 for women. The salaries paid in the provinces are about the same.

Normally the training college student takes the final certificate examination after a two years' course, and immediately begins teaching in a public elementary school. The student who takes the final examination after a one-year's course commands usually a rather lower salary at first. A few of the most brilliant students are frequently kept on at the training college, or sent abroad for a third year, with a Government grant, and these become teachers either at a secondary school or in the training college itself.

Salaries and Prospects. The accompanying table shows the starting salaries of certificated teachers with the various qualifications referred to. The maximum to which salaries rise is also shown. In London, men's salaries in elementary schools rise to £200, by increments of £5 a year during the first two years, and £7 10s. a year thereafter. Women's salaries rise by increments of £4 a year to £150.

SALARIES OF CERTIFICATED ELEMENTARY SCHOOL TEACHERS

—	—	Trained Teachers.		Untrained Teachers.		
		1st or 2nd Class Cert. or passed in 1906.	3rd Class Cert.	1st or 2nd Class Cert.	3rd Class Cert.	Passed in 1906.
Men	London	£100	£90	£85	£75	£80
	Rural Counties	85–130	80–120	70–90	70–90	
Women	London	88	80	76	70	75
	Rural Counties	75–110	70–100	60–75	60–75	

Head Teachers in Elementary Schools. Nearly all elementary school head teachers are drawn from the ranks of the assistants. A period of some years' service is commonly required, and the salaries offered to head teachers in the smaller schools are from £10 to £20 a year better than those paid to assistant teachers of the same standing. In the large schools which are found in London and the Midland towns the head teacher occupies a very good position. We give the London scale of salaries for head teachers.

SALARIES OF LONDON ELEMENTARY HEAD TEACHERS

Accommodation in School.	Men.	Women.
1–200	£10 more than salary under scale for assistants.	
201–400	£200–£300 (Increased by £10)	£150–£225 (Increased by £8)
401 and upwards	£300–£400 (Increased by £10)	£225–£300 (Increased by £8)

Head teachers in higher grade schools receive £15 a year above scale. The maximum salary paid to head teachers in most country districts is from £200 to £250.

Advantages of Elementary School Teaching. An elementary school teacher has the advantage of beginning remunerative work at a very early age as compared with those who follow the other liberal professions. Further, his training costs him practically nothing, and his salary increases very quickly, so that at the age of thirty-five or so, when he may expect to be burdened with an expensive family, his earnings have already touched the top limit.

The demand for teachers, as we have already pointed out, exceeds the supply, so that there are practically no unemployed in the profession. Retirement at sixty-five is compulsory, but the superannuation fund, if the teacher is wise enough to subscribe to it, provides a liberal pension. The work is not heavy, as it is confined strictly to school hours—that is, from twenty-five to thirty hours per week.

The prospects of promotion, too, are good. Every year some seven per cent. of the teachers employed in elementary schools are promoted to headships. A certain number migrate to secondary schools, and the establishment of such schools by the municipalities has opened a new and wide door of transition; while the recommendation of the consultative committee, that higher elementary schools should be staffed principally with elementary school teachers, has offered a new prospect of advancement.

On the whole the career offers more attractions to women than to men. The woman teacher receives, it is true, a smaller salary than the man; but, as compared with their respective earnings in other professions, the scale of pay is more liberal. Partly for this reason quite a number of girls from secondary schools and colleges become elementary school teachers without going through the normal course of pupil-teachership and the training college. Male teachers, on the other hand, are nearly all supplied by the pupil-teacher system.

Secondary Schools. Secondary schools differ widely in the prospects which they offer to the teacher. Their classification is somewhat difficult, as it is impossible to draw a hard and fast line at any point between Eton College and the small country grammar school. At the same time, it is necessary to recognise the distinction, and we shall designate the latter, together with the majority of London secondary schools, as schools of the second grade, reserving the term "first grade secondary schools" for those of public school standing.

The term "first grade secondary school" will, of course, include the girls' high schools, and such well-known boarding schools as St. Andrews and Wickham Abbey.

Second Grade Secondary Schools. In all secondary schools the majority of the teaching posts are filled by men with university degrees, or women with equivalent qualifications. In the second grade schools there are generally quite as many graduates from the new universities as from Oxford and Cambridge. Trained teachers are in a minority, but a few will be found—these have usually spent a third year either at the training college or abroad, but some have risen from elementary school teaching.

Generally speaking, the position of an assistant teacher in such a school offers little scope for the man of ambition. He may, it is true, secure a berth in a first grade school, but this is unlikely; he may, if employed in a municipal school, be promoted to the headship, but this can happen only to one man in fifteen or twenty. For promotion to the head-

ship of any other school a university degree is practically a sine qua non, and in the boys' schools the chances of any but an Oxford or Cambridge man are small. These heads are largely drawn from among public school masters, so that the secondary school master has a small chance of promotion as compared with the secondary school mistress, but his salary compares with hers more favourably than in the elementary schools.

Secondary School Teachers' Salaries. For the expenses and difficulties that must be faced in the course of training by the intending secondary school teacher, and for the helps by the way in the shape of scholarships and free places, the reader is referred to the articles on the Ladder of Learning [page 481].

The demand for such teachers at the present time is great, employment is certain, and the salary and social position of the teacher are rising. The salaries offered vary very much, but a qualified male assistant teacher may expect to earn from £120 to £250, and a woman teacher from £100 to £200 a year.

The Girls' Public Day School Company offer salaries starting at amounts varying from £70 to £135, and rising to £200 a year. Secondary schools in London and the large municipalities are rapidly approaching the standard of pay set up by the London County Council, who offer to assistant masters a salary rising from £150 by £10 increments to £300, or in special cases to £350, and to assistant mistresses a salary rising from £120 to £220 by £10 increments.

The salaries paid to secondary school teachers by the provincial municipalities may be gathered from the following instances of starting and maximum salaries of trained certificated teachers.

District.	Men.	Women.
London . . .	£100–200	£88–150
Edinburgh	85–160	65–110
Hornsey	95–200	85–150
East Ham	90–175	75–130
Birmingham	85–150	70–100
Lancashire	80–140	70–110
Leeds	85–150	75–100
Manchester	85–140	65–110
West Riding	90–135	80–105

It need hardly be mentioned that the work of secondary school teachers, including correction of exercises out of school hours, and in some cases presence in the playing-fields, is very much harder than that demanded of an elementary school teacher.

Subjects Taught. It must be remembered by the intending teacher in this class of school that by far the greater number of his pupils will be destined for a commercial or industrial life. Consequently, he may as well spend his time on Greek verbs as on Hebrew paradigms. The study of elementary mathematics, science, and above all, of modern languages, bulks larger in the second grade secondary schools than in either the public school or the elementary school. A special training in either science or modern languages is very valuable to the would-be teacher. A man or woman who has spent a year abroad can generally command additional pay on the strength of it; and many of the larger boys' schools employ a "head science master," at a salary of some £400 per annum. Such a post is within the reach of the non-graduate, and is a stepping-stone to the headmastership.

The salaries offered by the London County Council to head teachers, and recommended to all secondary schools aided by them, depend on the accommodation in the schools. The scale is given below.

HEAD TEACHERS' SALARIES IN SECONDARY SCHOOLS		
Accommodation.	Head Masters.	Head Mistresses.
1–200	£400–£500 (Increasing by £20)	£300–£400 (Increasing by £10)
201–400	£400–£600 (Increasing by £20)	£300–£450 (Increasing by £15)
Over 400	£600–£800 (Increasing by £20)	£400–£600 (Increasing by £20)

In secondary schools other than the municipal ones payment by a capitation fee is common. The Girls' Public Day School Company offer in some cases a nucleus salary of £250, together with a capitation fee of £1 10s. to £2 on the pupils in the school. For the most part the salaries offered are rather lower than those on the scale set out above.

First Grade Secondary Schools. The public schools demand rather different qualifications in their masters than the secondary schools of the second grade. In the first place an Oxford or Cambridge degree is almost essential; in the second place, a professional training is hardly considered, and a knowledge of modern languages or of any scientific subject is required only of perhaps one master in twenty. Masters are frequently appointed at the conclusion of their university course, though in some cases the heads will advise a few terms' experience elsewhere.

The distinction between schools of the first and second grade is largely social. Partly for this reason the public schools are inclined to insist that the masters appointed should themselves be public school boys. Naturally, old boys of the school itself have a great advantage in competing for posts—at Eton, probably half the masters are old Etonians.

Local traditions are much less strong in girls' schools, and social distinctions are less felt. The teacher requires much the same qualifications as for secondary school work, but a university degree is very commonly required.

The Athletic Schoolmaster. Some attention is naturally paid to the athletic prowess of an applicant for a post, though less than in a private school, and certainly less than is commonly believed; still it is quite sufficient to turn the scale as between a football or cricket blue and a "mere man" of similar intellectual attainments. This is largely due to a sense of the disciplinary effect which such a distinction will have on the somewhat turbulent lower boys of a public school.

Whatever the reason, athletic qualifications are of value to the future schoolmaster, and, naturally, prowess in cricket or football, which can be displayed in the playground, is more to be desired than distinction in rowing or other sports. Many a good oar at Cambridge has been spoiled to make a cricketer, because the undergraduate in question contemplated teaching as a career.

The important qualifications, then, for a public school master are—and the first is almost essential—an honours degree, a public school education, and athletic prowess.

The Public School Master's Salary and Prospects. The rewards offered vary greatly. Probably the best assistant mastership in the world is that held by a classical master at Eton. His salary starts at £300 a year, but he

has the right and the leisure to take forty private pupils at twenty guineas a head. Coupled to that the prospect of a house of forty boys after thirteen years' service, and you have a post which few men would exchange for the headship of any but a first-class public school.

The salaries in most public schools are from £250 to £400 a year for non-resident masters, and about £100 a year less for residents; usually, however, only junior masters are appointed to resident posts, with the exception of those masters who have houses of their own.

School Boarding-houses. In many boarding-schools there is a schoolhouse, which is either an appanage of the headship or belongs to the school itself; but in almost every school the majority of the boarders are distributed to private masters' houses, over which a certain amount of supervision is exercised by the school authorities.

Whether this is a desirable arrangement or no is a question much debated. It is urged, on the one hand, that it is essential that all the details of boarding-house administration should be supervised by a master. This may be granted, but it is at least open to question whether the supervising master ought to be financially interested in the housekeeping, and it is very strongly contended by many masters—who have not houses—that the business of an unlicensed victualler is beneath the dignity of the scholastic profession.

However that may be, the prospect of having a house is one of the principal baits which attract the public schoolmaster. The annual profits to be made out of such an establishment may be fairly accurately assessed as from £10 to £25 per boy, according to the wealth and standard of luxury prevailing among the parents who patronise the school. Naturally, the whole profit depends upon the house being full; it is the last four or five boys who pay, and the expenses of running the house are heavy, so that a boarding-house can hardly ever promise a safe or steady income.

Public School Headships. The prospect most cherished of the average assistant master or mistress is that of becoming the head of a first-grade school. The headmistresses for the most part receive salaries of from £500 to £800 a year, but those of the large boarding-schools probably make a total income considerably larger than this.

Headmasterships of public schools, on the other hand, are worth altogether from £1,200 to £5,000 a year. In the modern schools a great part of the headmaster's income consists of capitation fees on the number of pupils in the school, but the older and more venerable public schools, admission to which is sought by many more boys than can possibly be accommodated, naturally despise the capitation fee, and pay for the most part a fixed salary.

Many schools demand that the headmaster should be in orders, and in the case of boarding-schools with chapels attached this requirement is almost universal. The great day schools, however, have of late shown considerable disposition to appoint laymen, and in practically no case does it help an assistant master to be in orders, though he may find it useful to enter the Church before applying for a headship.

Private Schools. It is difficult to generalise as to the private schools dotted about the country. Comparatively few are open to inspection, and the available data are scanty. The owner, like every other capitalist, seeks as a rule to buy his commodity—teaching—in the cheapest market and to sell in the dearest.

Of late years these schools have been, to some extent, opened to inspection by the much abused Column B of the teachers' register. University graduates and others seeking recognition as secondary school teachers are often willing to accept a smaller salary in a *recognised* secondary school in which they can qualify, than they might demand in a school not so recognised. This is a strong inducement to owners to seek recognition, and to open their schools to inspection by the Board of Education.

So far as the assistant teacher is concerned, the position offered by a private secondary school differs little from that in other second-grade schools. Salaries are for the most part low, and the work is apt to be heavy, although this is by no means the universal rule. Private preparatory schools for the great public schools—particularly "scholarship hunting" schools—pay very well indeed, besides affording the masters excellent opportunities of promotion into the schools for which they prepare pupils, as such masters, being well known to the authorities, are frequently sent for to supply temporary vacancies on the staff of the public school.

In these schools a good degree is naturally looked for in the assistant master, and in all boys' private schools athletic attainments are very highly thought of, since the reputation of a private school depends in no small degree on the subsequent achievements of its pupils in the public school playing-fields.

Starting a Private School. The headmaster of a private secondary school is very commonly the owner. From his point of view it is largely a commercial undertaking, and its success depends on many other things than his academic qualifications. The would-be headmaster must have command of capital, and, as a general rule, it may be taken that the minimum capital cost of providing a secondary school with proper accommodation and fixtures is £30 a head in London, and rather over £20 a head in the country. The cost of providing a boarding-school will be rather more than twice as great.

Private schools for girls are in a peculiar position, since they usually lay stress upon their exclusiveness. The mistresses in such schools are chosen as much for their "accomplishments" as for their intellectual attainments, and in many cases the staff is practically synonymous with the family circle. The principal qualification for an assistant mistress is a knowledge of modern languages. It is naturally impossible to give any account of the very diverse rates of pay prevailing in these establishments. They probably compare very unfavourably with those offered to secondary teachers by the municipal authorities.

The Universities. Unquestionably the most desirable of all academic posts are those at the old universities, carrying, as do the best of them, a very fair salary, great dignity, and demanding, it must be confessed, very little work.

The teaching staff of every university consists of professors, lecturers, and demonstrators. Lecturers in scientific subjects are commonly demonstrators at the same time, and the teaching work which they do in many cases occupies only a part of the week, so that it is combined with study. This is more particularly the case in the American and Colonial universities, where such posts offer an excellent opportunity to British graduates to continue the study of special subjects under other auspices.

Demonstrators and Lecturers. The demonstrators and lecturers at a university are in almost every case chosen from among the more brilliant students at the close of their university course, so that the able student with no definite ambitions outside the university finds himself transformed almost imperceptibly into a lecturer on a salary of £150 to £200 a year. At Oxford or Cambridge the lecturers are nearly all Fellows of their colleges, and do private coaching as well, so that their total earnings not infrequently amount to £600 or £700. As a class, however, demonstrators and lecturers are—for the best men of their academic year—very poorly paid. Probably they have the best brains in the county.

Professors. The lecturer, after a few years' service, not infrequently migrates to some sister university in Great Britain or the Colonies, to fill a professorial chair, or else becomes head of a department in a technical institute. Most British professors are trained at Oxford or Cambridge, and probably a very large number of the present ones have served at the old universities as lecturers of the colleges or of the university. Such professors not infrequently return in the end to the university at which they were trained.

The emoluments attached to the various chairs at the new universities vary from £500 to £800 per annum. A few special chairs are still more liberally endowed. The professors at such universities are the actual teaching heads of the faculty, and have a great deal of real work to do, though most have leisure for literary work or for a certain amount of outside practice as scientific experts. The executive heads of the various universities are paid rather more highly than the professors, and the principal of London University draws a salary of £2,000 a year.

Professors at Oxford and Cambridge draw from £700 to £1,200 a year, and have very little actual teaching to do. They are no doubt in a large measure responsible for the educational policy of their respective faculties, but personally they do not as a rule give more than one or two courses of lectures in the year. The intention of the universities in filling these chairs is rather that their occupants should be free to engage in scientific or literary research, to the glory of their alma mater.

It is unnecessary to go into detail as to the infinity of college appointments from the mastership downwards. The first step to all of these is the college fellowship, which is given to the able student either with or without examination. The fellowship is the natural goal of the academic career, and comes, with its attendant appointments, almost automatically upon the brilliant scholar.

Colonial Universities. Salaries at Colonial universities range between much the same limits as at the English provincial ones, the professors receiving from £500 to £1,000 per annum. The assistants, however—demonstrators and so on—work usually only for half their time at these occupations, and have considerable leisure and opportunities for study. Salaries range from a small sum up to £150 or so.

Since the ablest students at these universities are commonly desirous of proceeding to Oxford or Cambridge, and since the inducements offered to young university men to take up an industrial career are greater in the United States and in the Colonies—where education is highly valued—than in England, it is not always easy to fill the inferior teaching posts in the Colonial universities. The result is that there is a considerable opening for English university men in Canadian and other universities, and an Oxford or Cambridge graduate is warmly welcomed.

These opportunities should be much more used than they are by Englishmen. Not only do they form an excellent "landing place" in the Colonies for men anxious to take up an industrial or scientific career there, but they afford an excellent training for many professions at home. A year or two at McGill University, in Montreal, for instance, is at once an invaluable experience to a British college-trained engineer, and at the same time opens to him the doors of all the great workshops in America.

Unfortunately there is no adequate system of communication between British and Colonial universities, by means of which these posts may be brought to the notice of students at home.

Technical Institutes. Nearly all that we have said of the universities applies to technical institutes, except that the scale of salaries is, on the average, about 40 per cent. lower than at the universities; a few, however, of the principal institutions, such as the Municipal School of Technology at Manchester, deserve rather to be classed with the universities in this and in other respects.

The demonstrators at the polytechnics are picked out, as in the universities, from among the day or evening students of those institutions. The salaries offered are from £50 to £100 a year, quite sufficient to tempt a boy without capital who realises that the most brilliant career in the institute is not an absolute guarantee of success in the outside world. The work involves both day and evening teaching, and is therefore by no means light; but the prospects are good, as the lecturer may well rise to be the head of his department.

Heads of departments at the London polytechnics are commonly paid from £200 to £500 a year. They are in many cases university men, and occasionally return to the new universities as professors, or go out to the Colonies in the same capacity.

The principals of the technical institutes receive salaries of from £500 to £700 in the provinces, and from £600 to £800 in London; except in the case where heads of departments are appointed to these posts, it is generally required of a candidate that he should have had previous experience in the conduct of an educational institution. Headmasters of secondary schools are not infrequently appointed.

Training Colleges. The training colleges are in a sense technical institutes. They teach a profession, and they draw their teachers from the ranks of their own students like the polytechnics. They are, however, mostly residential colleges, and the staff is resident in nearly every case. The scale of salaries in municipal training colleges is generally about the same as in the larger secondary schools, deducting the cost of maintenance of the teacher.

Generally it may be said that the assistant teachers in training colleges draw from £100 to £200 a year if men, from £70 to £150 if women, in addition to their board and lodging. These teachers very generally move into secondary schools after a few years, with a view to freedom from the necessity of residence.

The pay of head teachers is about the same as in technical institutes, £450 to £700 a year. These head teachers are nearly always graduates, sometimes of Oxford or Cambridge.

Private Tuition. We have spoken of the highest scholastic posts as falling to the most successful scholars who have reached their degree with no definite aim in life. Unfortunately there are

many such, into whose mouths the academic plums do not drop. Having no definite professional training and no settled purpose, their obvious means of livelihood is that of imparting the knowledge they have acquired.

Of these men some become masters in public or private schools, but the majority drift into private coaching outside the University. The usual fee for a graduate coach at Oxford or Cambridge is 7s. 6d. an hour. In London and elsewhere the usual fees are 5s. and upwards for men, and 4s. and upwards for women. The non-graduate must take what he can get, and many of his competitors are working for 2s. 6d. an hour.

Private coaching is not to be recommended as a serious profession. When fresh from the university a man is able to make an income by this means, which compares very favourably with that which he commands in a secondary school, and he may well spend a few years in coaching while looking out for an opening into some more substantial profession. On the other hand, he must remember that there is no certainty of employment. Methods of teaching change, and the coach of forty years of age, instead of bettering his position, is already beginning to suffer by the competition of younger men; whereas a regular teacher is nowhere superannuated before the age of fifty-five, while university appointments are nearly all for life.

Special Subject Teachers. Outside the ranks of academic teachers are those who teach crafts, whether industrial, commercial, or domestic. Most of these teachers are employed by the local authorities in day or evening classes, and since their services must be secured by the councils in the open market and in competition with private employers, the scale of fees paid by the London County Council for this class of work may be taken as very fairly indicative of those which the teacher may expect to command. It need hardly be mentioned that the demand for this class of teaching exists only in the large towns, where the conditions are much the same throughout Great Britain.

The special subjects—gymnastics, swimming, needlework, etc.—taught in elementary schools are usually taught by members of the regular staff; but, for the secondary schools, instructors are engaged at substantially the same rates as for the evening classes.

The Teaching of Crafts. The craft school has risen on the ruins of the apprenticeship system. A century ago the boy learnt his trade in the workshop from the man whose bench he shared. Now the value of floor space has killed apprenticeship in the large towns, and the boy goes to a trade school or technical class instead; but the man who teaches him in the school workshop must have the same qualifications as the man who taught a hundred years ago. In fact, the teacher of a skilled trade is, and must be, an artisan of practical experience, though as a very highly-skilled artisan he may command wages of 2s. or 2s. 6d. an hour. It is a valuable qualification for a trade teacher of this class to have taken an evening course in the theory of the subject of which he teaches the practical side.

In the same way the teachers of other technical subjects are craftsmen. The teacher of book-keeping is frequently a practising accountant, and the teacher of "first aid" a practising surgeon. The possibility of obtaining work of this character should be borne in mind by men starting in the skilled professions with a good college record behind them.

The teachers of gymnastics are drawn from a number of different classes. The great majority of the male teachers are retired Army instructors or non-commissioned officers. The best posts go commonly to men and women trained in Germany, or in some of the London schools. The South-Western Polytechnic has trained a number of very successful teachers, and Madame Osterberg's College at Dartford has an equally high reputation.

Special Woman's Work. The special subjects for which instructresses are required are art, swimming, nursing, needlework, and domestic economy, which includes cookery, laundrywork, and housewifery. The art work and the swimming are largely day subjects, but almost all the other special teaching is done principally at night.

Art teachers are usually, and domestic economy teachers invariably, required to have had special training as teachers. [For the training colleges available see Ladder of Learning, page 481.] The London County Council require domestic economy teachers to possess a diploma, and art teachers the art masters' certificate. The salary of domestic economy and needlework teachers in London rises from £80 to £120 a year by £5 increments. The salary of art masters rises in the same way from £175 to £200, and of mistresses from £125 to £150 a year.

The following is the scale of pay of special subject teachers in London evening schools.

RATE OF PAY IN LONDON EVENING SCHOOLS FOR MEN TEACHERS

Subject.	Evening Schools. (For evening of 2 hours.)	Commercial Centres. (For evening of 3 hours.)
Regular teaching	7s., or £13 6s. 8d. per ann.	15s., or £25 per ann.
Assistant teaching	5s., 4s.	—
Science and Art and Commerce	6s.	7s. 6d.
Special Commercial subjects ..	—	10s. 6d.
Manual training and Crafts ..	5s.	7s. 6d.
Gymnastics ..	7s. 6d., 5s., 4s.	—
Swimming	6s., 5s.	—
Literature	10s. 6d.	—
Nursing, etc., by doctors	£1 1s.	—
FOR WOMEN TEACHERS		
Swimming	5s.	—
Cookery and Laundry	5s., 4s.	—
Housewifery ..	6s., 5s.	—
Nursing (trained)	10s. 6d.	—

Inspectors. There are two educational inspecting authorities—besides the Treasury, which employs a very small staff—the Board of Education and the Local Authorities. The inspectorate under the Board of Education is a branch of the Civil Service outside the scope of this article. We may mention that the qualification is a first-class degree at Oxford or Cambridge, and the salaries rise from £200 to £800.

Inspectorships under the Local Authorities are generally given to teachers—usually those in the employ of the authority. A certain amount of teaching experience is essential.

The position and salary of an inspector is about on a par with that of a secondary school head teacher. Inspectors under the L.C.C. receive from £250 to £800 a year. School attendance officers, £80 a year.

Two scholastic movements in particular stand out very clearly before the observer of the present day. One is the improving social position and increasing salary of teachers in every grade; the other is the growing popularity among teachers of a training college course, and the increasing number of trained teachers in the profession. It is impossible to resist the conclusion that there is some connection between the two tendencies.

Future Prospects. In the past, the schoolmaster has been commonly looked upon as a failure. He has received the miserable wage of a man who has failed in life; and this attitude of the public was too often justified by the facts. The scholastic profession has suffered in the past, and still suffers in a less degree from being the dumping ground of able men with no definite aim or purpose in life. The existence of these men, unfitted by special training for any serious profession, has been dangerous and detrimental to the teacher who took his work seriously, no less than to the pupil whose education was imperilled through the incompetence of such men—good scholars though they might be—either to teach or to maintain discipline.

It is at last being recognised by the public that a teacher's vocation is a high one: that he is a labourer worthy, not only of better hire than he has generally received, but of the respect of all his fellow workers in whatever field. But the teacher must remember that the maintenance of this respect depends on himself. The public take a man, and his work, at his own valuation, and the teacher can claim the respect of this generation only so long as he does his duty to the next, entering the scholastic profession not merely to earn a living, but with a full sense of his high calling and a set purpose to raise and educate mankind in the pupils committed to his charge.

SECRETARIES

Private Secretaries. The profession of a private secretary may be classed as scholastic, not so much because his duties are educative—though more private secretaries than one are engaged, either tacitly or overtly, in the education of their chiefs—as because no particular technical training is required for the secretarial life. There is no one branch of knowledge in which the private secretary must excel, yet he should be in some sense acquainted with them all. The berth is pre-eminently one for a man with good general education and some knowledge of the world. It is one into which some men drift almost by accident, to remain there all their lives; while others use it as a stepping stone towards a more satisfactory position.

The Amanuensis. Broadly speaking, there are two classes of secretaries. The first is essentially a letter writer, a very necessary adjunct to every wealthy man much occupied with affairs; the second is an incidental luxury in literary and political life. The duties of a secretary of the first class are in many cases heavy, and the pay, except for rare and fortunate individuals, low. Such a secretary is, in fact, a clerk of more or less skill and responsibility; he has a clerk's duties, a clerk's position, and rather less than most clerks' prospect of promotion.

Still, if a man can be satisfied, for a time at least, with an income of £100 to £150 a year, he may do worse than become a clerical private secretary. There is always a chance of impressing his chief with his ability and character, and so securing transfer to a more responsible post.

Qualifications and Position. The qualifications required by a secretary of this class are substantially those of a clerk in a City office. He must have some knowledge of typewriting and shorthand, a presentable appearance, and sufficient acquaintance with the English language to be able to write a good letter. Above all, he must be able to produce evidence of high character, and must show himself possessed of common-sense. His employer wishes to be relieved of responsibility in the smaller matters of everyday life; and a secretary who can be trusted to look after things intelligently on his own account becomes indispensable to a busy man. He can make his own terms

On the other hand, a secretary of this class must be at the beck and call of his master. Not infrequently he lives in the house, and is hardly free from duties, morning, noon, or night; no Factory Act applies to his employment, and no code defines his social position. Altogether it is a strenuous life, and a poorly paid one.

The Political Secretary. But the position of a secretary of the second class is very different, and far more satisfactory. To begin with, he is a luxury, and the market for luxuries is somewhat inflated at present. If he be wise, he knows himself a luxury; but if he be skilful, his master thinks him a necessary.

The salary of such a secretary is from £200 to £500 a year, and his social position is not so far off his chief's. Many parliamentary private secretaries are less the servants of their immediate employers than apprentices to the game of politics, just as the editor's private secretary is an apprentice to journalism.

Posts of this class, however, are not so easily found as the ones before described. A luxury is expected to be a highly-finished article. Generally a parliamentary secretary is an Oxford or Cambridge man, though some of the most successful ones have not been through the university. But whatever his training, the qualifications of such a secretary are varied and peculiar.

Lord Brougham said once that the King knows as much law as his chancellor, but the chancellor knows where to find it. Even so the secretary—facts and figures, books and blotting-paper, he must know where to lay his finger on them all. Beyond this, unless he writes letters, which many do not, he holds something of a sinecure, and that not ill-paid.

To the average educated man, no training could be more valuable than a year or two as private secretary to some prominent M.P. He meets many important people; he appears occasionally on his chief's platform, and learns to face an audience without quailing. When duties press heavily on the Member, the secretary may be charged to make notes for a speech in the House, and so take a turn himself at the helm of the vessel of State.

And the field is an open one. Some posts, of course, go through influence, but the central party agent can always find a berth for a man who impresses him favourably.

PHOTO-ENGRAVING

How Line and Half-tone Blocks are Made. Photo-lithography Reproduction in Colours. Collotype and Photogravure

ENGRAVING continued from page 6291

By P. G. KONODY

THE term "Photo-engraving" comprises all methods of reproduction for printing in which photography takes the part of the artist in the older and more costly processes, such as engraving on wood and steel, or drawing on stone. The various methods used for the production of newspapers, books, picture postcards, etc., can be classified as follows: (1) Line process; (2) half-tone process; (3) photo-lithography; (4) three-colour process; (5) collotype; (6) photogravure.

Making Line Blocks. The first of these is the most simple. It is used for the reproduction of pen and ink sketches, and such prints or drawings as contain only black and white, with no intermediate half-tones. The original print is put on a copying board in front of a camera, and a negative is made in the ordinary way [see PHOTOGRAPHY]. In making a line negative, it is necessary that the lines should be perfectly transparent, and the background as dense as possible. For this purpose, the old-fashioned collodion, or wet plate process is recommended, as it gives crisper and sharper lines than dry plates do, owing to the thickness of the gelatin in the latter. Collodion is prepared by dissolving pyroxylin (guncotton) in a mixture of ether and alcohol, the proportion of which is governed by the weather (about 200 grammes of pyroxylin, 20 grammes of ether, and 20 grammes of alcohol). In summer, for instance, more ether will have to be used, as it evaporates very quickly. To this solution is added a quantity of iodide and bromide salts (about 70 grammes ammonium iodide, 25 grammes of cadmium bromide and about 20 grammes calcium chloride). The collodion thus prepared should be allowed to ripen for a few days. It can be obtained ready mixed.

Sensitising and Developing Collodion. A glass plate is then carefully cleaned by immersing in weak nitric acid, and polishing after drying with a chamois leather and a paste of prepared chalk and methylated spirit. The edges are coated with indiarubber dissolved in benzol, to prevent the film peeling off. The collodion is then poured on to the plate, drained off at one corner, and gently moved about to allow the ether and alcohol to evaporate [1]. Whilst still slightly moist, the plate is immersed in what is called the silver bath, a solution of nitrate of silver in water, to which a few grains of nitric acid and iodide of potash have been added. As this makes the collodion sensitive to light, it is essential that this operation should be carried on in the dark-room. The silver bath should also be kept covered.

The exposure is regulated by the nature of the original; thus, under-exposure will cause the lines to spread, whilst over-exposure will cover them up, so that it will be impossible to get a clear print of the negative. After exposure, the plate is developed with a protosulphate of iron solution in water, of which the following is a formula: 64 oz. water, 4 oz. iron sulphate, 4 oz. acetic acid, 1 oz. to 4 oz. alcohol. Methylated spirit has been added to make the developer flow over the plate, as the latter is rather greasy and repels water. Acetic acid is also contained in the developer; it clears the image and prevents scum forming on the surface. After washing, the plate is fixed with cyanide of potash or hyposulphite of soda.

Intensifying and Printing. To make the background denser, the negative is intensified by immersing it in perchloride of mercury solution, and blackening it afterwards with ammonia if the lines are delicate. If they are fairly coarse, a solution of equal parts of bromide of potash and sulphate of copper in water can be used, and after washing, nitrate of silver solution. This intensifier is more powerful than the previous one, and gives the operator a better chance of rectifying mistakes. A solution of iodine and iodide of potash is now poured over the plate, which is washed and then cleared with weak cyanide of potash. This is the time to remedy slight imperfections, either in the preparation of the plate, or in the exposure. The plate is then blackened with hyposulphite of ammonia or sulphide of sodium.

The negative taken in this way is printed on a metal plate which has been carefully cleaned with pumice powder. Before this is done, another point has to be considered. The print on the metal itself would be exactly like the original drawing, consequently a print off this plate would be reversed on the paper, like an image seen in a mirror. To avoid this, the film either has to be stripped off the glass plate, reversed, and put on to another glass [this is described under COLLOTYPE], or the picture has to be photographed in the first instance through a prism, or by means of a silver mirror, which can be attached to the camera in front of the lens at an angle of 45° to it. It may also here be added that, though daylight can be used in exposing the negatives, or printing on metal, electric light is used by all the photo-engraving houses, as it is less subject to variation.

Printing on the Block Plate. We now come back to the metal plate, which is sensitised by a solution of potassium or ammonium bichromate in water, to which white of egg has been added (1 egg to 5 oz. of water, 10 grammes potassium bichromate, and a few drops of liquid ammonia). The plate is fixed on to a whirler, coated twice, and dried over a gas stove [2]. It is then exposed behind the negative in a printing frame, just as a piece of silver paper would be in ordinary photography. A few minutes are sufficient to make the albumen and bichromate on the exposed parts insoluble in water. The plate is then rolled up with a stiff, fatty ink which has been thinned by means of a volatile oil, such as oil of lavender. After letting the oil evaporate, the metal is put into cold water, and the surface gently rubbed with cotton-wool. This takes off the unexposed bichromate and also the ink adhering to it, and only leaves the coating and ink on the exposed parts—that is, the lines of the picture. The plate is now dried and covered with powdered bitumen, which sticks to the greasy ink and is dusted off

the plain parts with a camel hair brush. It is heated until the bitumen melts and forms a protection for the picture against acid.

Etching and Finishing the Line Block. The plate is now ready for etching, but before it is put into the acid trough, the margin, back, and large open spaces in the picture should be covered up with shellac dissolved in methylated spirit, so that no acid need be wasted in etching metal which can be cut away quickly enough by machinery afterwards. For etching, the plate is put into an earthenware trough containing weak nitric acid, and gently rocked. After a little while it is taken out, and the acid-resisting surface strengthened by means of soft litho ink, with which it is rolled up; a soft nap roller is best used for this purpose. The plate is then dusted in with dragon's blood or bitumen and carefully brushed in four directions.

Rinsing under the tap will remove any particles of dust on the plain zinc, leaving only those that have stuck to the soft ink. The latter spreads slightly over the edges in the subsequent heating over a gas stove, and thus prevents the acid underbiting the lines. Care should be taken not to overheat the plate, as it will make the ink run too much. This process is repeated until the plate is etched deep enough—that is to say, till the lines stand out sufficiently from the ground to print well on the letterpress machine. All ink is then washed off with hot potash or turpentine and the plate rolled up again, this time with a very stiff ink and a glazed roller. This is done to get rid of the shoulder which has formed in getting the depth. One or two of these finishing baths are generally sufficient if the plate has been etched well. When all the shoulder has disappeared, the plate is cleaned again, the shellac scraped off the back, and the block is ready to be mounted. For this purpose all metal forming the margin or open spaces in the picture itself is cut away either by a fret saw or a routing machine, and the plate is tacked on to a piece of oak or mahogany which is afterwards planed down to the exact height of type—that is, nearly $\frac{11}{12}$th of an inch. The block is now finished. Ground tints are laid on line blocks by mechanical means before etching to give shading to them [**3**].

Half-tone Blocks. The next process, called half-tone, is much more complicated. It is used for pictures which have no sharp and black-and-white outlines, but a variety of tones more or less gradually blended into one another, which cannot, therefore, be reproduced by line. As the machine will only print a level surface, it is necessary to produce a block, the surface of which, whilst perfectly level, must be regulated so that light and shade are expressed by a kind of grain in relief, which is very close in the shadows, and opens up as it gets lighter in tone. The simplest way to produce such a grain is to photograph it at the same time as the picture. For this purpose there are on the market so-called "screens," which are produced by ruling lines diagonally on glass plates, then filling these lines up with lampblack, and placing two such plates together, to form a net. When photographed a short distance behind this screen, the negative will show the picture itself, cut up all over by a net which varies in strength, according to the nature of the image. Thus, on the negative the darkest parts will show a strong transparent net with tiny solid dots in the centre. This net gets thinner as the tones go lighter, till in the highest lights only transparent dots will remain in a solid net. The fineness of the grain itself is varied according to the nature of the work. For poster work, for instance, the screen will contain about 25 lines to the inch; for newspaper advertising a 50 screen is commonly used; most of the SELF-EDUCATOR illustrations are printed from blocks with 110 lines to the inch; whilst for finest bookwork 400 can be used. A photograph of aerated-water syrup tanks is reproduced in **4** in four different screens.

Exposure Through the Screen. Great care has to be taken to give the plate exactly the right exposure to light. It is best to use square diaphragms, or others with extended corners, as these give a square dot in the tones, which etches better on the metal than a round dot. It is also advisable to flash a white card in front of the picture for a few seconds, to give more body to the dots in the dark parts. It is not advisable to have the latter too black, as too much detail is lost that way. The negative is then developed, fixed, and intensified, in the same manner as a line negative. After intensification, when the negative is cleared with weak cyanide of potash, a good photographer can even improve on the original, especially if it be dull and flat, by forcing the shadows a little, or by etching those parts of the negative which lack brilliancy. A good negative should contain fine pinpoint dots in the shadows, a square dot, with extended corners that join on to the next, in the middle tones, and fairly fine, transparent dots in the high lights. If no prism or mirror has been used, the plate is stripped and reversed in the same way as a line negative, and the surface can afterwards be protected by albumen, gum, or thin gelatin solution poured over it; then it is drained and dried.

Sensitising and Etching the Half-tone Plate. The sensitising solution for the metal plate consists of fish glue, ammonium bichromate and water; sometimes ammonia or white of egg is added. (Formula: 1 oz. clarified fish glue, 2 oz. water, 30 gr. ammonium bichromate.) The copper or zinc is cleaned very carefully with pumice powder or charcoal, coated, and put on a whirler. It is then turned slowly over a covered gas flame till the coating is perfectly dry, and exposed behind the negative for a few minutes. Then it is taken out and put into cold water, which dissolves the fish glue and bichromate where not exposed to the light. To show more clearly what the result is like, the plate is put into a solution of some aniline dye, which shows up the picture. Under-exposure makes the film come off the metal, whilst over-exposure fills up the dots in the dark parts. If rightly exposed, the plate is rinsed and dried. After this it is held over a gas flame and "burnt in." The image will at first vanish altogether, but gradually reappear, till it has reached a rich reddish brown colour in the darker parts and a silvery bluish tone in the high lights. It is then cooled off, and is ready for etching. If a black line is wanted round the picture, it can now be drawn with thin litho ink.

For etching, the plate is shellacked at the back for protection. Copper plates are etched with perchloride of iron at about 40° Beaumé; zinc plates in a weak bath of nitric acid, with some pyroligneous acid and sal ammoniac added (Formula: 5 oz. water, 6 oz. nitric acid, 1 oz. sal ammoniac, 1 oz. pyroligneous acid), to counteract the action of salts formed by the lead, etc., always contained in commercial zinc. The plate is left in this bath till a sufficient depth is reached, and the darker parts begin to open up. It is then taken out and proved on a hand press. If it is found that some parts require more etching, those that have had sufficient are covered up with litho ink, and the process repeated until no more etching is necessary.

Any spot or faults are then engraved by hand, and the plate is ready for mounting, as described above.

Photo-lithography. Photo-lithography is really a part of the half-tone process. In the ordinary way a print from a half-tone block can be made on a special transfer paper with litho ink, and then transferred on to the stone. It is, however, quicker and less costly to make a print direct from the line or half-tone negative. The half-tone negative made for this purpose must be stronger in contrast than the negative for half-tone process on metal, as no subsequent etching is possible on the stone. The line negative need not be altered. Neither must be reversed, as they are not printed on the stone direct, but on paper first, which reverses them on to the stone. The transfer paper, which has a gelatin or albumen surface, is immersed in a solution of bichromate of ammonia, and then dried. It is exposed behind the negative in the usual way, and then rolled up and developed exactly like a line plate. When dry it is ready for transferring to the stone.

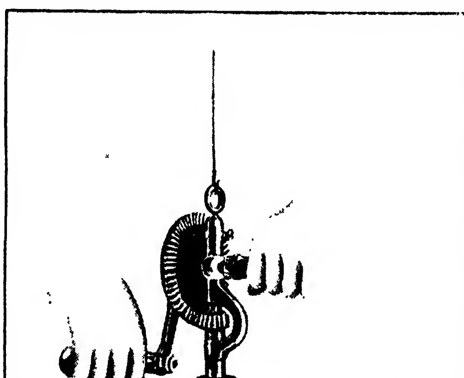
Pneumatic negative holder

The Physical Basis of Three-colour Work. The next process, called three-colour work, is also a half-tone process, but, as the name indicates, has for its object reproduction in colours instead of in black and white only. Before going into the process itself, it will be necessary to explain a few things about light and colours in general [see PHYSICS, page 2431]. According to the now universally accepted theory, light is the vibration of the ether. A luminous body sends out waves of light in all directions, waves of different length striking the eye as differently coloured light. By being struck simultaneously by waves of different length, the retina receives the impression of white light, which is no single colour, but a mixture of colours. In the same way, if one series of rays be removed, the rest will strike us as one colour only.

All the spectral rays need not, however, be contained in the white light, as a suitable choice of two will give the same impression. These are called *complementary* colours — as, for instance, red and blue-green, orange and cyan-blue, etc. According to Young's theory there are only three kinds of nerve fibres in our eyes sensitive to light, and these communicate to us the primary sensations of red, green, and violet. These three colours are, therefore, called the fundamental colours. If all the three nerves are acted on simultaneously by light rays, we see white.

Pigments absorb colour rays. Now we must distinguish from light-emitting substances those which only reflect or absorb certain rays. Some absorb parts only, and reflect others, which combine together in a colour mixture, and thus give us the impression of colour. Substances, either in a solution or a powder, that absorb certain rays in a high degree are called pigments or dyes. To distinguish them it is necessary to keep in mind that a colour ray emits light, whilst a dyestuff only reflects borrowed rays.

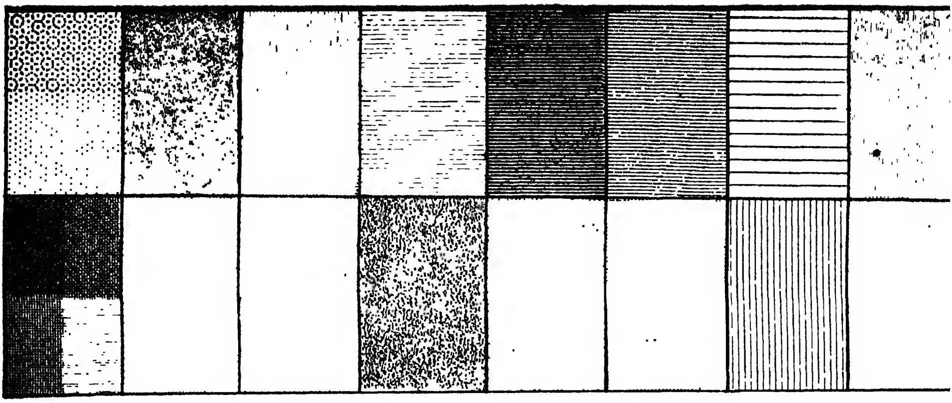
The Principles of the Process. For commercial purposes it is essential that a colour reproduction should be made with as few printings as possible to avoid expense; and it has been found that by mixing three pigments nearly all colours can be reproduced. These printing inks must be very pure and also fairly permanent if exposed to light. It will suffice here to say that the inks adopted are a yellow, red, and blue, which are a compromise between the various conditions.



2. WHIRLER AND STOVE

The next thing is to produce negatives to correspond with these inks. They must show no action of light in those parts where the colour of the original corresponds with the ink, and the shades arrived at by blending this colour with the other two primary colours must be represented by gradations in the negative governed by this first colour. We must, therefore, exclude light rays of the particular colour which must be transparent in the negative, and only let those rays act on the plate which are absent in the reflected light of the pigment. Thus, for the red negative the plate must be sensitive to green, and equally for the yellow and blue negatives the plates must be sensitive to their respective complementary rays. To exclude light not wanted we have to employ so-called light filters. These consist of tanks from $\frac{1}{16}$ in. to $\frac{3}{8}$ in. wide, which are filled with aniline dyes in solution. The correctness of these dyes is tested with the spectrum. They have to correspond with the light-sensitive qualities of the plates used.

Dry and Emulsion Negatives. The negatives can be made with dry plates or emulsion.



3 VARIOUS TINTS USED FOR GROUNDS OF BLOCKS

For the former there are various brands of plates on the market specially prepared for the purpose. For the latter, Dr. Albert's emulsion is now generally used. It may be added here that though the latter gives much better results it requires great cleanliness, and cannot be worked in the same room, or dark slide and camera, as the collodion process, as any free nitrate of silver upsets the emulsion. There are days when the emulsion cannot be worked at all, and as its composition is a secret, it is almost impossible to find a remedy for an unknown cause.

The first negative to be made is the one for the yellow print. Any ordinary dry plate will do for this, as it is not sensitive to yellow, while the lack of red sensitiveness is partly compensated by the ultra-violet sensitive qualities of the plate. For this reason no filter is necessary to exclude yellow rays. A tank containing Höchster new blue 1 : 5,000, or a dry gelatin filter can, however, be used if the exposure is very long; otherwise the filter is merely filled with ordinary water.

A set of dry filters can be procured at any house supplying materials for photo-engraving; but liquid filters are preferable, as they can be regulated very easily if they are not quite true. The best position for them is directly behind the lens. As they deflect light it is best to focus the original after they have been inserted. Plain emulsion, with a standard glycin developer (1½ minutes' development), or ordinary collodion, can also be used for the yellow plate. The emulsion process corresponds with wet plate in every detail, except that the silver bath is left out, the plate being sensitive to light without it. The coating has to be done in the dark, where the emulsion itself must also be kept.

The Negatives for the Red Printing. For the second negative, for red printing, a plate is coated with emulsion, as before, but afterwards sensitised with sensitiser "A" (diluted 1 : 10), by floating it over the plate twice; or it can be mixed with the emulsion (1 : 10). For this purpose it is gradually added in small quantities, and shaken vigorously after each addition. Sensitised emulsion must be kept cool, and well shaken before coating. It must, however, be used up quickly, as it will not keep long, and increases in speed as it gets older. As the plate is very sensitive to light, only dark-red light may be used in the dark-room. Before developing, the plate must be well washed under the tap. The filter used is picric acid, about 1 : 1,000, or a corresponding dry filter. For gelatin plates, either orthochromatic or panchromatic plates can be used. Acid green and bichromate of potash solution serve as filter, or a dry filter can be used.

The Negative for the Blue. For the third negative, for blue printing, emulsion is used, mixed with "C" sensitiser in proportion 1 : 40. This is best worked in complete darkness, or with very dark green light. The plate must be washed before exposure. This emulsion will keep in the sensitised state. A mixture of 6 parts Biebrich's scarlet (1 : 1,000) and 10 parts aurantia (1 : 1,000), serves as filter. The same filter will do for red-sensitive or panchromatic dry plates. It is possible to get plates highly sensitive to colour by taking ordinary dry plates, and sensitising them with essine, silver cyanine, etc.; but the beginner will have sufficient difficulties with ordinary plates, or with emulsion without experimenting any further.

Another point which has to be taken into consideration is that if the angle of the half-tone screen is the same in each negative, a very peculiar effect will be given to the finished block, for the three grains will form what is called a Scotch plaid pattern. This difficulty is overcome by using two screens—one ruled at 45°, the other at 105°. For the third plate, the second screen is reversed, giving the angle of 30°. As the cost of screens is considerable, a circular screen has been constructed, which can be turned to any angle required, and thus the expense of a second screen is obviated.

The ratio of the exposure for the three plates is about 1 : 2 : 8, but varies considerably according to the original. The etching, etc., is exactly as in ordinary half-tone process, but, of course, after the first etch, a rough proof in three colours has to be made, to judge whether, and how much, further etching is necessary. With emulsion it is necessary to flash white card for the dark parts, as in half-tone process. This is not done with dry plates.

Collotype Reproduction. This is a purely photographic process, based on the fact that bichromated gelatin not only becomes insoluble when exposed to light, but also retains greasy ink which it otherwise repels. The grain necessary for the gradations of the tones is caused by the reticulation of the film itself.

In the first place a negative is procured either by dry plate or collodion process. If not taken through a prism or from a mirror, it must be reversed. This is very simple with collodion. The film is cut round, the negative put in water, and a piece of paper squeegeed on. The film comes off the glass easily, and is transferred to another sheet, and then back to a clean glass. Should the film be

too weak to stand this operation, it is first coated with a solution of Para rubber in benzol; then, after drying, with ordinary fairly thick collodion. Dry plates give more trouble to reverse, as the film does not come off the glass easily, and stretches considerably. To avoid this, the gelatin must be hardened with alum or formic acid. To make it leave the glass, it is soaked in a mixture of hydrofluoric, acetic, and citric acids, to which glycerin has been added. Instead of glass, the film can be reversed on to celluloid sheets, which, besides other advantages, are lighter, and take up less room.

Preparing the Collotype Negative. The negative is then marked off with strips of very thin tinfoil about an inch wide. This is best done on a retouching desk, where the picture is carefully squared up with pencil on the film side, and the tinfoil stuck on. The latter must be the very thinnest to ensure contact when printing. That the edges must be absolutely square and sharp is obvious. The negative itself must be full of detail and very soft.

The next thing is to get a suitable support for the gelatin, from which the negative is to be printed on the machine. For this purpose, either glass or metal plates can be used. If glass is taken, one side of it must be carefully grained to give the film sufficient grip. This is done by putting emery paste between two glasses and moving them about gently till an even grain is arrived at. It should be neither too fine nor too coarse. The plate itself must be about ½ in. thick, to avoid breakages, and the edges should be bevelled, as they might otherwise cut the inking rollers in the machine. Copper, zinc, or aluminium can also be used. Zinc is cleaned with emery powder and a brush, and then passed in a weak nitric acid and alum bath. (Formula: 60 minims nitric acid, 1 quart water, and 1 oz. alum.) Copper is ground like a glass plate, and aluminium is treated with weak sulphuric acid (1 : 31) or with a strong potash bath. Glass, before being coated, has to have a substratum of albumen and potassium silicate. (Formula: 7½ parts albumen, 3¼ parts of potassium silicate, and 9 parts of water.) Instead of the albumen, stale beer may be used. The mixture is well beaten up and filtered, and after dusting the plate, is poured on, drained off, and dried. The plate is then washed to remove superfluous silicate, and dried again. Before coating, the plates are evenly heated to about 120°, great care being taken to prevent them from sweating. This is best done in a drying oven on a levelling tripod, where the plates are also dried after coating.

Coating the Plate. The solution consists of gelatin or isinglass, some bichromate salt, ammonia, chromic alum and water. The gelatin should be fairly hard, as this gives the plate a longer life on the machine, though it gives more trouble in etching. Both bichromate of potash and ammonia are used. The proportion of the two is ruled by the fact that the former is slower than the latter. A plate coated with the two gives more detail in the dark parts, and more definition than if one salt only is used. The proportion of the bichromate to the gelatin is defined by the salts crystallising out, if in excess. The proportion of gelatin to water is about 1:10, and a little chromic alum is added to avoid excessive relief. The gelatin is first swelled in cold water, and the salts used are dissolved in another vessel. The gelatin is then heated, but not more than from 120° F. to 140° F., and the salts are gradually poured in and stirred. The solution is then filtered through chamois leather, if possible by a filter pump. The solution must be kept warm during the filtering and coating. The plate is fixed on a tripod and warmed, as previously described, and the liquid poured on. It may be guided a little with a clean glass rod to spread it evenly over the plate, and the utmost precaution must be taken that no bubbles or particles of dust remain.

Drying and Exposing. After coating, the plate is dried at about 120°. This takes about two hours. During and after this time it must be kept in the dark, as, once exposed, the action of the light continues and spoils the plate. When dry, the plate should be perfectly even and matt. If glossy, it shows that the gelatin was too cold. Any vibration or cold draught during drying will be shown by wavy or streaky marks. The plate is exposed to light in frames, exactly as in half-tone process, and if several negatives have been stripped on to one plate, they can all be printed at the same time. All waste space between pictures has, of course, to be masked with tinfoil. For exposure, it is best to use an actinometer. If glass plates are used, an additional short exposure to the plate from the back is advisable, as this gives the film more hold on the glass and prevents excessive relief of the picture.

The plate is then washed in cold water, till all unexposed bichromate is removed. This takes about two hours. The subsequent drying also takes a few hours, but at least a day should be allowed to pass before the plate is put on the machine, to give the gelatin time to harden.

4. HALF-TONE SCREENS; RESPECTIVELY 50, 80, 110 AND 150 GRAINS PER INCH

The So-called "Etch." The plate is then put into a bath of water, glycerin, and salt, ammonia being sometimes used instead of the latter. The object is to make the plate absorb moisture. This is called an "etch" (though it is nothing of the kind). It is done to enable those parts which have been exposed least, and which, therefore, absorb more water, to retain the smallest quantity of fatty ink in the printing, whilst the fully exposed parts hardly absorb any water, and therefore retain nearly all the ink. After about half-an-hour, the plate is taken out and wiped with a sponge and dabbed with a clean rag to dry it. The ink used must be very stiff, only thinned down with a little varnish. It is rolled up very carefully with a map roller till the plate, which will not take any ink at first, looks black all over. It is then rolled with a composition roller, which cleans it up, and is now put into the press. An albion, lithographic, or even a letter-copying press will do. It is best to put a few sheets of paper under the plate to prevent breaking, and to back the proof sheet with blotting paper. If on the proof the shadows are filled up, and the high lights are dirty, the plate is cleaned with turpentine, and re-etched. This is repeated several times until a satisfactory result is obtained.

Skies or dirty margins are cleaned up by etching the plate with a weak cyanide of potash, or a strong hypo solution, on a brush. If the plate is wanting in contrast, an etch is given without cleaning the ink off. For a short run, the plate margins can be masked with oiled paper instead of being etched with cyanide. When a proof shows a satisfactory result, the plate is ready to be put on the machine.

The Art of Photogravure. Photogravure is an intaglio process—that is to say, the surface of the plate does not represent the picture, as in all the other processes, but when the plate is inked in, the surface itself is wiped clean, and the picture is produced by the paper being pressed into the crevices to pick up the ink. The process of producing the plate is not complicated, but requires great skill in the final stages, and a good deal of artistic sense and judgment.

In the first place an ordinary negative is made from the original, and from this a transparency either on a dry plate by contact (and if another size is wanted, in the camera), or on a pigment paper. For the latter purpose, a so-called autogravure tissue is procured. Of the two kinds, it is better to procure the one not sensitive to light, as the other does not keep. Before use, it is sensitised in a bath of bichromate of potash and water with a little ammonia added, for about three minutes. A piece of plate glass is then carefully cleaned, rubbed over with French chalk, coated with plain collodion, and the tissue squeegeed on to it. This must be dried in the dark, for, when tissue is once exposed to light, the process of making the gelatin insoluble continues. The negative is then safe-edged—that is, all the edges of the picture are covered with strips of black paper or black varnish.

Another glass plate is then cleaned, coated with bichromated gelatin, and, after drying, exposed to light, to make the gelatin insoluble in hot water. This is to serve as support to the tissue during and after development. The tissue is then exposed to light behind the negative, and as this carbon process cannot be watched, an actinometer must be used with a piece of P.O.P. First the speed of the tissue (which varies according to the make) will have to be tested by comparing it with silver paper which is exposed simultaneously.

After exposure, the paper is put into cold water till it loses all tendency to curl. It is then squeegeed on to the gelatinised plate, and after standing for a few minutes, is developed in water at about 120° F. The backing paper will then come off easily. The water is now renewed, and the picture can be dried as soon as it has been well developed and all soluble matter removed. Under or over-exposed plates will be useless, as all the detail must be clearly defined both in the high lights and shadows.

The copper plate is now dusted in with finely powdered bitumen. This is done in a so-called "dusting box" containing a fan, which violently whirls up the dust. The copper plate, carefully cleaned with whiting and ammonia, is introduced in the centre on a large board, and the dust is allowed to settle. The longer the plate is left in the box, the finer and closer the grain will be. The time is from five to ten minutes. The plate is now heated, and the bitumen melted on. If the graining is not sufficient, the plate can be put back into the box again, and the process repeated.

Finishing and Etching the Plate. For the next stage, a special autogravure carbon tissue is prepared as the one before, except that the glass plate must not be collodionised. It is exposed behind the transparency, the latter having been safe-edged previously. After exposure, it is taken out, immersed in water, and rubbed gently with a sponge to let the water soak in evenly. The copper plate is also sponged and the tissue squeegeed on to it, and then weighted, after backing it with blotting paper. It is developed as before and is ready for etching, the margins having previously been dried and varnished.

The solution for etching consists of perchloride of iron in water, the perchloride having been neutralised with ferric oxide while hot. There should be five baths, varying in strength from 45° to 32° Beaumé. These baths can be used over and over again, as they improve with use. They will have to be tested occasionally for strength. The plate is first put into the weakest solution (45° Beaumé), where it remains till the copper under the shadows discolours (about one minute). The next two solutions, which attack the half-tones, take about one and a half minutes, while the final baths take from two to three minutes respectively. The plate should be etched one minute after the highest lights have been attacked. Finally the plate is cleaned with carbonate of soda, the film rubbed off, and the margins cleaned with benzol, and brightened up with weak caustic potash and very weak sulphuric acid. When the plate is quite finished, defects can be remedied by rouletting and burnishing. After this, the plate is steel-faced and is ready for proving.

Classes and Books. Classes in the above processes are held at the Polytechnic, Regent Street, and the Bolt Court School of Engraving, Bolt Court, Fleet Street, London, as well as in similar institutes all over the country. Useful books on these subjects are: "Half-tone Process," by J. Verfasser; "Collotype Process," by W. Fithian; "Three-colour Process," by A. v. Hübl; "Photogravure," by W. T. Wilkinson; "Manual of Photo-engraving," by H. Jenkins, 1902 (Inland Printer Co., Chicago); "Photo-mechanical Processes," by W. T. Wilkinson (Hampton & Co.); "Collotype and Photo-lithography," by Dr. J. Schrauss, translated by E. C. Middleton (Iliffe & Son); "Photo-lithography," by G. Fritz, translated by E. J. Wall, 1895 (Dawbarn and Ward).

FAVOURITE GARDEN FLOWERS

The Queen of Flowers. Lilies, Chrysanthemums, and Carnations. Bulbs of Spring and Autumn. Dwarf and Bedding Plants and Flowers. Ferns

By H. HAVART

NO matter in what part of the kingdom a young gardener may find himself, he is sure to be called upon to pay special attention to the five favourite garden flowers: the rose, lily, chrysanthemum, carnation, and sweet pea. There are, of course, many other favourite garden flowers, and details of their culture are given in this and further articles.

The Culture of the Rose. The rose has often justly been called the "Queen of Flowers," and it is well to remember that her Majesty requires regal treatment. Failure with roses is generally due to the fact that they are planted in the wrong sort of soil. It is impossible to get good roses in bad ground, and, where the soil is not suitable for their cultivation, it must be taken away, and proper material introduced. The soil in which the rose thrives best is a good rich loam two or three feet in depth, resting on a subsoil of clay. The clay subsoil, being impermeable, retains all moisture, and so keeps the roots of the roses cool during the hot months of summer. Where the soil is very light it must be made heavier by the addition of thick, heavy loam and clay, otherwise the gardener is merely courting failure. Roses are generally grown in the forms of "Standards," "Dwarf Standards," "Bushes," or "Climbers."

A standard is a rose which has been grafted on to a stem about three feet in height. A dwarf standard has been grafted at about half that distance, while a bush usually springs from the ground without showing any main stem at all, having been grafted close to the roots. Roses on their own roots—that is to say, roses that have not been grafted at all—are invariably grown as bushes.

Roses are usually grown as standards when extra large-sized blooms are required for exhibition purposes, or where space is limited. In places where plenty of room is available there is no doubt that the best way to grow the rose is in its bush form, as it blooms far more freely under these conditions.

The Best Varieties of Roses. Roses are divided into several sections, or groups, the most important of which are: Teas, Hybrid Perpetuals, Noisettes, Hybrid Teas, Bourbons, Monthly roses, and Ayrshires, titles which are derived chiefly from the land of their birth, or the time of flowering. Altogether there are nearly two thousand varieties in cultivation, and the number is added to every year.

The following twenty-four sorts recommended by "The Century Book of Gardening" as suitable for town and suburban culture are, perhaps, as judicious a selection as could be made for all purposes:

Red: General Jacqueminot, Alfred Colomb, Abel Carrière, Dupuy Jamain, Cheshunt Hybrid (climber).

Pink: Mrs. John Laing, Baroness Rothschild, La France, Captain Christy, and Pink Rover (climber).

White: Boule de Neige, Merveille de Lyon, and Aimée Vibert (climber).

Yellow: Marie van Houtte, Madame Hoste, Emily Dupuy (climber), and Medea.

Apricot: Francisca Kruger, Safrano, Rêve d'Or (climber).

Salmon: G. Nabonnand, Bouquet d'Or (climber), Dr. Grill, and Felicité Perpetue' (climber).

How to Propagate Roses. The three chief methods of propagating roses are by grafting, budding, and cuttings. Grafting [19] and budding are usually performed upon the stem of a wild briar whose sturdy growth makes it eminently adapted for the purpose. This briar is called a stock, and the main stem is cut down to the desired height of the standard, or bush, as the case may be. A V-shaped notch is cut in the top of the stock, from one to three inches deep, according to its diameter. The end of the graft (the rose which it is desired to propagate) should be cut wedge-shaped in order to fit the notch in the stock, and carefully inserted, the junction being thickly covered with clay to afford protection. The operation of budding consists in lifting, with a very sharp knife, a bud, and about a quarter of an inch of the bark round it, and inserting it in a stock. The stock is prepared by cutting a T-shaped slash in its bark, raising the bark gently with the knife, so that the bud may be inserted underneath it, and, when once the bud is in position, binding it round fairly tightly at top and bottom, to ensure its retaining its position.

Cuttings are slips taken off with a slanting cut, and containing two or three "eyes." They are best potted up in small pots in a mixture of sand and leaf mould. If put in a frame and well exposed to the sun they will root in about a month, but must be kept free from frost all the winter, and gradually hardened off the following spring.

The operation of pruning roses is carried out in the spring, and is better performed with the secateur than the pruning knife. Climbing roses do not, of course, require so much pruning as the standard or bush sorts. Probably no two rose-trees require exactly the same sort of pruning, but the golden rule to be observed is to see that the branches in the centre are well thinned, so that light and air have free access.

The best time for planting roses is from November to March—the earlier the better. All newly-planted roses should have protection from frost during the winter months. This may be afforded by a mulch of straw, bracken, or similar material.

The Lily. Though not so popular as the rose, perhaps, lilies of varied sorts must be found in profusion in every garden which pretends to be at all representative.

Generally speaking, lilies do not like a heavy soil; consequently, with the exception of a few varieties, the heavy clays which are to be found so frequently in the neighbourhood of large towns and cities are not calculated to grow them to the best advantage. A light rich soil, with plenty of sand and leaf-mould in it, is what the lily revels in, and it is one of the few flowers which has no liking for the presence of animal manure.

The most popular forms of lilies suitable for culture in gardens are given in the table on next page.

The Chrysanthemum. The immense popularity to which the chrysanthemum as an exhibition flower has attained during recent years has militated somewhat against its general employment as a garden plant. In fact, it is not too much

to say that the efforts of most growers have been directed more to producing isolated blooms of gigantic size, than to growing the plant for general effect.

THE MOST POPULAR LILIES		
Name.	Height.	Colour of flower.
Auratum ..	About 6 ft.	White with yellow band
Bulbiferum ..	2 ft. to 3 ft.	Orange red, black spots
Madonna ..	tall, varies	White
Easter	2 ft.	White
Tiger	3 ft.	Red, purple spots
Speciosum rubrum	2 ft. to 3 ft.	White, pink spots, crimson markings
Orange	6 ft.	Orange, black spots
Scarlet Martagon	3 ft.	Bright red
Elegans ..	1 ft. to 2 ft.	Orange

It is a perfectly hardy flower, and may be grown in the garden border with the same facility as the dahlia. Chrysanthemums are apt, certainly, to be damaged by rains and frosts in the late autumn, but they may be protected from this by an awning of some light material, such as waterproof calico. If grown in pots, they are generally transported at the first sign of frost into a cold greenhouse, and left to finish blooming there. This is the method attendant with least risk, and is generally adopted.

Chrysanthemums are divided into three classes: Incurved, Japanese, and Pompon. The incurved variety, as its name implies, has all the petals curving inward, and overlapping, so that it somewhat resembles a flattened ball in shape. In the Japanese variety of chrysanthemum the petals throw themselves about in every direction, so that the flower looks like the head of a mop, earning for it the colloquial name of "ragged chrysanthemum." The Pompon is a dwarf with small, closely petalled flowers, rarely more than two inches in diameter.

Growing Chrysanthemums for Cutting and Exhibition. The best soil in which to grow chrysanthemums is equal parts of loam, leaf mould, sand, and rotten manure. The young plants should be put in about March or April, according to the weather, about three feet apart every way. If they are simply to be grown for the purpose of cutting, there is no need to tamper with them again, except to give them an occasional dose of liquid manure, but if they are destined for show or decorative purposes in pots it is usual to remove many of the buds so that the whole strength of the plant can be concentrated upon two or three blooms, which will necessarily be of gigantic size. Chrysanthemums grown for this purpose, however, are usually cultivated in pots, commencing with a small thumb pot, and re-potting each time into a larger size, until they are finally placed in nine inch pots, which should contain the best loam, with a little finely powdered charcoal. It is necessary to tie chrysanthemums grown for large blooms to sticks, otherwise they will be topheavy, and fall over.

Like so many other flowers which the nurseryman has taken in hand, the chrysanthemum has innumerable varieties. A few of the best for general culture are Soleil d'Octobre (golden yellow), Madame Desgrange (white), Montague (purple crimson), Ryecroft Glory (yellow-shaded bronze), Vivian Morel (pale pink), Madame E. Roger (green). The last-mentioned variety is somewhat of a freak, and would be grown more as a curiosity than for any ornamental value; it is, however, very hardy, as it does well in many parts of London.

The "Buttonhole" Flower. If the carnation were grown for no other purpose, it would always be sure of a prominent place in gardens by reason of its value as a "buttonhole" flower. To be seen at its best in the open garden, however, it should be grown in beds or clumps. A good plan is to grow the bold, self-coloured sorts in beds, and have little clumps here and there, dotted about the borders, of picotees, flakes, and bizarres. These last three terms are the names by which the striped and marked varieties of carnation are known.

Layering Carnations. A rich, loamy soil is necessary for the carnation. This soil must be well drained, and just a little sand mixed with it. The richer the soil the more vigorous the carnation, but on a light soil the plant will never do well. The chief methods of propagation are from seed, and by the operation known as *layering* [22]. Layering is carried out in July or August, when the plant is in full vigour. Select a good strong shoot near the base of the plant, and clean off all the leaves on that shoot with a sharp knife, except half a dozen at the top. Cut half way through the shoot from below in an almost horizontal direction, for a distance of about 2 in., taking care to cut through a joint in the stem on the way. Push the wounded part of the shoot into the ground, which has been previously prepared by having sand mixed with it, and keep it in that position by pegging it down. Special pegs may be procured for this purpose, but a common hairpin answers the purpose admirably.

Carnation seed must be sown in May, in pots or boxes of rich loamy soil. They must be stood in a sheltered spot, and, when the plants show a few leaves, they can be put out in beds of the same material, and left till late autumn. If they have the protection of a frame during winter, many of the young plants will bloom the following season.

Among the best carnations for the open garden are: White: George Macquay, Trojan [20], Alice: Pink: Duchess of York, Asphodel, Endymion, Raby Castle, Ketton Rose: Yellow: Miss Audrey Campbell: Buff: Mrs. Reynolds Hole, Prince of Orange. Scarlet: The Cadi, Isinglass, King Arthur: and Crimson and Dark Red: the old Clove Carnation, Uriah Pike, Mephisto, Boadicea.

The picotee and other fancy varieties of carnation are more numerous even in variety than the good self colours. Six good ones are Cardinal Wolsey, Ladas, Perseus, Dervish, Mrs. Robert Sydenham, and the Czar.

The Sweet Pea. There is probably no more popular annual flower in the garden than the sweet pea, and certainly none which yields a more bountiful supply of bloom for cutting. It may be had in practically every colour from white to what may, by a very slight stretch of imagination, be called a black, and is of the easiest culture. The sweet pea thrives in any ordinary garden soil, and may be sown either in autumn or spring. Seed should be put in the ground 2 in. or 3 in. apart, and at a similar depth. It is customary to attribute failure with sweet peas to the ravages of birds, and certainly they do a great deal of damage. This may be guarded against to a great extent, however, by rolling the seed in red lead before putting it into the ground. When the young plants show themselves, and are likely to be nipped off, the surface soil should be liberally dusted with soot.

Sweet peas are usually seen in gardens trained up bean sticks placed against walls or fences, or in clumps. A method which has recently been put into practice with good effect, is to sow them in rows, a bean stick being driven firmly into the ground at each end of the row. At about 3 in. above the ground, a string is stretched from pole to pole, and the young plants lifted up, so that

their heads rest on the string. As they grow higher and need more support, other strings can be stretched across and so on, until they reach their full height. Practically, the only support to be seen is the pole at each end of the row, and even this may be hidden in a simple way by letting a fast-growing climber, such as the nasturtium, Japanese hop, or canary creeper, run up it. Unless it is desired to save seed of any particular plant for future use, the flowers should never be left on sweet peas until the seed pods form, as this weakens the supply of bloom. On the contrary, the blossoms should be cut almost before they are fully expanded, and then the plants will go on yielding a prolific supply of bloom right through the summer months. As regards sorts, all of those named "Eckford" are good, and there are several of these christened after different members of this famous grower's family. Apart from these, a few of the best are Blanche Burpee (white), Captain of the Blues, Venus (pink), Countess of Radnor (heliotrope), Cardinal (red), and Primrose (pale yellow).

17. A NEW BEDDING PANSY

The Bulbs of Spring. It is impossible to overestimate the value of bulbs in the garden, no matter whether they be the spring or autumn flowering kind. At present, the former are much more generally cultivated than the latter. This has been particularly the case during recent years, now that the custom of naturalising such things as daffodils, crocuses, snowdrops, and anemones, in the grass has arisen.

Hyacinths are grown in pots or glasses. For pot culture, a mixture of ordinary garden soil with sand and a little leaf-mould answers well, or the leaf-mould may be dispensed with if it is not readily available. October is the best month to plant the bulbs, and they should be barely covered with soil. A leading firm of growers says: "After potting, give one good watering, and then place the pots outdoors on a bed of ashes, cover with 6 in. of cocoa fibre, and leave them exposed to all weathers. When the bulbs have well rooted, and made about 1 in. of top growth, they may be removed indoors, first into a subdued light, until the foliage has attained its full green colour, and then in the sunniest situation at command in the greenhouse or conservatory. It is a good plan to place an inverted flower-pot over the young growths for a few days after being removed from the plunging bed, as by so doing they are protected from possible draught. Abundance of air, a moderately moist atmosphere, and plenty of water at the roots, are then necessary for early well-developed flower spikes."

18. PROPAGATING BEGONIAS FROM LEAVES IN A PAN

In quite small suburban houses, hyacinths in glasses are the rule rather than the exception. During the winter it is best to fill the glasses with rain-water to such an extent that the bottom of the bulb just touches the water. At first, keep the glasses in a dark place, filling them up with water as it evaporates; by this means, healthy root growth is promoted. By the time the glasses are nearly full of roots, they may be gradually exposed to the sun in a window. This treatment ensures large and healthy trusses of bloom. Hyacinths which have flowered in pots one year, will flower in a border for several years in succession afterwards, but the resulting flowers will not be so large.

The Narcissus (Daffodil). The daffodil [21] is undoubtedly the most valuable spring-flowering bulb we have in our gardens, and there is no capacity in which it cannot be used. It may be grown by thousands on banks, lawns, and in meadows, increasing enormously, or it will flourish bravely on the sooty window-sill of a city slum. The best way to grow it in pots is to use three bulbs to a five-inch pot. The soil it likes is just ordinary garden soil, with a mixture of sharp sand. As daffodil bulbs vary so much in size a good general plan is to plant the bulb at one and a half times its own depth. After flowering, the bulb should not be lifted out of the ground until the foliage has quite died down; but where this cannot be avoided, owing to the ground being required for other purposes, they should be carefully lifted, and re-planted in some spare corner until the foliage has quite withered.

The narcissus family is divided into several important groups, including the Trumpet section, the Star daffodils, and the Poet's daffodils. They number several hundred varieties, ranging in price from a few shillings per hundred to fifty guineas a bulb.

The Brilliant Tulip. What the daffodil gives us in delicacy of colour the tulip supplies in brilliancy, and it is entitled to rank among the best early flowering bulbs. It is not, however, adapted for culture in the grass, but does well in beds of soil as recommended for the daffodil. The genus is divided into three sections: Early flowering, May flowering (Gesneriana) and late flowering (Darwin). There is also a curious distinct breed called the Parrot Tulip, so named for its peculiar shape and colour. One tulip above all others suitable for town culture is Kaiser's Kroon, a brilliant scarlet tulip with yellow edges; while other good sorts, arranged in order of time of flowering, are: the Duc Van Thol group, Ophir d'Or, Proserpine, White Swan, Bouton d'Or, Gesneriana Spathulata, Golden Crown, Royal White, May Queen, Salmon King, the Bride, and the Sultan, the latter approaching nearest to the much sought after black tulip.

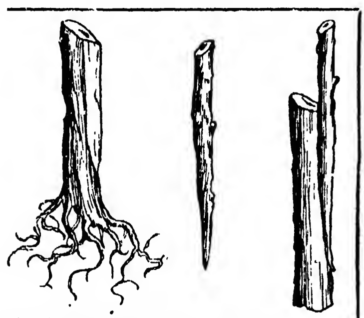
The Iris, Gladiolus, and Lesser Bulbs. Although different varieties of iris may be made to give flowers from the beginning of the year on into August, the great majority of them are spring flowering bulbs. These are what are known as the Spanish and English sections. September is the best month for planting the bulbs, which should be

put in deeply in any ordinary garden soil. There is a long list of sorts of all colours from white to nearly black, and splashed and marked with every conceivable hue. Some choice species of the iris include: Alata (Scorpion iris), Atropurpurea, Iberica, Reticulata, and Unguicularis.

The spring flowering section of gladiolus bulbs is not a large one, only one or two varieties blooming as early as May. As, however, those which do not come into flower until June and July are planted at the same time as the ordinary spring flowering bulbs they are best included here. Gladioluses require shelter from the wind, and also shade from the full heat of the sun. October is the best month to plant, though good results have been obtained with bulbs planted as late as Christmas. A layer of bracken or straw should be spread over them to protect them during the winter, while deep planting, say at a depth of six inches, also effects an insurance against damage by frost. The Bride (pure white) and Byzantinus (light crimson) are the best of this early flowering section.

Crocuses, snowdrops, anemones, scillas, alliums, dog's-tooth violets, chionodoxa, and muscari are the most important of the dwarfer growing spring flowering bulbs. Their culture is exceedingly simple. In fact they merely require putting in the garden or woodland, or wherever it is proposed to grow them, at any time during the months of October or November when the ground is dry. The rule of planting at the depth of a bulb and a half holds good in this case.

Autumn Flowering Bulbs. Just as the spring flowering bulbs are planted in autumn, so should the autumn flowering bulbs be planted in spring. With the exception of the gladiolus, however, the culture of autumn flowering bulbs has been somewhat neglected, though their presence would be a great help at a time when gardeners are apt to rely greatly upon the dahlia and chrysanthemum. It is possible to get exactly the same effect with the crocus in autumn as it is in spring. As a writer in the "County Gentleman" says. "Their culture is simplicity itself. They should be planted in any ordinary garden soil, and just covered with earth, or, if in pots as specimens, in ordinary potting mould. . . . The best autumn flowering crocuses are the Asturicus varieties, which represent the mauves and purples in all shades: Sativus, the purple saffron crocus; Hadriaticus, pure white; Zonatus, rose and orange; and Speciosus, bright blue, recalling, when planted out in the grass, the beauties of the grape hyacinth in the spring."



19 A METHOD OF GRAFTING ROSES.

The autumn flowering gladioluses are varieties of the species known as Gandavensis, and they may be relied upon to provide those brilliant masses of scarlet so often needed but so rarely seen in the autumn garden. It is merely necessary to plant them out in March in decent soil, and leave them to take care of themselves. They are somewhat shy of frost.

The belladonna lily (*Amaryllis belladonna*) is the most beautiful of all the autumn flowering bulbs, but it should only be planted on the south side of a house or wall, as it is not quite hardy in other situations. It grows nearly a yard high, with large lily-like white flowers, tinged with pink towards the centre. It needs deep, fairly rich soil, and if the bulbs are planted in autumn, which is the best time to ensure a display of bloom the following year, they should be protected with a layer of fibre during the winter. They soon establish themselves and will bloom freely every year.

The tiger flower (*tigridia*) should, as far as culture is concerned, be treated the same way as the gladiolus. The flowers are six inches wide, bright red in colour with crimson spots, and the plant attains to a height of 2 ft. or more. Each flower only lasts a day, it is true, but a succession of flowers lasting in all nearly two months are borne on the same stem.

Other autumn flowering bulbs include Crocosmas; Sternbergias (the best authorities say that this is the lily mentioned in the Bible); Leucojum; the autumn flowering Scilla.

The Dwarfer Flowers of the Garden. The proper place for dwarf flowers in the garden is obviously in front. Many of them are of great value for edgings, while others help to form a carpet at the foot of taller growing things.

Although the violet is frequently found wild in the hedgerows and copses of the country, the practice of cultivating it, either for private use or for market purposes, is not a general one. The French grower thinks nothing of having two or even three acres of ground covered with violets, while the English grower is content with a few square yards. As violets like shade, they are essentially suitable for carpet plants, and they thrive in any moderately good soil. It is well not to leave them for more than two years in the same spot, however, as they deteriorate in quality after that time. They are best planted in May for the following season's display, a little manure from the hotbed being forked in when planting. The most popular sorts are Neapolitan, Marie Louise, La France, the Tsar, and Princess of Wales. Belle de Chatenay is one of the best white sorts.

Pansies, Lily of the Valley, and Lobelia. The pansy [17] is a sister of the violet, as both belong to the same genus (Viola). They are one of the easiest garden flowers to grow, and may be used as edgings or to cover the surface of a bed of roses, or other flower. Pansies may be planted either in autumn or spring, the former for early flowering. They should be put in about 9 in. apart. To obtain plants from seed in the open air it should be sown in the middle of summer (say, July), and the little plants transferred to the flowering beds in the ordinary way in the autumn, when they will bloom the following spring. Both the violet and the pansy are subject to attacks from green fly, and, occasionally, red spider.

The lily of the valley is so frequently seen forced in pots in company with other exotics in florists' shops in the middle of winter that the fact that it is a perfectly hardy garden flower is apt to be overlooked. It can be grown almost anywhere, and suburbs near to the smoke of London appear to suit it well. The corms should be planted in October, just at the time when the spring flowering bulb planting is going on, and the bed in which it is proposed to plant them should have a liberal dose of leaf-mould mixed with the surface soil. The corms

should be placed about 3 in. apart, and just covered with soil, and they will start into growth in early spring. It is a good plan to change the position of lily of the valley beds, or, at all events, re-make them, every five years.

The dwarf section of the lobelia family is known technically as *Lobelia Erinus*. It is the familiar little blue flower so often seen as an edging plant in gardens, and also as a prominent feature in window-boxes, for both of which uses it is admirably adapted. The lobelia is only half-hardy, and requires the protection of a greenhouse in winter. The plants can be raised from seed sown in boxes of light soil at Christmas-time, or thereabouts, and given a gentle heat. If the common mistake of sowing the seed too thickly has not been made, they will be ready for putting out in May without further transplantation. Emperor William is one of the best sorts, and White Ladie is a beautiful white kind.

20. BORDER CARNATION (TROJAN)

Virginian Stock, and Other Dwarfs. The Virginian stock is one of the very hardiest of dwarf growing annual flowers, adapted for an edging, and its culture is simplicity itself. It is only necessary to take a stick and go out into the garden on a bright day during April or May, and drag the stick along the edge of a bed or border, so that it leaves a furrow behind it. Into this furrow sprinkle the Virginian stock seed gently, and just cover it with the earth which has been disturbed. In a very few weeks, a substantial edging, from 4 in. to 6 in. in height, will make its appearance covered with thousands of tiny flowers—red, white, or mixed, according to the variety used. One sowing of Virginian stock will bloom for many weeks, and it may be renewed by successive sowings.

The most useful variety of the Alyssum family of dwarf-growing plants is the sweet alyssum, a white, fragrant little flower, useful as an edging, or charming in effect if sown to form a broad sheet, and flowering all through the summer and well on into the autumn. It is best sown in the open air in spring, and if the precaution of sowing thinly is taken there is no need for transplanting.

21. "EMPEROR DAFFODIL
For bed, pot, or window-box

Nemophila is another of the dwarf hardy annuals, and should be treated in the manner already described for this class of flower, with one difference. In addition to sowing in the spring for summer flowering, a sowing should be made in the autumn, where tulips and other of the taller flowering spring bulbs are being planted. The nemophila will then bloom with them in the springtime as a carpet of delicate pale blue or white as the case may be. Nemophilas will flourish in any soil, and so are eminently adapted alike for culture in town or country. The plant should never be used, however, where cats are likely to cause any trouble. For some mysterious reason, cats are particularly fond of this plant, and have been known to travel a long way to get at a garden in which there was a bed of it. As their appreciation takes the form of lying down and rolling over and over in it this naturally means the destruction of everything in the bed.

The garden forget-me-not (*Myosotis dissitiflora*) is probably the most useful of all the dwarfer flowers of the garden, inasmuch as it blooms in spring, and so forms a carpet for the bulbs. Seed may be sown in the autumn at the same time, and in the same beds, as the spring-flowering bulbs are put in, and they will all come up and flower together. The plants are easily propagated by digging them up and dividing the roots during the flowering season, or if they are allowed to remain where they are the seed will ripen, drop off, and sow itself during the late summer months. This is not the forget-me-not of the stream side, about which poets talk so much, the latter being known as *Myosotis palustris*.

Other dwarf flowers of spring are *Arabis alpina*, *Limnanthes Douglasi*, *Saponaria calabrica rosea*, and *Silene pendula*, while the stonecrops are at all times useful, apart from their place in the rock garden, in covering up odd corners. The flowers just mentioned are all hardy annuals and merely require the treatment already set forth for such things.

Carpets of Flowers. Upon few subjects has more wordy warfare been waged than that of carpet bedding. The extreme school of "wild gardeners" execrate it, and there is no doubt that, if carried out to excess, these flat beds made up into carpet-like designs are both dull and uninteresting. The rational gardener, however, will be quick to recognise that there is a place for them in every garden that has any pretensions to size. Carpet beds may be of any shape the designer pleases, but this is usually regulated by the size and shape of the place in which the bed is to be put [see Frontispiece opposite page 6529]. A very good plan is for the gardener to work out designs on paper, drawing them to scale, during the long winter evenings. A good idea of what the general effect will be like may be obtained by colouring these plans as near as possible to the hue of the plants it is intended to employ. Before proceeding to cut out the bed it is best to mark an outline of it in whitewash.

The majority of carpet-bedding plants are raised from seed, sown in boxes in March, and subjected to a bottom heat of about 80°. One of the most important plants for carpet bedding is the alternanthera, of which several varieties are useful. They range in colour from yellow to brownish-red, the variety aurea being a brilliant yellow. The pyrethrums, or golden feathers, are another mainstay of the carpet bedder, and the different varieties give him grey, pale green, and gold for his beds. Antennaria

is the plant generally employed to get the delicate silvery white effect so often seen in the best carpet beds, while for very deep red effects the beet is occasionally employed with advantage. The deep blue and white varieties of lobelia are also valuable aids to carpet-bedding. No carpet bed would be complete unless it contained some of those curious flat rosette-like plants called *Echeveria secunda*. They are raised from seeds sown on fine soil in gentle heat, and merely require protection from frost in winter.

Where a centrepiece is desired for a carpet bed, and such a thing is often an improvement, it is best to employ the fishbone thistle (*Chamæpeuce cassabonæ*), a graceful plant, with shining dark-green leaves marked with white and brown.

The following are in general use as carpet bedding plants, but they require no special treatment: *Alyssum maritimum*, *Mentha pulegium*, *Iresine lindeni*, and *Sedum glaucum*.

Summer and Autumn Bedding Plants. Among gardeners the term "summer bedding plants" is understood to comprise those plants which, although invaluable for giving us a display of bloom, say, from May until September, are too delicate to withstand the rigours of our winters, and need the protection of a frame or greenhouse, or at lest a shed, if they are to be kept alive. Until comparatively a few years ago, summer bedding was confined to the laying down of strips of blue lobelia, scarlet geraniums, and yellow calceolarias, which occurred in garden after garden with never varying monotony: but things have now happily altered for the better, and a wider range of effect is possible. In the genial climate of the south and west of England some of the plants described hereafter as needing protection during the winter may remain in the open ground all the year round with impunity, but this favoured area is of such small extent that for practical purposes it is necessary to treat summer bedding plants as being only half hardy. The flowers enumerated hereunder are those most generally in use for the purpose, and may be supplemented, where space and opportunity affords, by any of those mentioned in other sections.

The Geranium, Fuchsia, and Begonia. The geranium, as most people know it, is not a geranium at all, but a pelargonium: it originally sprang from the wild geranium, but has been crossed with various species in order to obtain fresh varieties. It is the most popular of all summer and autumn bedding plants, and one of the easiest to cultivate well. It will grow in any ordinary garden soil, and is increased by taking cuttings, or slips, when the flowering season is practically over—say, in September. These slips should be cut off the parent plant at a very acute angle with a sharp knife, and should be put into little pots containing some fairly good soil, and with a pinch of sand at the bottom of the hole where the cutting is stuck in. As soon as there is any fear of frost they should be got in under glass, and they will quickly root and be ready for planting out the following May. Cuttings may also be struck in the spring, in slight heat, and will be ready for planting out at practically the same time, but they will not make such sturdy plants. Very little water should be given during the winter.

Fuchsias thrive in soil similar to that suitable for geraniums. They are, however, propagated in a somewhat different manner. It is customary to take old plants which have been stored in a cellar or somewhere else away from frost during the winter, and start them into growth in the heated greenhouse. When the young shoots appear, and are about two or three inches in length, they should be taken off and potted up as directed for geraniums. They should be thoroughly hardened off by exposure to light and air before being planted out. In some gardens, especially near towns, the buds of the fuchsia have a provoking habit of dropping off instead of opening into flower. The general cause of this is insufficient water, or, if the fuchsias happen to be growing in pots instead of in beds, it will probably be found that they are "pot bound"—that is to say, the pot is not large enough to contain the roots which have been formed. When this is discovered to be the case the plant should be re-potted at once.

The begonia of so much value for summer and autumn bedding is what is known as the tuberous-rooted begonia. It is best raised from seed or leaves sown in early spring in pans [18] or boxes in sandy soil and brought on in a temperature of not less than 60°. In three weeks or a month's time the plants will be ready to be put into pots, after which they should be gradually hardened off for planting out in June. Great care should be exercised in the sowing, as the seed is so very minute. In a rich, light soil begonias will continue to flower until cut down by frost. When this happens it is usual to lift them up, and store the tubers which will be found to have formed at the roots, in silver sand in a dry place. These tubers can be started into growth again in the spring. There are many sorts, in all shades of white, yellow, salmon, and red, and some double ones.

Dahlias, Calceolarias, and Other Bedding Plants. When the summer begins to wane there is probably no more important bedding plant in the garden than the dahlia, as it forms stout bushes three or four feet in height, giving a generous supply of bloom for cutting, right into the very late autumn. There are four principal kinds: the double dahlia, which is the old-fashioned almost spherical-shaped flower so often found in cottage gardens; the pom-pom, which is a smaller edition of the double dahlia; the cactus, distinguished by its almost claw-like petals; and the single dahlia. The dahlias are generally propagated from cuttings, which are obtained by starting a tuber into growth in a heated greenhouse in January or February, and taking off the cuttings as the young shoots appear. These are then treated in the manner described for seedling begonias. When the dahlias are thoroughly hardened off, and ready for planting out, a stick some four feet in height should be pushed into the ground at the side of the hole dug to receive each plant, and to this stick the young dahlia should be tied sufficiently tightly to prevent it being swayed about by the wind. After flowering, the bulbs should be lifted and stored in a box of soil in a frost-proof place during the winter.

The yellow calceolarias are a familiar sight in the summer bed. They are propagated by cuttings taken in the autumn in sandy soil, and placed in a cold frame, where they will root during the winter, and so be ready for planting out with the rest of the bedding stuff.

The canna is as effective in the summer garden for its foliage as for its flowers, most of the varieties having rich brown leaves. A group of cannas in the centre of a large bed is particularly effective, reaching, as the plant often does, to a height of six feet. They are propagated by spring cuttings, in the manner described for fuchsias, or by dividing the old roots, and potting them up. They need a sunny position, or they fail to develop. The best sorts are Antonin Crozy (crimson), Antoine Chantin (salmon colour), and Paul Bert (yellowish red).

The heliotrope is best known under its old-fashioned name of "cherry pie," and the little

flower is a great favourite because of its delicious perfume. It is propagated in the same way as the fuchsia, or forced from seed and hardened off. It is generally a failure in moist soil, and, when desired there, should be kept in the greenhouse.

Petunias and Tobacco Plants. The petunia is a hardy annual, raised from seed sown in heat in February, and planted out in May. Particular care must be taken in planting out as the roots of the plants are very brittle, and liable to damage if they are at all carelessly handled. Seedling plants often yield bloom with very curious markings, and if it be desired to perpetuate these it must be done by cuttings taken in August, and placed in pots or a frame in soil which is well mixed with rotten manure and kept moist. They must be wintered in a cold frame, and care taken that the frost does not get at them. Good bedding sorts are Countess of Ellesmere (crimson with paler throat), Delicata (white with purple stripes), and Doctor Hogg (purple with white throat).

No garden is complete without its tobacco plants, as the varieties of nicotiana are popularly called. They should be treated as half-hardy annuals, and raised from seed sown in heat in February, when they will be ready for planting out with the rest of the summer and autumn bedding stuff. The one most frequently met with is *Nicotiana affinis*, particularly sweet scented in the evening, and reaching a height of about two feet. A taller variety is called Sylvestris—three feet in height, the flowers of which do not shut when exposed to the full glare of the sun, as is the case with Affinis. A very interesting variety is called Sanderæ, having red flowers.

22. LAYERING CARNATIONS

The Hardy Ferns. In order to grow hardy ferns to the best advantage they must have a shady position in the garden. It is not, of course, impossible to grow ferns in the sun, but it is hopeless to expect them to do well there, as they soon get scorched up. Ferns dislike being moved; hence, to get the best results, the fernery should be established at some spot in the garden where it is likely to remain for a number of years. A sloping bank makes an ideal spot for a fernery, but, no matter where it may be, it is essential that the ground should be well drained. Ferns will not flourish when they have a lot of stagnant moisture about their roots, though, at the same time, the majority of them thrive admirably in the neighbourhood of a running brook or stream. The ideal soil for the fernery is a mixture of good loam and peat, the former predominating.

Ferns are usually propagated by taking the seeds, or spores, which are found upon the backs of the fronds, and spreading them carefully upon the surface of a lump of peat, keeping the peat thoroughly moist, when the majority of the seeds will successfully germinate. Those ferns which have running roots, however, may be divided in the usual manner. In order to ensure that fresh bright green appearance so much to be desired in ferns it is necessary that the foliage should have plenty of water. In small indoor ferneries this moisture is often supplied by the introduction of a small fountain. Out of doors the best substitute is frequent soaking with the hose, the rose of which has holes of the smallest size.

There are several varieties of spleenwort (asplenium) ranging from one to two feet high respectively. The most important is the black spleenwort (*Adiantum nigrum*) which, in addition to being grown among other ferns, may be planted with success at the foot of such shrubs as azaleas to act as a carpet. Its fronds are also useful when bouquets have to be made up, or to mingle with cut flowers for general decorative purposes.

Royal and other Popular Ferns. The Royal fern (*Osmunda regalis*) is rightly named, as it is the largest and most imposing of all our native ferns. It has been known to attain a height of eight feet, though its average altitude is not so much as this. It wants damp peaty soil, and may, in fact, be planted with its roots in water in a shady spot. There are several varieties, natives of North America, useful where large collections are being made, but otherwise not of great importance.

One of the most popular ferns is Hart's Tongue fern (*Scolopendrium vulgare*), deriving its name from the shape of the fronds. Like most other ferns like shade and moisture, but has the characteristic of thriving particularly well in a soil containing lime. It is attractive when grown in pots for the table.

The Lady fern (*Athyrium*) is another family of ferns much overladen with valueless varieties, but the type is worthy of cultivation under orthodox conditions in the fernery, or among evergreen herbaceous plants. It dies down during the winter, and, therefore, requires no water then.

A very useful hardy little fern is Polypody (*Polypodium*), the fronds of which are green all the year round, and which may be grown on walls or in rock work. It is one of the easiest of ferns to propagate, being easily increased by dividing the roots—an operation best carried out in the springtime. It prefers a liberal admixture of sand in the soil in which it is grown.

The Shield fern (*Aspidium* and *Polystichum*) is one eminently suited for culture in town gardens, as it will thrive in a comparatively poor soil provided it has plenty of water during the hot months. The Shield ferns are particularly useful for planting under trees, where there are often bare spots upon which grass refuses to grow. The well known Holly fern is a variety of this family, of which considerably over 100 members are found in catalogues.

There are several other families of ferns, individual members of which are worthy of a place in our gardens, where a speciality is being made of the fernery. The system of nomenclature by which they are distinguished is a very confusing one, and the young gardener who hopes to get on in the world can occupy his time far better in doing more useful things than, for instance, trying to identify *Athyrium filix-fœmina flore pleno superbum percristatum*, which is a rather insignificant variety of the Lady fern. In any case too many ferns in a garden are a mistake, and unless the place is of any considerable extent it is perhaps a mistake to lay down a fernery at all.

Continued

THE CONSTRUCTION OF DOCKS

Dock Walls and Foundations. Dock Gates. Caissons. Graving Docks and Floating Docks. Sea Walls. Lighthouses

By A. T. WALMISLEY

THE preliminary consideration for a dock is the choice of a site. Low-lying lands along tidal portions of rivers and estuaries are generally utilised, and thereby the amount of excavation is much reduced, and what is required to be dug out can be employed in making up the backing of the quays. Bends in the rivers furnish very suitable sites for docks, the surfaces being low. In sharp bends the dock is carried right across the bend, with an entrance at each end. The bends of the River Thames at London, also of the River Medway at Chatham, have thus served as sites for docks.

There are various types of docks, and their design depends upon the condition of the site, the nature of the traffic, and possible future extension. The length given to a dock depends upon the site, and the width is regulated by the size of the vessels using the dock. The depth depends upon the water-level at neap tides, depth of the approach, river, or channel, and the draught of the vessels that will frequent the dock. The deepening of a dock is a very expensive process, involving the consideration of the underpinning of all adjacent walls where their foundations are shallow. Hence the depth of a dock at the outset of its construction is of primary importance.

Dock Walls. Dock and quay walls form a very important feature in the construction of docks, as upon their design, the foundation, and the materials used, the total expenditure of a dock mainly depends. The object of dock and quay walls is not only to utilise the area of the dock, but also to enable vessels to lie alongside for loading and discharging, which they cannot do against a sloping bank unless it is piled out. Fender piles are introduced, and a coping that will bear the run of loose chains surmounting the quay wall. The foundations adopted for dock walls depend upon the nature of the soil to be built upon. In firm ground, the walls are generally built upon it direct, the excavations being increased in depth accordingly. If the ground is soft for some considerable depth below the intended level of foundation, other means have to be resorted to—namely, bearing piles, driven until they reach a hard stratum, the tops of the piles being connected by walings, and upon this staging the wall is built. If the ground is soft, a layer of concrete is put in between the piles and walings, and the wall is then built upon this continuous layer of concrete, which must be thick enough to distribute the pressure.

Pressure upon Dock Walls. Quay walls act as retaining walls, since they retain the earth at the back. The presence of the earth tends to overturn the wall by causing it to slide forward, or to turn on its outer edge. The pressure depends upon the nature of the soil and its condition, and is always increased by the presence of water at the back of the wall; also by the weight of cranes; and the effect of goods traffic on rails, if provided, must be duly considered.

The pressure varies with the depth, and may be provided for by increasing the width by means of steps from the top towards the bottom, the face of the wall being generally built on a batter. The width at the base is generally from one-third to half the height, according to circumstances. Counterforts are also built at certain intervals. A straight batter to a dock wall is preferable to a curved one, as it enables vessels to approach close to the wall. Its foundation is also easier to construct when a firm stratum is obtained. The ground is excavated vertically to a depth sufficient to secure the wall from being pushed forward, and the foundation, generally of concrete, is then put into position. The foundations are generally put in in short lengths, to reduce the cost of pumping and to avoid possible slips. The remaining concrete forming the wall is then carried up in layers, with proper precautions as regards the laying of one course over another.

Failures in dock walls are caused chiefly by slips of the ground at the back of the wall and by the pressure of the water behind at low water tending to push the wall forward. A concrete toe is generally built at the foot of a wall to add to the stability of the wall and to obviate the effect of scour. The coping of a dock wall is generally of granite, but special concrete is used in some of the new walls at Liverpool. Coping-stones are dowelled together, so that they may not be displaced by blows.

Foundations. While rock is the best material for foundations, it is sometimes treacherous, and beset with difficulties unless properly dealt with. In some cases the surface of the rock is irregular, but is easily dressed to the required level when the rock is not too hard to admit of this treatment; but when such a course cannot be adopted the rock may be roughly dressed and levelled to receive a course of face stones bedded in cement mortar. In the case of extreme unevenness of surface of the rock, mass concrete may be deposited from skips or bags, confined in position by boarding or bags of sand. Bags of concrete are sometimes used instead of mass concrete, but do not make such a satisfactory job.

It is often found expedient to bench the rock if it is inclined, and light charges of dynamite or other explosives are used to attain this result. Prior to building upon rock, all sand, gravel, or mud, together with all weed and other sea growth, must be removed to provide a clean surface for the adhesion of the superstructure. A small grab is suitable for such work, but if the surface of rock is too irregular, the work must be executed by divers.

Sand is an excellent foundation, being practically incompressible, but must on no account be allowed to escape from its natural position. In building breakwaters upon a sand foundation, rubble stone is deposited over the site and extended well seaward, forming a wide apron to protect the sand from scour. Sand may be found by boring to overlie some stable ground, when it can be removed by a sand pump and the firmer rock bed laid bare. Boxes filled with sand have been known to retain heavy weight resting on the sand without depression

until the sides of the boxes have received a shock, with the result that the sand has immediately sunk.

Mud foundations, if not of great thickness, should be removed to the more solid ground underneath. If depth of water permits, piles may be driven over the entire area to be occupied by the superstructure with proper cills and layers of planking. The mud should then be removed for a depth of 4 ft. or 5 ft. below the pile heads, and good concrete put in. Sheet piling along each side will increase the security against scour and undermining.

Gravel may be similarly treated, but is not so liable to sinkage as sand described above, while clay depends upon its character, whether hard and compact or soft and treacherous, like mud. Clay must be protected from scour.

In the case of foundations upon rubble, after a deposit of rubble a lime bed for the reception of blocks may be formed of small broken stone, which divers can pack and arrange to the required level. Sometimes the surface may be sealed by a layer of soft concrete in small bags.

Cylinder Foundations. Cylinder foundations are not economical if several cylinders have to be sunk together, hence it is better to make one cylinder sufficient for one girder of a bridge than to use two or four cylinders to support a platform suitable for a pier. They are usually adopted for foundations in deep water, required to be sunk to a considerable depth in the ground. Where rock has to be dealt with, cylinders can be used provided the rock is first levelled off by divers or other means to ensure a level bed being obtained for the cylinder. The cylindrical form is preferable to an oblong, square, or flat elliptical section in plan, as it best resists internal pressure and collapse, and is suitable for soils such as clay, which is likely to swell. Cylinders should not be sunk nearer together than 3 ft., and for considerable depths in sand not nearer than one-fourth to one-fifth of their diameter. One or two large cylinders used in preference to a number of smaller ones are liable to get out of the vertical in sinking. The thickness of metal generally used for cylinders ranges from 1 in. to 1¾ in. The cylinders should be cast in such length that vertical joint flanges are not required. The rings are usually cast in lengths of 9 ft. It is almost impossible to sink cylinders so that their tops are level, their subsidence under a load not being uniform or the strata perfectly horizontal. The top or making-up ring should not be cast until the test load has been removed from the cylinder. The cutting ring should have a chisel-pointed cutting edge, and its form should be suited to the material it has to penetrate. The cutting ring is best made of wrought iron because of its not being so liable to fracture from blows, and its more uniform strength. It should be well strutted and stayed to prevent deformation. The upper rings are best of cast iron, being cheaper, and they are more easily and quickly bolted together. If the cylinders have to be sunk to a considerable depth, the diameters should be sufficiently large to allow for any unavoidable deviation in sinking which may occur. The joints of cylinders may be caulked with iron-rust cement for half of the outer thickness of the rings, and the remaining space filled in with Portland cement. Cylinders are sometimes lined with tarred felt to allow for the expansion of the concrete in the hearting or filling, the freezing of water or unequal contraction, and expansion of iron and material used for filling in the cylinders.

Sinking Cylinders. A cylinder foundation should be weighted with a load equivalent to that which it will be called upon to sustain, and the equally distributed load on the hearting of the cylinder should remain for some days to ensure no future settlement.

Rocks are usually not loaded with more than 8 to 10 tons per sq. ft., according to the description of the rock; sandstone rock, if soft, 1½ to 1¾ tons per sq. ft.; soft clay, ¼ ton per sq. ft.; damp clay, 1½ to 2 tons per sq. ft.; loose sand, 2½ to 3 tons per sq. ft.; solid clay and firm sand, 4 tons per sq. ft.; blue clay, 5 to 8 tons per sq. ft.; soft chalk, 1 to 1½ tons per sq. ft.; hard chalk, 2½ to 4 tons per sq. ft.

The sinking of cylinders can also be executed by the Plenum, or compressed air method, though usually the cylinders are forced down by weight, the material in the interior being excavated by dredgers, grabs, or excavators, or the exterior may be excavated by divers, or the interior dredged till rock is reached, the bed being levelled by divers if necessary, and sufficient concrete deposited to keep back the water, and then the water pumped out of the cylinder. Cylinders can be sunk in loose soil, mud, silt, sand, and gravel, overlying impermeable stratum at a moderate depth, by the aid of pile staging erected around the site.

Cylinder Rings. A number of rings to reach, when sunk, a little above the water-level, being bolted together and caulked, are lowered into position by a travelling crane working on a stage. The loose soil being taken out by a grab dredger, fresh rings are added as the cylinder sinks until impermeable soil is reached. The water is then pumped out, and the excavation continued. Great care must be taken that the cylinder is perfectly vertical at the beginning of the sinking. The excavation should be carried out uniformly over the whole surface to ensure the cylinder sinking equally. Should two cylinders have to be sunk close to each other, or less than a diameter of a cylinder apart, they should be sunk alternately, not simultaneously, otherwise there is a tendency to draw towards one another. In lowering the water in a cylinder by pumping, blows frequently occur—that is, the soil will rush up from below, and possibly fill the cylinder.

Such blows also occur in sinking cylinders from the compressed air escaping under the cutting edge. They generally take place in loose, porous soils by changes in the water-level owing to great range of tide or wave action, but may be arrested by carefully lowering the air pressure so as not to endanger the lives of the men. In sinking cylinders, boulders varying in size are frequently encountered and often tilt the cylinder. They are often difficult to remove, requiring to be drawn into the cylinder, pushed outwards, split or drilled. As regards the kentledge required for sinking a cylinder, balks of timber are placed across the top of the cylinder and medium-sized stones packed upon them, or pig iron is usually employed. The weight must be adjusted so as to be distributed equally to ensure uniform sinking. Placing the kentledge on the top of the cylinder raises the centre of gravity, and the kentledge is often laid upon stages placed within the cylinder, thus reducing the tendency of the cylinder to tilt. The quantity of kentledge required depends upon the nature of the soil through which the cylinder has to be sunk, its size and depth in the ground. In calculating the kentledge required, when the compressed air system is employed the lifting power of the air pressure must be added. The hearting usually consists of Portland cement, concrete, brickwork or masonry.

In the compressed-air system of sinking cylinders the chief points to be considered are sufficient supply

of air for the expulsion of the water, and for the men in the working chamber, together with the provision of ready entrance and exit for the men, introduction of plant and materials, and discharge of material excavated.

Well Foundations. Upon the suitability of well foundations as an alternative to the use of cylinders, the following points have to be considered. The soil should be loose strata, not firmer than sand. The probability of debris and boulders and other obstructions, such as hard stratum, would render the employment of cylinders preferable, while in compact soil the sinking of a brick or concrete cylinder, on a curb, would be difficult, and an iron cylinder with a fine cutting edge would be preferable. The well system is economical in sand and silt, if the water is of moderate depth. Suitable plant and excavating apparatus must be used, if the depth is too great, by the employment of compressed air. Well foundations may consist of masonry, concrete, or brickwork, and the remarks on cylinder sinking are generally applicable to well sinking.

Borings. Borings should be taken to ascertain the nature of the soil to be excavated, and also the strata to be built upon. Ample borings should be taken upon the site, as the depth and thickness of the different strata vary considerably. Care should be taken in examining the materials taken from the boring tool and allowance made for the alteration in their consistency due to the action of boring. Trial pits are preferable, and afford more reliable information than borings, and should be used in preference to borings, when the question of water permits of their use. In a trial pit, the inclination or dip of a strata may be taken with the aid of a clinometer.

Cofferdams. A cofferdam is generally comprised of two rows of timber piles driven into the ground to a sufficient depth, the distance between the rows being 3 ft. to 5 ft., the intervening space being filled in with clay puddle. The clay should be carried down to as impermeable a stratum as possible. Horizontal walings are attached to the piles to prevent them yielding to the pressure of the clay puddle inside. Further support can be given by means of struts inside, and by a bank of approved earthwork or chalk against the inner fall. Cofferdams are used to keep back the water from the site of a proposed dock, to permit of the building of the walls. Temporary earthenwork dams, though cheaper in the first case, become costly in their removal owing to the large amount of material used, so that a cofferdam is deemed preferable [see also page 1402].

Pumping. The levels of the foundations of docks, walls, etc., are generally considerably lower than the ordinary water-level found in the ground, hence pumping is necessary when diving is not introduced to enable the excavation to be carried down to the required depth. Pumps should be sunk at the lowest point, and be in duplicate so as to meet all contingencies. As the lift frequently exceeds 30 ft., chain pumps and centrifugal pumps are employed. An experienced contractor can generally suggest to the engineer a reliable mode of procedure in such a case.

Dock Gates. A dock gate, when closed, is subjected to the direct water pressure on the gate itself, which increases with the depth and varies with the length, and produces a strain on the gate similar to that on a uniformly loaded girder. It also has to resist the pressure transmitted to the meeting-post by the other gate. This compressive strain acts in the direction of the length of the gate, and may be regarded as equal to half the water pressure on the gate multiplied by the tangent of half the angle at which the two gates are inclined when properly closed. The angle depends on the inclination of the faces of the sill, or the projection of the sill in proportion to the span, commonly called the *rise* of the gates. Gates are usually curved so as to form, when closed, a continuous circular arc, and acting as an arch sustaining horizontal normal pressures, the transverse strain disappears and the whole strain becomes converted into a compressive strain acting in the direction of the length of the gate, is the same on each horizontal section, and increases with the depth owing to the increased increment of water pressure. This strain is evidently equal to the pressure on a circuit of surface multiplied by the radius of curvature. The rise given to a gate affects considerably the compressive strain on the gates, the strain varying inversely as the rise. A small rise increases the strain on the gates, and the length of the gate is at the same time reduced. With a large rise, the reverse is the case.

Materials for Dock Gates. Dock gates are constructed of wood and iron, wooden gates being better able to resist shocks and possessing more elasticity. Wooden gates are composed of heelpost and meeting-post at each end, connected to a framework of horizontal ribs to which a sheeting of planks is fastened, forming the skin to the gate to retain the water. All joints are caulked to ensure the skin being watertight. Greenheart is the best wood for gates exposed to salt water.

Iron is better suited for large gates, but to resist corrosion it should be thoroughly painted at water-level and covered with black varnish below water-level. Iron gates are built with a double skin of plates connected to a framework of vertical and horizontal ribs made up of plates and angles and tees, with manholes to admit of access inside the gate. The exposed edges of all plates should be kept clean and free from mud deposit, as the mud aids corrosion. The heelpost, meeting-post and sill-piece are made of greenheart.

Forms of Dock Gates. There are various forms of dock gates—*straight* dock gates, meeting at an angle; *curved* gates, meeting at an angle, and, when closed, taking the form of a Gothic arch; and *segmental* gates, forming a circular arch when closed. The sill is generally made straight for any design; a straight proprietary sill-piece is fastened to the bottom of the curved gate. Sluices are made near to the bottom of the gates, and closed by sliding doors, raised or lowered by rods worked by a screw on the top of the gate. The heelpost is supported at the bottom on a steel pivot let into the heelpost stone, and turning upon it. At the top it is held by anchor bars built into the wall and also long tie-rods anchored in the back of the wall, thus allowing the gate to revolve. An additional support is given to the gates in the form of a roller near its outer end, the centre of the roller being fixed in the same vertical line as the intersection of the centre of gravity of the gate and the centre of the heelpost; in curved gates it falls outside the gate. The roller is made slightly conical for rolling along its curved path, and adjusted by means of a rod attached to the top of the gate to ensure its always bearing upon its path. Rollers are not necessary for small gates, and in iron gates are often dispensed with, a counterbalance weight of water ballast being placed in the gate near the heelpost to reduce the strain on the anchor straps. In very large and wide gates two roller paths

concentric with one another are provided to each gate. Gates may be opened and closed by chains attached to the gates and passing round drums turned by capstans or by hydraulic engines. Four separate chains are required, and they are attached more than halfway down the gate near the lower support of the roller to avoid straining the gate and to facilitate motion. Chain passages are constructed in the walls of the dock, with guide rollers for the chains. Hydraulic rams are also used, but when introduced are attached at a higher level, so that their actuating machinery may be above water-level.

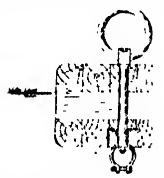
Single skin gates are not much used now. As gates are seldom opened except at or near high water, double-skin gates are more buoyant, and adapt themselves better to the usual requirements. In case of a fracture by a vessel running into a gate, there are two skins to break through instead of one, and the water in the dock is less liable to be lost in consequence. Double skin gates are in themselves heavier than single skin gates, and double-skin gates are liable to leakage and difficult to repair consequent upon the deposit of mud within them, besides their buoyancy under the influence of a difference of level between high and low water.

For greenheart gates, the difficulty is to obtain the material. At Liverpool they have the pick of all the best timber; but even there there is difficulty in obtaining enough for a large pair of gates.

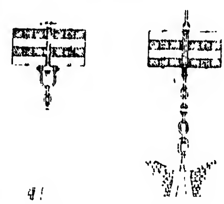
Caissons. There are two types of caissons—sliding and floating. The advantage of their adoption is to shorten the length of the entrance. They dispense with the hollow quoins. They facilitate maintenance and repairs, and when made to be capable of carrying a road or railway along their top they obviate the cost and inconvenience of a swing bridge across the entrance.

Sliding caissons are usually constructed rectangular in section, and are drawn backwards and forwards by hauling gear fixed at the inner end of the caisson chamber, the weight of the caisson on the sliding ways or rollers being adjusted by the amount of water admitted to the water chambers. The power applied may be steam, compressed air, electricity, or hydraulic power. A sliding caisson is found to effect a saving of time in adjustment and removal. Rolling caissons are of similar construction, and have rollers to the bottom of the caisson, or slide on rollers attached to the dock floor. A chamber is provided on one side of the walls of the dock to receive the caisson when not in use.

Floating caissons, termed "ship caissons," are built of plate-iron sides, with angles and tee stiffeners and diagonal braces. They are divided into several water-tight compartments and air chambers by means of the bulkheads. Flotation is provided by the air chamber, while others are ballasted. and so can be floated in and out of position. The width on the top depends on the nature of the road or footpath to be carried over. A recess is formed in the bottom of the dock to receive the keel of the caisson, and the projections on each side of the dock walls at the entrance for the caisson to press against. The caisson being required to close the dock entrance, is floated into its place against the side wall projections, and water is then admitted into the air chambers, causing the caisson to sink into the recess in the dock floor.



7. BUOY, ORDINARY PATTERN



8. MOVING BUOY

Graving Docks. An ordinary graving dock is a chamber of sufficient size and depth to receive the vessel that is required to be cleaned or repaired. For this purpose the vessel must be placed high and dry, and adequately supported. Graving docks are also called "dry docks." They communicate with a wet dock, or have access to deep water outside, and the entrance is closed by a pair of dock gates or by a caisson. The side walls are formed to the outline of a vessel, with steps or altars to receive the timber props supporting the vessel in an upright position. The keel of the ship to be examined or repaired rests upon keel blocks. Upon a vessel entering a graving dock at or near high water, the entrance is closed, and the water is allowed to run out by means of the sluices to the level of low water; the sluices are then closed, and the remaining water in the dock is pumped out. As the water lowers in the dock, the vessel is gradually propped up by timbers. The dimensions of graving docks vary according to the class of vessel to be provided for. Portsmouth graving dock has a length of 491½ ft., and is 110 ft. wide at the top, with a maximum depth of 42½ ft. Graving docks, being fixed structures, are lined with brickwork, concrete, or masonry; the facing to the walls being liable to rough usage, caused by the props used in supporting a vessel, are, where possible, protected by special recesses to receive such props.

Slipways. Slipways require a large space, but are less costly in construction and pumping than a graving dock. Vessels are liable to strains if any settlement in the foundations occurs. The vessel is deposited upon a cradle and hauled up the slipway by hydraulic or other power. The centre of the cradle sustains the weight, the bilge blocks merely serving to steady the vessel at the sides. A slipway provides better ventilation and light than a graving dock, but the cradle has to be specially adjusted to provide an even keel.

Floating Docks. The use of floating docks depends on the physical conditions of the site. In the United Kingdom there are comparatively few floating docks, because, owing to the rise and fall of the tide, graving docks are preferred when a site is free from springs. In non-tidal or only slightly tidal waters, such as those of the Baltic and the Mediterranean, floating docks are chiefly used.

The One-sided Depositing Dock. This has only one side wall, arranged to regulate the descent of the dock under water and to give stability fore and aft. Transverse stability is afforded by a floating outrigger attached to the dock by several pairs of hinged beams. So long as the outrigger keeps an even keel, the dock keeps a similar position. This type of dock is also capable of depositing vessels upon fixed stagings erected along the foreshore; the pontoon, instead of being continuous in construction, is composed of a number of short pontoons, with a space between them like a rake, which fits into another rake, formed by a stage. The shore stagings are thus constructed with the projections arranged so as to be capable of occupying the spaces left between the pontoons.

The One-sided "Off-shore" Dock. Instead of being controlled by means of a floating outrigger, this type of dock is provided with columns which are sunk in the foreshore, and the booms are

attached to them. In a combination of the "depositing" and "off-shore" types the pontoon is a continuous structure, and the booms are attached to the floating outrigger. The outrigger is used not only for stability, but to carry the boilers of the dock and small workshops.

It must not be forgotten that considerable depth of water is required for the installation of the floating dock. Dredging is often resorted to in obtaining a hole deep enough to receive the dock, but such a hole is apt to silt up and needs periodical re-dredging. A floating dock is further dependent upon the displacement of the vessel to be lifted not exceeding the dock's lifting capacity, whereas a vessel that can enter a graving dock can be docked irrespective of its weight. A sheltered position is also essential.

Groynes and Sea Walls. Groynes are used for the purpose of gathering the shingle and raising the beach of a fore-shore. They stay the littoral drifting action. Groynes themselves cannot be regarded as a protection, but are serviceable in the effect they produce on the beach. They do not creat fresh material, but rely on wasting cliffs, etc., to contribute fresh supplies, which they collect. Their formation has been discussed at length in the article beginning on page 5577, where also the construction of sea walls is considered.

Buoys. Buoys [7 and 8] are used for denoting positions in navigable channels. Their location is rendered serviceable by night as well as by day by charging them with compressed gas of a special kind which, as it issues forth, burns in a suitable apparatus, and cannot be extinguished by the waves. They are constructed of wrought iron and are of sufficient capacity for six weeks' illumination (burning night and day), and cost from £300 to £500 each, exclusive of moorings. The shore apparatus for making and compressing the gas costs £500 to £1,000, and storage tanks and buildings £500. Solid wooden buoys are liable to get waterlogged. Cask buoys are often used for mooring of vessels. Can buoys are used to locate the fairway of a channel. Bell buoys, or buoys with a hanging bell attached at the top, are useful at night or in foggy weather, the ringing of the bell being caused by the oscillation of the buoy; but light-giving buoys are the most satisfactory, the bell buoys having the disadvantage of limited range of sound in windy weather and absence of sound during calm weather.

Beacons. A wooden beacon may be formed with a wood pole well secured at its base in the ground or in a mound of stone, with a ball at the top. These beacons are used to indicate tides of a channel or estuary, and maintain their position during the rise and fall of the tide. In this way they are preferable to buoys, but buoys can be anchored where a beacon would not be available.

Iron beacons are usually constructed of iron tubes or of wrought-iron bars sunk into the ground or rock, rigidly braced together at the top of the beacon, and surmounted with a painted ball having distinguishing marks thereon in bold colours.

9. CAPSTAN

Capstans [9] are indispensable upon every commercial quay. They are sometimes worked by hand levers, sometimes by hydraulic power, and sometimes by electricity, which is now preferred to steam power for use upon a quay.

Lighthouses. Lighthouses serve to mark the sites of projecting headlands, entrances of harbours, and outlying rocks, also to indicate to a mariner the position of his course. Lighthouses are generally built conical in form, and constructed of stone or iron, with a lantern at the top. Stone is preferable to iron, as the former is not subject to corrosion. Lighthouses built on an isolated rock in the sea have the following serious difficulties to combat. The foundation of a lighthouse being below high-water level, or very little above low-water level, can be put in only during calm weather by the aid of divers, or executed as tide work. There is no shelter for workmen, and materials can be landed on the rock only as required. The approach to the rock is uncertain and at times dangerous. The distance of the depôt from the site is often considerable. The preparation of the foundations presents the greatest difficulties. Unsound rock must be removed and level benchings formed to receive the foundation courses, which are bolted or otherwise secured to the rock. The hardness of a rock upon which a lighthouse stands is of paramount importance in securing sufficient stability to the structure to be erected upon it. In stone towers the courses are dovetailed together both horizontally and vertically. The rate of progress depends upon the level of the rock and the exposure of the site, and is necessarily very slow at the beginning of the work. In lighthouses constructed sufficiently high to be out of the reach of the waves, store-rooms and dwellings for the lighthouse keepers are provided. Constant care and supervision is needed to maintain the efficiency of a lighthouse and its lantern. Oil, gas, and the electric ligh are used as illuminants, but of these three the first-named is preferred. Electric light possesses great intensity, but is reckoned to be inferior to the other lights in foggy weather. The distinction in character of the respective lights is made by a definite number of flashes in quick succession, following a certain period of obscuration, which enables the mariners to recognise any particular light.

In foggy weather signals are made by ringing a bell, or blowing a horn or trumpet and steam syrens. A similar arrangement of combinations of sounds can be made as above, worked from a lighthouse.

Screw Pile Lighthouses. This form of construction is adopted on sandbanks where the foundation is unsuitable for a more solid base. Such construction presents little obstruction to the waves, but requires protection from drifting ice.

Lightships are moored in different positions to serve as a warning to vessels of dangerous shoals, where lighthouses would either be impossible to build or too costly for the required purpose.

HARBOURS AND DOCKS *concluded; followed by* CIVIL ENGINEERING ABROAD

continued from page 6374

COMPOUND ANGLES

Ratios of 15° and 75°. Formulæ for Sum and Difference of Two Sines or Cosines. Multiple Angles. Logarithms

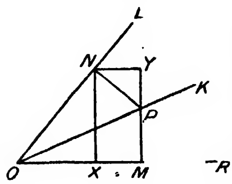
By HERBERT J. ALLPORT, M.A.

22. *Continued.* To prove that

$\sin (A - B) = \sin A . \cos B - \cos A . \sin B$

and

$\cos (A - B) = \cos A . \cos B + \sin A . \sin B.$



Let ROL be the angle A, and LOK the angle B. Then ROK is the angle (A − B). Making the same construction as before, we have ∠s PMO, PNO right ∠s. ∴ a ⊙ on OP as diameter passes through M and N. Hence ∠YPN is the supplement of ∠NPM, and ∴ is equal to ∠MON (*Prop.* 41), *i.e.*, to ∠A. Then

$$\sin (A - B) = \frac{MP}{OP} = \frac{XN - PY}{OP} = \frac{XN}{OP} - \frac{PY}{OP}$$

$$= \frac{XN}{ON} \cdot \frac{ON}{OP} - \frac{PY}{PN} \cdot \frac{PN}{OP}$$

$$= \sin ROL . \cos LOK - \cos YPN . \sin LOK$$

$$= \sin A . \cos B - \cos A . \sin B.$$

Again,

$$\cos (A - B) = \frac{OM}{OP} = \frac{OX + NY}{OP} = \frac{OX}{OP} + \frac{NY}{OP}$$

$$= \frac{OX}{ON} \cdot \frac{ON}{OP} + \frac{NY}{PN} \cdot \frac{PN}{OP}$$

$$= \cos ROL . \cos LOK + \sin YPN . \sin LOK$$

$$= \cos A . \cos B + \sin A . \sin B.$$

In the above proofs we have only considered the cases in which the ∠s A, B and (A + B) are each less than a right angle. It is left as an exercise to the student to draw the figures and modify the proofs for other values of the angles.

23. Ratios of 15° and 75°. The results of the last article enable us to find the ratios of 15° and 75°.

Example. Find the value of tan 75°.

$$\tan 75^\circ = \tan (45^\circ + 30^\circ) = \frac{\sin (45^\circ + 30^\circ)}{\cos (45^\circ + 30^\circ)}$$

$$= \frac{\sin 45^\circ \cos 30^\circ + \cos 45^\circ . \sin 30^\circ}{\cos 45^\circ \cos 30^\circ - \sin 45^\circ \sin 30^\circ}$$

$$= \frac{\cos 30^\circ + \sin 30^\circ}{\cos 30^\circ - \sin 30^\circ}$$

[Cancelling numerator and denominator by $\frac{1}{\sqrt{2}}$, which is the value of both sin 45° and cos 45°]

$$= \frac{\frac{\sqrt{3}}{2} + \frac{1}{2}}{\frac{\sqrt{3}}{2} - \frac{1}{2}} = \frac{\sqrt{3}+1}{\sqrt{3}-1} = \frac{(\sqrt{3}+1)^2}{3-1} = \frac{4+2\sqrt{3}}{2}$$

$$= 2 + \sqrt{3}.$$

The other ratios of 75° can be found in a similar way. In the case of 15°, we use the fact that 15° = 45° − 30°.

24. Formulæ for tan (A ± B). We have

$$\tan (A+B) = \frac{\sin (A+B)}{\cos (A+B)} = \frac{\sin A \cos B + \cos A \sin B}{\cos A \cos B - \sin A \sin B}$$

$$= \frac{\dfrac{\sin A . \cos B}{\cos A . \cos B} + \dfrac{\cos A . \sin B}{\cos A . \cos B}}{\dfrac{\cos A . \cos B}{\cos A . \cos B} - \dfrac{\sin A . \sin B}{\cos A . \cos B}}$$

$$= \frac{\tan A + \tan B}{1 - \tan A . \tan B}.$$

Similarly, we get

$$\tan (A - B) = \frac{\tan A - \tan B}{1 + \tan A . \tan B}.$$

By the same method the student can prove that

$$\cot (A + B) = \frac{\cot A . \cot B - 1}{\cot A + \cot B},$$

and

$$\cot (A - B) = \frac{\cot A . \cot B + 1}{\cot B - \cot A}.$$

25. The "S, T" Formulæ. We have already proved that

$$\sin (A + B) = \sin A . \cos B + \cos A . \sin B,$$
$$\sin (A - B) = \sin A . \cos B - \cos A . \sin B,$$
$$\cos (A + B) = \cos A . \cos B - \sin A . \sin B,$$
$$\cos (A - B) = \cos A . \cos B + \sin A . \sin B.$$

By adding and subtracting the first pair of results we get

$$\left.\begin{aligned} \sin (A+B) + \sin (A-B) &= 2 \sin A . \cos B \\ \sin (A+B) - \sin (A-B) &= 2 \cos A . \sin B \end{aligned}\right\} \quad . \quad . \quad (1)$$

Similarly, from the second pair we get

$$\left.\begin{aligned} \cos (A+B) + \cos (A-B) &= 2 \cos A . \cos B \\ \cos (A-B) - \cos (A+B) &= 2 \sin A . \sin B \end{aligned}\right\} \quad . \quad . \quad (2)$$

Let A + B = S, and A − B = T. By solving these equations we find $A = \frac{S+T}{2}$ and $B = \frac{S-T}{2}$.

Substitute these values of A and B in (1) and (2). Then

$$\sin S + \sin T = 2 \sin \frac{S+T}{2} . \cos \frac{S-T}{2},$$

$$\sin S - \sin T = 2 \cos \frac{S+T}{2} . \sin \frac{S-T}{2},$$

$$\cos S + \cos T = 2 \cos \frac{S+T}{2} . \cos \frac{S-T}{2},$$

$$\cos T - \cos S = 2 \sin \frac{S+T}{2} . \sin \frac{S-T}{2}.$$

These results should be remembered *in words*, thus

(i.) *The sum of the sines of two angles equals twice the sine of half their sum, times the cosine of half their difference.*

(ii.) *The difference of the sines of two angles equals twice the cosine of half their sum, times the sine of half their difference.*

(iii.) *The sum of the cosines of two angles equals twice the cosine of half their sum, times the cosine of half their difference.*

(iv.) *The difference of the cosines of two angles* [the cosine of the *less*, minus the cosine of the *greater*] *equals twice the sine of half their sum, times the sine of half their difference.*

The student must also be able to make a ready use of the results (1) and (2); *i.e.*, he must remember that the product of a sine and cosine can be expressed as the sum of two sines, and so on.

EXAMPLE.

3A A

$$= \frac{1}{2}\left\{\cos\left(\frac{3A}{2}+\frac{A}{2}\right)+\cos\left(\frac{3A}{2}-\frac{A}{2}\right)\right\}$$

$$= \frac{1}{2}\{\cos 2A + \cos A\}.$$

26. Trigonometrical Ratios of Multiple Angles.

By putting B = A in the formula

$$\sin(A+B) = \sin A \,.\, \cos B + \cos A \,.\, \sin B,$$

we get

$$\sin(A+A) = \sin A \,.\, \cos A + \cos A \,.\, \sin A$$

i.e., $\sin 2A = 2 \sin A \,.\, \cos A \quad . \quad . \quad . \quad . \quad (1)$

Again, from

$$\cos(A+B) = \cos A \,.\, \cos B - \sin A \,.\, \sin B,$$

we get

$$\cos(A+A) = \cos A \,.\, \cos A - \sin A \,.\, \sin A;$$

i.e., $\cos 2A = \cos^2 A - \sin^2 A. \quad . \quad . \quad . \quad .$

Since $1 = \cos^2 A + \sin^2 A$,

it follows that

$$1 + \cos 2A = 2\cos^2 A$$

and $1 - \cos 2A = 2 \sin^2 A$,

or
$$\left.\begin{aligned}\cos 2A &= 2\cos^2 A - 1\\ \cos 2A &= 1 - 2\sin^2 A\end{aligned}\right\}. \qquad (3)$$

Also, from

$$\tan(A+B) = \frac{\tan A + \tan B}{1 - \tan A \,.\, \tan B},$$

we get

$$\tan(A+A) = \frac{\tan A + \tan A}{1 - \tan A \,.\, \tan A};$$

$$\tan 2A = \frac{2\tan A}{1-\tan^2 A}. \quad . \quad . \qquad (4)$$

These four formulæ are important, and must be remembered. They are, of course, true for *all* values of A, so that it is just as useful to know the results obtained by putting A instead of 2A. Thus we have $\sin A = 2 \sin \frac{A}{2} \,.\, \cos \frac{A}{2}$, and so on.

27. Sin 3A in terms of sin A.

Sin 3A

$= \sin(2A + A)$

$= \sin 2A \,.\, \cos A + \cos 2A \,.\, \sin A$

$= (2 \sin A \,.\, \cos A) \,.\, \cos A + (1 - 2\sin^2 A) \,.\, \sin A$

$= 2 \sin A \,.\, \cos^2 A + \sin A - 2\sin^3 A$

$= 2 \sin A \,.\, (1 - \sin^2 A) + \sin A - 2 \sin^3 A$

$= 2 \sin A - 2 \sin^3 A + \sin A - 2 \sin^3 A$

$= 3 \sin A - 4 \sin^3 A.$

In a similar way we obtain

$$\cos 3A = 4\cos^3 A - 3 \cos A.$$

LOGARITHMS

28. By algebra we know that

(i.) The index of the *product* of two powers of the same quantity is obtained by *adding* the indices of the powers.

(ii.) The index of a *quotient* is obtained by *subtracting* the indices of the powers.

(iii.) The index of a *power* or a *root* is obtained by *multiplying* or *dividing* the indices.

These facts are made use of to shorten arithmetical calculations. A power of the number 10 can be found which is practically equal to any given number. For example, 2 is approximately $10^{\cdot 30103}$. The number 10 thus used is called the *base*; the index ·30103 is called the *logarithm* of 2 to the base 10. Hence,

DEFINITION. The *logarithm* of a number to a given base is the *index* of the power of the base which is equal to the given number.

Logarithms to the base 10 are, in general, incommensurable numbers. They have been calculated to seven significant figures, for all numbers from 1 to 100,000.

$\text{Log}_{10} 2 = \cdot 30103$, and $10^{\cdot 30103} = 2$, are different ways of stating the same fact.

29. From the index laws of Algebra we have

(i.) The logarithm of the *product* of two numbers is equal to the *sum* of the logarithms of the numbers.

(ii.) The logarithm of the *quotient* of two numbers is the logarithm of the dividend *minus* the logarithm of the divisor.

(iii.) The logarithm of a number raised to the *power p* is *p times* the logarithm of the number.

30. Since $10^0 = 1$, *the logarithm of* 1 *is* 0. Also, since $10 = 10^1$ and $100 = 10^2$, the logarithm of a number between 1 and 10 lies between 0 and 1, and that of a number between 10 and 100 lies between 1 and 2, and so on. Thus, *the logarithm of a number greater than* 1 *is positive.*

Again, $\quad \cdot 1 = \frac{1}{10} = 10^{-}$

$\qquad \cdot 01 = \frac{1}{100} = 10^{-}$

and so on, so that *the logarithm of a positive number less than* 1 *is negative.*

It is clear that the logarithm of a number between 1 and 10 is a positive decimal fraction: the logarithm of a number between 10 and 100 is equal to 1 + a decimal fraction, and so on.

Also, the logarithm of a number between 1 and ·1, *i.e.*, between 10^0 and 10^{-1}, lies between 0 and −1, and is therefore a negative decimal fraction. This *is equivalent to* −1 + *a positive decimal fraction.* Similarly, we see that the logarithm of a number between ·1 and ·01 can be written in the form −2 + a positive decimal.

DYEING MIXTURES

How Wool, Silk and Cotton are Dyed Together. Wonderful Colour Effects by Simple Methods

Continued from page 6372

By HERBERT ROBSON

WHEN the dyer has to deal with a mixture of animal and vegetable fibres in a fabric it is obvious that he has a more difficult problem to face than when he has simply to dye cloth woven solely of wool, cotton, or silk. In the days when the natural colours reigned alone it was necessary, generally speaking, even when a mixed fabric, say, of wool and cotton, was to be dyed a self-colour, to dye the weft and the warp separately before weaving. The general employment of the artificial dyestuffs, and especially the advent of the direct cotton colours, has changed all this. The dyer can dye a mixed fabric a single colour in one or more baths, or he can dye one fibre alone in the fabric, leaving the other white, or even, treating the cloth in a single bath, he can make the different fibres take up different colours. In short, he can ring the changes in a variety of ways, producing a vast variety of effects, the most important of which will be touched upon. This facility has naturally had a strong influence upon the manufacture of mixed fabrics; they are now woven in infinite variety and in ever-increasing quantities.

Mixed Effects. It is evident also that by taking advantage of the varied properties of the different dyestuffs, and of the action of certain chemicals upon the textile fibres, the dyer can produce mixed effects upon a fabric composed of whole wool, cotton, or silk. What lies in his power in this way would, in itself, furnish matter for a long treatise, but a few examples must suffice. It is obvious that if, say, the warp is mordanted before weaving and the weft is left unmordanted, then, on dyeing with a mordant colour, the warp alone will take up colour. If a suitable direct colour be added to the bath the fibres will be dyed in different shades. If, in the case of wool, part of the cloth is chlorinated, that part will take a darker shade than the rest, and the same effect is obtained on cotton by taking advantage of the effect of caustic soda upon the fibre. For instance, if the fabric is "slop-padded" —that is, treated on one side only with lye—that side will take up more colour out of the bath than the other. The intelligent student of this course will readily gather the infinite possibilities of variety in the light of these examples.

Again, in dyeing with yarn or cloth, merely mechanical contrivances can be brought into use to the same end. Portions of the yarn can be protected mechanically against the action of the dye-bath; to take a simple example, the hank or warp can be tied in tight knots at determined intervals. Cloth may be dyed in a tilted bath or passed unevenly through the dye liquor, or may be raised slowly out of a dye-bath, the composition of which is gradually changed.

Chemical resists and discharges are also employed to obtain a variety of effects, but these are used mainly by the textile printer.

Preparation for Dyeing. Union goods must be well scoured before dyeing and thoroughly wetted out. For dark shades they are sometimes entered dry into the dye-bath. In the case of thin cloths especially, they must be crabbed [see page 6198] and steamed to prevent "cockling"—that is to say, a shrivelled-up appearance of the cloth caused by the woollen shrinking in the dye-bath. Crabbing machines are sometimes provided with a hollow, perforated roller through which steam can be admitted, but the decatising machine, used also in finishing, is often employed. After thorough crabbing and steaming, the cloth is "set" and it is scoured in the usual manner. The simplest way seems to give the best results, and that is to add the scouring agent to the water in the crabbing machine, and to follow this by steaming the cloth.

Dyeing Mixed Goods. Broadly speaking, the dyeing of wool and cotton mixture cloths is simple. The goods may be treated in a bath of an acid colour and this goes on the wool only. If the cotton is slightly tinted, all that is necessary is to rinse well before dyeing the cotton. A simpler way still is to dye in a single bath with a direct cotton colour alone, or combined with a wool colour. In practice, however, trade requirements necessitate the use of a variety of methods that are not quite so simple. As regards their behaviour to wool and cotton, the dyestuffs may be divided into five groups, and these will suggest the variety of effects that may be obtained on union cloth.

1. Colours which dye wool and cotton equally, or nearly so.
2. Colours which dye the two fibres different hues.
3. Colours which dye wool a deeper shade than cotton.
4. Colours which dye cotton a deeper shade than wool.
5. Colours which dye wool alone.

The direct cotton colours can be categoried in the first four groups, and there are a number of wool colours which leave the cotton threads perfectly white when dyed in an acid bath. Some of the colours in group 4 leave the wool almost untouched.

The customary methods of dyeing may be grouped as follows.

One-bath Process. The goods are dyed with direct cotton alone or in combination with wool colours. This method is so simple that it has largely superseded other methods of dyeing. Colours may be chosen which dye the two fibres a solid shade, the wool deeper than the cotton, the cotton deeper than the wool, or dye the two fibres different hues. It is impossible to find space to enumerate all the direct colours suitable for these effects, and a few examples will be given from the diamine and dianil ranges.

(*a*) Colours dyeing wool and cotton alike:

Thioflavine S, Oxydiamine Yellow GG, Diamine Orange F, Diamine Rose GD and BD, Oxydiamine Red S, Diamine Red in several brands, Diamine Fast Red F, Diamine Brilliant Blue G, Diamine Green G, Union Black and Oxydiamine Black in a variety of brands, Dianil Yellow 3G, R and RR, Aurophenine O, Dianil Orange N, Dianil Red R, 4B 10B, Dianil Claret Red G, Delta Purpurine 5B, Dianil Blue BX, Dianil Indigo O, Dianil Black

N, E, Dianil Brown 3GO, 3R, and Dianil Copper Brown O.

(*b*) Colours which dye the two fibres different hues:

Diamine Brown VS, Diamine Nitrazol Brown B, Diamine Blue BX, Diamine Blue 3R, Dianil Brown 5G, Dianil Japonine G, Dianil Blue E, ET, and Dianil Black in several brands.

(*c*) Colours which dye wool a deeper shade than cotton:

Diamine Gold, Diamine Scarlet B, 3B, Diamine Bordeaux S, Diaminogene Extra, Dianil Yellow G, Cresotine Yellow G, Toluylene Orange R, Dianil Scarlet G and 2R, Brilliant Dianil Red, Dianil Black T, and Dianil Green G.

(*d*) Colours which dye cotton a deeper shade than wool:

Diamine Fast Yellow A, Diamine Orange G, D, Diamine Nitrazol Brown G, Diamine Catechine F, Diamine Sky Blue, Diamine Blue 2B, 3B, BG, Diamine New Blue R, Diamine Black BH, Diamine Dark Blue B, Diamine Bordeaux B, Diamine Violet N, B, Dianil Orange G, Dianil Brown in several brands, Dianil Fast Brown B, Dianil Blue in several brands, Dianil dark Blue R, 3B, Dianil Black in several brands and Dianil New Black.

If a wool colour is used for shading it must be capable of going on to the wool in a neutral salt bath.

The dye-bath is simply prepared with the required amount of dyestuff, usually from ½ per cent. for light shades to 2 per cent. for full shades, and from 30 per cent. to 50 per cent. of Glauber's salt. The material is entered at about 120° F., and the temperature is gradually raised to about 200° F. if a self-colour is required. As a rule, the wool will take more colour than the cotton if the temperature is raised to the boil. The dyer, therefore, must watch his goods and raise or lower the heat according to requirements.

It is always better to work for a lighter shade than the pattern, as it is always easier to add colour than to take it away. When the cotton is dyed to pattern, the colour to shade the wool is added if this is requisite. The addition of a little borax to the bath will cause the wool to take up less colour.

Ordinary Two-bath Processes. In this method the wool is dyed in the ordinary way with acid colour, and then the cotton with a direct cotton colour. The cotton, if required, may be topped with a basic colour. This process is best for producing "shot" or "changeant" effects—that is to say, the eye catches different colours on the fabric according to the direction the light strikes it. Some examples may be given.

Wool crimson, cotton green. Dye the wool with 3½ per cent. Naphthol Red C, 10 per cent. Glauber's salt, and 2 per cent. sulphuric acid; the cotton with 2¼ per cent. Diamine Sky Blue FF, 1¼ per cent. Thioflavine S, and 10 per cent. Glauber's salt.

Wool blue, cotton brown. Dye in a bath at 150° F., with 3 per cent. Diamine Orange G, 0·81 per cent. Naphthol Blue G, 0·91 per cent. Formyl Violet S4B, and 20 per cent. Glauber's salt.

Wool violet, cotton yellow. Dye the wool with 1½ per cent. Acid Violet 6B, 10 per cent. Glauber's salt, and 1 per cent. sulphuric acid; then dye the cotton with 3 per cent. Mikado Golden Yellow 8G, and 10 per cent. salt.

Wool green, cotton red. Dye the wool with 3 per cent. Guinea Green B, 0·25 per cent. Curcumine extra, 10 per cent. Glauber's salt, and 2 per cent. sulphuric acid. The cotton is dyed with 1½ per cent. Mikado Orange 4RO, 0·75 per cent. Erika 2GN, and 20 per cent. Glauber's salt.

Wool claret, cotton black. Dye the cotton first with 5 per cent. Diamine Black BH, diazotising and developing with phenylene-diamine in the usual way; then dye the wool in a fresh bath with 1 per cent. Brilliant Cochineal 2R, 1 per cent. Brilliant Cochineal 4R, and 10 per cent. bisulphate of soda working at the boil.

Wool olive green, cotton dull lilac. Dye the wool with 2½ per cent. Naphthol Green B, 0·5 per cent. Orange GG, and 10 per cent. bisulphate of soda working at the boil. The cotton is dyed in a bath which contains 1 per cent. Diamine Violet N, 0·25 per cent. Diamine Sky Blue, 20 per cent. Glauber's salt, and 3 per cent. soda working at a low heat.

Cross Dyeing. In the method known as cross dyeing the cotton warp is dyed before weaving, and the woollen or worsted weft is dyed in the piece. For instance, the cotton warp is dyed with Cross Dye Black 4B, the piece is woven up with the woollen weft thrown over the face, crabbed, steamed, and singed, and the woollen is then dyed with Acid Violet F or Disulphine Blue in a bath of Glauber's salt and sulphuric acid. Cross Dye Black and Cross Dye Drab are sulphur colours very suitable for this class of work, as they are very fast to acids and boiling water. The Acid Violet F and Disulphine Blue are used in extremely small proportions, say, 1½ oz. to 100 lb. weight of the goods, and the result is a bright-faced material which could be obtained in no other way. Cross-dyed goods have a softer handle than those dyed wholly in the piece.

Mordant Colours. The wool may be dyed with an acid colour, the cotton mordanted and dyed with a basic, or the cotton may be mordanted, and the piece may be dyed with a basic colour.

Cotton or ramie effect threads. A very popular style of dress material is made with a white cotton or ramie "effect" thread running through the goods, and showing on the face of the material in lines, stripes, dots or figures. Bleached or bleached and mercerised cotton must be used, as these goods are always dyed in the piece; the wool colours which will not even tint the cotton are alone admissible. As a rule, the acid and the chrome developing dyes are most suitable. A few examples will suffice.

Mode Shade with White Cotton Effect. Mordant for 1½ hours at the boil with 4 per cent. bichromate of potash, and 3½ per cent. tartaric acid. Rinse and dye in a fresh bath with 1½ per cent. Anthracene Chrome Blue B, ½ per cent. Brilliant Milling Blue B, 2 per cent. acetic acid. Enter at 120° F., raise to the boil in half an hour, and boil for one hour. Then add 3 per cent. acetic acid, and boil for another hour.

Black with white cotton effect. Prepare the dye-bath with 6 per cent. Carbon Black BD. 20 per cent. Glauber's salt, 3 per cent. acetic acid Enter at about 130° F., raise to the boil, boil for half an hour, then add 2 per cent. sulphuric acid, and boil until the bath is exhausted.

Black with white cotton effect. Prepare the dye bath with 6 per cent. Cashmere Acid Black MC or MCS, 20 per cent. Glauber's salt, 5 per cent sulphuric acid. Run the cloth in lukewarm, raise to the boil in half an hour, and dye at the boil for another half hour.

Dyeing shoddy. Union goods are sometimes woven from "shoddy"—that is to say, soft woollen rags worked up for re-manufacture. This generally contains "burls"—that is, cotton twisted into hard lumps in the shredding process. These

cloths are usually dyed in dark colours—for instance, a logwood black on a tannin and iron mordant. Sometimes, however, the colours are stripped with sulphuric acid or other agents, and the goods are dyed in the same manner as other unions. For lighter shades, the burls are sometimes picked out with burling irons.

Half-silk. Hummel in his manual, published in 1895, dismissed wool and silk, and cotton and silk (half silk) mixtures as of little interest, but lately they have come more and more into vogue, and are now of high importance. Half-silk goods, broadly speaking, are treated like unions, but with greater precautions as silk is more difficult to handle than wool.

Preparations for Dyeing. The goods are first singed, which must be done on the gassing machine, and as silk is more inflammable even than cotton, great care is needed. The goods are then scoured and rinsed in very soft water. A five-hole washing machine is suitable for this operation. The first scouring bath is made with good olive oil soap or white curd soap. For 100 lb. of half silk, about 40 lb. of soap is used, but for a second batch of 100 lb. of goods the addition of about 20 lb. of soap is sufficient. The bath should not be used for more than three batches, as an old bath will give the goods an unpleasant odour. The second hole is filled with soap solution made with 10 lb. of soap, and little addition is needed for subsequent batches. The next hole is a weak bath of soda to remove most of the soap. The fourth is water slightly soured with sulphuric acid, and the fifth is water alone in which a thorough rinsing is given to remove the acid. Only heavy goods require crabbing and steaming. If it is required to bleach the material this is done with sodium or oxygen peroxide.

Dyeing Half-silk. The colouring matters may be grouped in the same way as those for wool and cotton, with the exception that the last group is eliminated. In fact, the treatment of the two descriptions of mixture cloths only differ in so far as the physical properties of the fibre interwoven with the cotton are different. In dyeing half-silk, very little Glauber's salt must be used, and none at all for light shades, as the salt injures the lustre of the silk. The half-silk bath must be more alkaline than is requred for half-wool, and this secured by adding soap and carbonate or phosphate of soda. Soap is of great assistance in preserving the lustre of the silk.

In the one-bath process the half-silk is entered into the lukewarm dye-bath, which is then gradually brought to rather under the boil, at which temperature it is kept for about an hour. For light shades the bath contains soap, soda, or soap and phosphate of soda. For dark shades a little common salt is also added.

The cotton is allowed to dye in the cooling bath, and if the silk is to be darker the bath must be less alkaline. If, as happens with many dyes, the silk does not get sufficiently dyed, it must be topped with acid or basic dyes in a fresh bath with from 3 to 6 per cent. of acetic acid, cold for basic dyes, lukewarm for acid dyes. For getting two-colour effects (*changeants*), both wool and silk can be dyed together in some cases. For example, either Alkali Blue or Direct Yellow is dyed in one bath, followed by a rinsing and souring. The more usual practice, however, is to use dyes which leave the silk white, and then to dye the silk in a fresh bath with an acid dye of a colour contrasting with the cotton. Another method is first to dye the silk with dyes which leave the cotton white, and then to dye the cotton with a basic dye on a tannin antimony mordant. To load the silk the fabric is often put through a stannic chloride bath of 22° Tw. between mordanting and dyeing.

The tannin method is now used only in cases when greater purity and warmth of shade is demanded than can be got with a substantive dye. The general method of dyeing the silk as well as mordanting and after-dyeing the cotton is the same as for unmixed fabrics, except that, as in dyeing half-wool in more than one bath, it must be remembered that the after dyeing of the cotton always injures the shade more or less. The following are two illustrative recipes.

Magenta on Half-silk. Make a bath with 2 per cent. Fuchsine S. Enter lukewarm, and gradually heat up to 190° F., adding acetic acid to exhaust the bath. Finally boil the bath up, lift, rinse, mordant the cotton in a cold tannin bath with about 8 per cent. of tannin, and soured with a little hydrochloric acid, give a slight rinse, pass through a cold tartar emetic bath, rinse thoroughly, and finally dye in a cold acetic bath with 0·75 per cent. of Diamond Fuchsine I in needles. Finally rinse and centrifuge.

Shot Effect (Green and Red) on Half-silk. Dye the silk as above with Quinoline Yellow and Light Green SF yellowish. Mordant as above, and dye the cotton in a cold acetic acid bath with Safranine XX, and Auramine II, rinse and wring.

If the cotton dye goes too much on to the silk the mordanting was not done cold enough, or the goods were insufficiently rinsed after mordanting, or were not dyed cold enough, or there was not enough acid in the dye-bath. If the tannin bath is too weak the cotton will come out too light. There must be not only the proper total amount of tannin, but the solution must not be too weak—that is, the bath must not be too long. If a bronzy appearance is seen on the silk the water used has not been properly softened, or the soap was not rinsed out properly before dyeing, or too much dye was used.

Wool and Silk. A very great variety of fabrics composed of a mixture of wool and silk are on the market. The warp and weft are woven in a large variety of ways, and the difference of affinity and receptivity for dyes is taken advantage of by the dyer to produce many charming effects which have caused wool-silk fabrics to be always in request. A very ordinary form is a smooth fabric with silk warp and wool weft, but the warp or weft is sometimes thrown out on the face of the fabric in pattern.

Poplin, a dress fabric for which Ireland is famous, *Gloria*, largely used for umbrella and sunshade cloth, and *Henrietta* are famous examples of wool-silk mixtures. This last is a light weight dress fabric sometimes made from single worsted yarn, but in the best qualities with silk mixtures. On the other hand, in low qualities, cotton warp is substituted for the silk.

Before the advent of the artificial dyestuffs, even when a self-coloured fabric was required, it was necessary to dye the warp and weft of a wool-silk fabric separately, and when a shot effect was desired it was secured by a twill weave in the fabric, and by using two already dyed fibres of different colours. Before the advent of the direct cotton colours combinations of acid and

basic dyes were used, but now the dyer can treat the wool-silk fabric in a single bath, even to produce a shot effect.

Preparing the Fabric for Dyeing. The bleaching and other preliminary operations differ little from the procedure adopted for pure wool, with the exception that the lustre of the silk must not be spoiled. In some dye-houses the material is wrapped round a roller and soaked for about ten minutes between rollers in warm soap solution. The stuff is then re-wrapped and left so for half an hour. With very hard yarns the soaping is done on a full-width washing machine. Bleaching is done with peroxide of sodium or hydrogen, with or without a subsequent sulphuring. After sulphuring, careful bluing is necessary to get a bluish-white. With this end in view, the goods are thoroughly rinsed the moment they leave the sulphur chamber, and given a bath containing a trace of acid violet and some acetic acid, in which they remain ten minutes at the most. With a strongish bath, or after a longer time, the silk will become distinctly bluer than the wool, and the appearance will be ruined. It is of great advantage to be able to dye the piece, whether for a self colour or for a shot effect, in a single bath. Then all the grease and dirt which have become attached to it during spinning and weaving can be removed before dyeing, leaving the fabric in a perfectly clean condition. Thus no after-cleansing is required, whereas when the fibres are dyed in the yarn the goods must be cleansed after weaving to free them from dirt, and this has a deleterious effect upon the brilliancy of the colour of the finished fabric, more especially in the case of light colours.

Dyeing Self Colours. Half-wool is ordinarily dyed in the vat, but pale shades, the most difficult to get uniform, are dyed with a hand winch. It is a good plan to line the vat with calico to prevent rubbing the material on the wood, which causes streaks.

The acid dyes are ordinarily used in a simple bath with Glauber's salt and sulphuric acid. In dyeing self colours the dyestuffs may be conveniently put into two classes.

1. Those going on silk and wool equally from a boiling acid bath. A slight difference of the shade is sometimes of little importance, and at others it is aimed at to obtain a pleasing effect.
2. Those going on wool deeper than silk.

This is corrected for self colours by topping the silk with a basic dye.

The acidity of the bath and its temperature have a great effect upon the evenness of colour. The more acid the bath the more dye goes on the wool. The exact procedure varies, and no hard and fast rules can be laid down. If, however, the silk is not sufficiently dyed or differs in shade from the wool it is a good plan to leave the goods in the cooling-bath for half an hour. If more dye is added during the cooling, most of it will go on to the silk. If this does not effect the purpose, the silk can be shaded in a fresh cold or lukewarm bath with basic dye and acetic acid. The basic dye should not be added to the cooling-bath, as it will be liable to rub off. With the view of obtaining bright colours it is of great importance to dye as far as possible in old baths. Independently of the saving in time and of Glauber's salt and sulphuric acid, fresh baths never give such lively hues as standing ones, especially if the water used is not quite faultless. The saving in time is important, for every second the boiling lasts beyond what is necessary, the duller the final shade. Pink, for example, must never be boiled for more than half an hour, and hence skill is required in shading.

Pink is largely dyed with Acid Rhodamine IR and 3R in a boiling bath with from 4 per cent. to 8 per cent. of tartar preparation, according to shade. This dye, however, dyes silk much deeper than wool, so that it is mixed with Chromotrope 2R for light pink, and with Fuchsine S for bluish pink. The combined dyes can be made to give a yellowish pink by adding Orange II, which dyes wool and silk nearly the same. For pale blue, Alkali Blue is very good. It is dyed with borax and soap at from 60° C. to the boil. Then rinse well, and sour in a fresh bath with sulphuric acid. Cream is dyed with Azoflavine FF, shading with Quinoline Yellow or Orange II. Nile green is dyed with Patent Blue II and Quinoline Yellow, or, if a pure shade is wanted, with light Green SF yellowish and Quinoline Yellow, and on the hand winch, for it is difficult to get pale shades level with light green. The following are also useful dyes: Bordeaux Fast Red A7, Fast Ponceau G, Orange II, Acid Violet 4R, Brilliant Croceine, Ponceau R and 4RB, Navy Blue, Acid Violet 6BN, 5BF, 3BN, Wool Blue S, Patent Blue V, N, C, Fast Blue, Fast Dark Blue, Guinea Violet; and for deepening: Wool Green with Orange II or Fast Red. Black: Palatine Black 6B, Naphthylamine Black 4B, Wool Black GR. Add Acid Violet for blue black.

Some of the dianil colours dye wool and silk alike in a neutral salt bath at the boil. These are the various brands of Dianil Yellow, Brown, Claret Red, Blue, and Black, Dianil Orange G, and Dianil Red 4B. It will be noted that these give a good variety of shades and the bath is simply made with Glauber's salt, the amount varying with the shade desired. If the silk is dyed too light the bath is cooled down a little, and the material is worked for some time at a lower temperature.

Shot Effects. For shot effects, very familiar on gloria in umbrella and sunshade cloths, the usable dyestuffs may be classed as:

1. Those which will dye the wool almost exclusively.
2. Those which will dye only the silk.

In the case of a large number of acid colours which go readily on wool, scarcely tinting silk, the dye-bath is prepared with 10 per cent. of acetic acid and the requisite percentage of the dyestuff. The material is entered at the boil and boiled for an hour or more. The shade must be dyed deeper than the pattern, as a little colour will be taken off by the cleaning-bath necessary to rid the silk of tint. This is made with one gallon of acetate of ammonia to 1,000 gallons of water, and the goods are worked in this until the silk is clear of colour. In many instances the silk is so little tinted that a lukewarm bath of water is all that is required. The silk is sometimes dyed with a basic colour in a boiling acid bath, but there are many dyestuffs which dye silk in a cold acid bath without affecting the wool.

The following colouring matters go on the wool alone: Palatine Red, Azo Crimson S and L, Wool Scarlet 4R, Orange GG, Tartrazine, Naphthol Yellow S, Indigo Extract, Azo Acid Blue 6B, Azo Acid Black, and Victoria Violet 4BS.

Those dyestuffs which give a full shade on silk in the cold, and have little affinity for wool, include the following well-known basic colours: Magenta, Safranine, Rhodamine, Acridine, Orange NO, Phosphine Malachite Green, Turquoise Blue, Methylene Blue, Methyl Violet, Coal Black H.

QUANTITY SURVEYING

The Methods of Ascertaining and Stating the Quantities of the Various Classes of Material and Labour in Building Work

Continued from page 6349

By F. H. A. HARDCASTLE

QUANTITY surveying is a process in building enterprise which comes, in point of time, between the preparation of the drawings and specification by the architect and the making of an estimate by the builder. A bill of quantities purports to set out, in the terms usually employed in the building trade, the quantity of materials and labour which will have to be supplied, and, generally, the services which must be rendered in erecting and completing a particular building for which tenders are desired.

Qualifications. To make a successful quantity surveyor the qualities of character requisite are a love of accuracy and thoroughness and what may be termed intelligent doggedness; intellectually, a taste for analysis, for calculation, for construction, and for mechanical contrivance. The young man who hopes to attain his results by brilliant dashes has no place here.

The general education which must precede technical training includes clearness and neatness in writing—especially in the making of figures—the ability to write English with precision and distinctness, a thorough knowledge of arithmetic and mensuration, and a firm grasp of elementary mathematics, including plane and solid geometry—as taught at South Kensington—some familiarity with mechanical and—if possible—freehand drawing, and bookkeeping. With this equipment a lad of 16 or 17 will be ready to begin the study of the technical work of quantity surveying.

Squaring. Measurements in a quantity surveyor's office are calculated in duodecimals, and the first work he would there be put to is what is known as "squaring dimensions." An example follows:

EXAMPLE OF SQUARING DIMENSIONS

	31 0 24 0 6	627 0	Excavate general surface not exceeding 6' 0" deep and throw out and Fill earth into carts and cart away	13/	10 0 7½ 2½	16 11	Fir framed in floors
	153 4 2 9	421 8	2 B in mortar	[illegible]	3 6 5 3	91 9	2" deal moulded casements with cross bars and hung at bottom
	5 0	9 10	Render float and set on brick walls	2 5/	14 6	145 0	4½" × 3" fir wrought all round and framed, rebated, and twice beaded frame
	5 0 6 0	57 9	Cube brickwork in mortar	6 3/	3 7 4 4	96 10 3	¼" steel
72/	2 0	144 0	Rough cut birdsmouth		2 2 1 4	2 10 8	Planing on steel
[illegible]	0 8	100	Ends of timbers cut and pitched				

Of the three columns on the left hand side of the paper the middle one is for the actual measurements, or "dimensions," which are known as "cubes" (*i.e.*, solids), "supers" (*i.e.*, areas), "runs" (*i.e.*, lineal measurements), and "numbers." The column on the left is for "timesing" (*i.e.*, multiplying); in the column on the right are put down the results of the "squaring." The result is usually calculated to one place of duodecimals: if any remainder fall short of 6 it is neglected: if 6 or over, a unit is added. In some cases, as in measurements of steel, iron or copper, the squaring is carried to two places. The third item given above is a semicircle of 5 ft. diameter, its superficial area being set down in the third column. The next item represents a solid mass semicircular on plan and 6 ft. deep; in the third column is its cubical content. The process of "timesing" is as follows: "2/" means twice; "3/2/" means first multiplied by two and then by three, or six times; "1·3/2/" means multiplied by two, and then by three *plus* 1 (or four)—*i.e.*, 8 times. The figure "1" is said to be "dotted on"; "3/$\dot{1}$/" means three times three, or nine times. The student will do well to practise squaring dimensions (which he can easily invent) until he becomes proficient.

Abstracting. The next process in the work is "abstracting," somewhat analogous to "posting" in bookkeeping from the day-book to the ledger, and consists in transferring the results of the "squaring," together with the descriptions of all the items on the columns of dimensions, to the sheets of abstract, at the same time arranging them under the various trades to which they belong, and in the order in which they are finally to appear in the bill. Abstract paper is usually ruled as shown in the illustration, the vertical lines being rather less than an inch apart. Sometimes these lines are made by folding the paper. The chief difficulty in abstracting is in the "setting-out"—that is, in judging of the amount of space to leave for the different items. It will be readily understood that quantities of the same item occur many times in different parts of the sheets of dimensions, and one of the objects of abstracting is to collect them so as to form one item in the bill. Example of abstracting:

EXAMPLE OF ABSTRACTING

Bricklayer							Joiner
	Reduced Brickwork in Mortar			Deduct			
	Cube	1 B	1½ B	Cube	1 B	1½ B	
	420 0 26 6	1000 0 3 9 [illegible]	[illegible] 1 0 8 [illegible]	400	[illegible] 100 8 [illegible]	11 11 [illegible] [illegible]	9" 1¼" deal moulded skirting and backings 150 0 — Fitted ends 6 — Internal mitres 6 — External mitres 6 — Returned and mitred ends 2
	446 6 50 0	400 4 600	[illegible] [illegible]		100 520 10	270 0 [illegible]	
Less ⅛th ÷	396 6 44 3	3,010 8 720 10	1,151 7 44 3				
	354 3	2,290 10	[illegible] [illegible]				1¼" deal moulded and square faced framing two panels high 50 0 — Extra on ditto for panel formed as door, 2' 6" × 1' 6" including the requisite splayed and rounded fillets mitred round as stop and fixed with screws 1
	Less ⅙rd	976 7	[illegible]				
		1,313 3	[illegible]	13 rods 196 feet			

The only dimensions that sometimes undergo a change in their way to the abstract are those of brickwork. In the usual or "London" system of measurement, brickwork is reckoned in superficial "rods" (*i.e.*, 272 ft.), reduced to a thickness of 1½ brick, and the items are abstracted in a way to facilitate this. Thus 500 ft. super. of 2 B (*i.e.*, wall 2 bricks, or 18 in. thick) would be abstracted as 1,000.0 under the head of 1 B; 500.0 of 3 B, as 1,000.0 under 1½ B; 500.0 of 2½ B as 500.0 under 1 B, and 500.0 under 1½ B; 500.0 of 2¼ B as 500.0 under 1 B, and 250.0 under 1½ B, and so on. When the columns have been added up, and the deductions subtracted, the total of 1 B is "reduced" to 1½ B

by deducting one-third (or multiplying by two and dividing by three), the result is then added to the 1½ B, and the sum divided by 272. Expertness in abstracting can be attained only by practice. The following general maxims, however, may usefully be borne in mind. Do not be afraid to use plenty of paper. Be careful to put the figures exactly under those to which they will have to be added. Do not take any liberties with the dimensions. Abstract the descriptions precisely as they are given by the taker-off, and, above all, do not use any abbreviations of your own invention. Abstract all notes and memoranda as carefully as any of the dimensions. As each item is abstracted a vertical line is drawn through it on the sheet of dimensions. The abstracts are then checked, the items thereon being ticked in red, and the corresponding items in the dimensions cut through in red. This done, the abstracts are "made up"—that is, the columns of figures are cast, deductions abstracted, and then results brought into superficial yards, cubic yards, cwts., qrs., and lb., etc., as the case may be. This work, for the sake of clearness, is commonly done in violet and checked in red, or done in red and checked in black.

Billing. Billing consists in taking from the abstracts, when prepared as above described, the various items thereon and throwing them into the form of bills ready for pricing. The following is a usual order of bills. No. 1, Preliminary. This bill consists of general items not susceptible of measurement and not belonging to any particular trade, and yet important to be borne in mind as forming an element of cost - for example, provision of water for the works, sheds and latrines for workmen, office for the clerk of works, insurance from fire and making good after that or any other accident, keeping the building in repair for a stipulated time after completion, risks under the Employers' Liability Acts, and other matters extracted from the conditions of contract and the preliminary clauses of the specification.

No. 2, Excavator and Concretor; No. 3, Bricklayer and drains; No. 4, Mason; No. 5, Tiler (or Slater) and Slate Mason; No. 6, Carpenter; No. 7, Joiner and Ironmonger; No. 8, Plasterer; No. 9, Founder and Smith, Gasfitter (or Electric Lighting Engineer), Bellhanger, Hot-water Engineer; No. 10, Plumber; No. 11, Glazier; No. 12, Painter and Paperhanger; No. 13, Summary.

At the head of each bill are put the general clauses from the specification touching the labour and materials proper to the trade for instance, the nature and quality of the bricks, stone, slates, timber, steel, etc., the composition of the concrete and of the mortar, the bond of the brickwork, the gauge of the slating and the like. Of the order of the items in the various bills it is not possible to give more than a general account. Suffice it to say that, usually, "cubes" come first, then "supers," "runs," and "numbers." Within these divisions the order followed is, generally speaking, that of increasing value.

Taking-off. We now come to "taking-off," or the measurement of builders' work from the drawings and specification prepared by the architect. Here it is that the chief work of the quantity surveyor is found, and on his excellence in this will his standing in his profession rest. During the whole of the time the student is engaged in the subordinate class of work already described he should keep his eye on the "taking-off" and lose no opportunity of qualifying himself for it, spending an evening or two every week in studying building construction at classes such as are held at the various polytechnics or under the Education Department, South Kensington. It has been said that in order to take-off properly a surveyor must understand every process in every trade. This is perhaps a slight, but only a slight, exaggeration. The student will do well, therefore, to keep his eyes open and observe any building work, however trivial, that may be going on, if it is only a carpenter putting in a sash-line or a plumber bending a pipe or wiping a joint. Every opportunity, too, should be seized of going over buildings in progress, especially while the workmen are there. True, much information may (and must) be got from books, but the student should make a point of *getting into contact with the work itself*, and should not be satisfied until he has seen an example of whatever he has read of in his studies. Failing this, he will find himself at an immediate disadvantage when he comes into contact with other surveyors, and especially with builders.

General Rules of Measurement. In the following pages it is assumed that the student has become familiar with building terms.

In measuring a length, always measure from left to right. In measuring a "super"—for example, a door the first dimension taken should be the width, the second the height, and the item would be booked thus:

3 0		2″ deal moulded both sides,
7 0		four-panel door.

In measuring a "cube" for instance, a stone the first dimension taken is the length, the second the distance from front to back, and the third the height. This order should never be departed from. Walls, plastering, slating, etc., are measured as if the openings in them did not exist. These will be deducted later. In booking the dimensions care should be taken to avoid crowding. Not infrequently it is necessary to go back and insert a dimension, and a good rule is to leave room between every two dimensions for another. In writing the descriptions it is important to keep well clear of the line on the left, bearing in mind that the squaring has still to come. If any dimension is arrived at by calculation the process should be shown on the right-hand side of the column, thus:

		N 84 0
		E 43 0
		127 0
		Ddt. 10 6
		116 6
116 6		1½ B in cement. *North and East*
14 0		*walls ground floor to first.*

Generally state at the end of the description the situation of the work in question in the building. Read carefully through the specification before beginning to take off. Never put down an item that you do not yourself understand, or do not see how it is going to work, even if you can quote chapter and verse for it from the specification. The architect is entitled to expect you to consult him upon it. Settle your order of taking off, and having settled it, be exceedingly chary of departing from it even if another way seems less cumbrous in a particular case. It is often important to be able to go back, perhaps a year or two later, and follow a measurement without hesitation.

Order of Taking-off. Until some thirty years ago it was the practice to take off each trade separately, but that custom is now quite out of date, and modern surveyors, broadly speaking,

measure not a *trade*, but a *thing*, whether it happens to involve one trade only, or several. The exceptions to this rule are joinery, plastering and painting. The following order of taking-off is recommended:

Excavation and concrete foundations; brickwork; damp-proof course; external facings; internal facings; formation of internal openings and recesses; fires; ventilation; external openings; floors; stone or concrete staircases; quarter partitions; roofs; eaves gutters and rain-water pipes; internal plumbing and water supply; drains; hot-water engineering; gasfitting; bellhanging; joinery; plastering and paperhanging; painting.

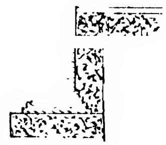
Excavation, Concrete and Walls. If the architect has not supplied a plan of the foundations it is often worth the surveyor's while to make one himself.

The first item of digging is sometimes a superficial one for removing the vegetable soil to a stated depth, say 10 in., but the general excavation is taken by the foot cube. If the contour of the site is irregular, an average depth may be got by a series of ordinates. When the "surface excavation"—to bring the level down to that of the concrete under the ground floor—has been taken, the excavation for the basement is measured, first to a depth of 6 ft., describing it as not exceeding 6 ft. deep, thence to a depth of 12 ft. (or less, as the case may be), describing it as "commencing at 6 ft. deep and not exceeding 12′ 0″ deep," and so on. The description must be worded so as to provide for any old foundations, roots of trees, drain-pipes, etc., that may be encountered. The excavation for the trenches should next be taken, first those below the basement, described as "Excavation for trenches commencing at basement level and not exceeding 6′ 0″ below same," and so on. Now, as to dealing with the earth excavated. In the case of, say, a mansion in a park, where the surplus earth can be easily disposed of, it will probably be sufficient to say of the excavation from the trenches "part returned filled in and rammed, the remainder wheeled, spread and levelled as directed." But usually, and in particular in large towns, where the removal of the earth often costs more than the digging, the portion carted away should be kept separate from that returned and filled in. A convenient way of doing this is first to measure all the earth taken from the trenches as returned and rammed, and then to take items of "deduct return and ram, and add cart away," thus:

150 0 3 3 5 6		Excavate trenches not exceeding 6′ 0″ deep, and throw out, and Return and ram around foundations.
150 0 3 3 2 0		Concrete as described, and Deduct return and ram, and Add fill and cart away.
150 0 1 11 9		Deduct return and ram, and Add cart away. *For footings.*
150 0 1 2 2 9		Ditto Ditto And Ditto *For wall.*

The area of the sides of the basement and of the trenches may now be measured for strutting and planking, keeping them separate. Next take the concrete foundations, using the dimensions of the trenches for this purpose, and not forgetting the "leg" required when a shallow trench abuts on a deep one [see sketch].

Next come the external walls, beginning with the footings, then the internal walls, chimney breasts and stacks, and piers. Great care is necessary to avoid missing any of the internal walls. A good plan is to take first all that run from left to right, and then all that go at right angles to these. The dimensions of the concrete for the external walls may sometimes be used for the brickwork.

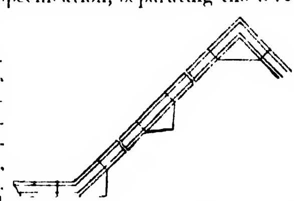


The walls may be conveniently taken floor by floor, but chimney breasts and stacks should be taken one by one, from bottom to top. The damp-proof course should next be taken from the measurements of the brickwork—as, for instance, all the one-brick walls collected and the total booked as a dimension by 9 in., and so on. Then the vertical asphalting on the outside of the basement walls next the earth as a "super" dimension, not forgetting to give the total length of the internal angles as "solid fillet at internal angle."

Any requisite steel girders, etc., to support walls on the upper floors should be taken with the brickwork, or noted to be taken later. The chimney breasts usually grow wider as they go up, and require 3 in. or 4 in. self-faced York stone corbels where they set off. Keep separate any brickwork in cement, also any brickwork hoisted more than 40 ft. above the ground-floor level, giving the stages 40 ft. to 60 ft., 60 ft. to 80 ft., and so on. All right angles are included in the price of the brickwork, but a lineal measurement is taken of all others—"birdsmouth," if internal angles; "squintquoin" if external.

External Facings—Chimneys. Measure the weathering on the tops of the chimney caps (super), next the cornices and neckings, etc., beginning with the projecting brickwork (super), and following with the cornice (lineal), as thus: "24.0 Extra on ordinary brickwork for red-brick moulded cornice, as sketch, five courses high, two square and oversailing, and three moulded." Number the mitres and returned ends, and measure the cement weathering on top. Take the general facing down to the roof line.

Copings. Take the brick copings (run), and describe as in the specification, separating the level from the raking and numbering mitres, etc. Similarly, measure the stone coping, describing the material and the labour—for instance, 64 ft. run, 12 in. by 4 in. Rubbed Portland stone coping, weathered, moulded, and twice throated (as sketch), and set and pointed in cement; 20 ft. run, 12 in. by 4 in.; ditto raking to gables.



No. 4 external angles.

No. 2 internal angles.

No. 3 fair ends with returned and mitred moulding, etc.

No. 2 kneelers (as sketch), 13 in. by 12 in. by 10 in. (labour and material).

No. 2 bonders, 10 in. by 12 in. by 10 in. (labour and material).

No. 1 apex stone, 16½ in. by 12 in. by 11 in. (labour and material).

Number the cramps as specified. Take fair raking cutting (run) to facings on both sides of the wall under the raking coping.

Cornices, etc. The brick cornices, string courses, etc., will be measured as already described for the cornices of chimney stacks. If of stone, take them by the foot run, numbering the mitres, etc.—for example,

150 0		18 in. by 12 in. Portland stone cornice, rubbed, weathered, and moulded (as sketch), and set and joggle-jointed in cement.
No. 2		Stopped ends.
No. 6		External angles.
No. 2		Irregular angles.
No. 4		Internal angles.

General Facings. The general facings may now be taken, *between* the string courses, etc., but *over* all openings—*e.g.*,

N. elevation	44	6
E. elevation	30	0
S. elevation	20	0
At break 2/.9	1	6
	10	0
	14	6
W. elevation	30	0
	150	6

150 0 28 6		Extra on ordinary brickwork for facings of best red Farehams, the joints raked out and afterwards neatly pointed with a weathered joint.

If the facings be of stone we should, instead, get an item such as the following:

150 6 28 6		Rubbed Portland stone ashlar, average 6¾ in. on bed and setting and pointing as described.

Internal Facings. Measure the surfaces of the walls faced with brick; also the limewhiting or distempering, taking the description from the specification. In the case of glazed brick facing, give the run of the internal angles as "Extra for waste at internal angles."

Internal Openings. Begin on the lowest floor, and take the formation of all doorways, borrowed lights, archways, and recesses. Example of doorway:

	3 0 7 0	1 B. deduct *Between kitchen and passage.*
	3 9 6	1 B. deduct *For lintel.*
	3 9	9-in. by 6-in. concrete lintel, including 2 in. by 2 in. by ¼ in. R.S.T. the whole length; also any requisite casing (brickwork deducted).
2/	No 5	Extra on brickwork for concrete fixing bricks, 9 in. by 4½ in. by 3 in.
	3 9 9	3-in. tooled York threshold, edges jointed, and bedding in cement.
	No. 2	Ends ditto, cut and pinned in cement.

Some surveyors here follow with the joiner's work for the opening.

If, instead of a lintel, we have an arch, we get:

3 2 9		Centring to segmental arch.
No. 1		Extra labour and waste and cement for segmental arch in cement, 3 ft. span, 1 B. on soffit, 1 B. high.

Fire. Example of measurement places:

3 0 3 0		1½ B. deduct.
No. 1		Extra to segmental arch 3 ft. span, 1 B. × 1 B. a.b. (a.b. means "as before").
5 0		2¼ in. × ⅜ in. wrought-iron chimney bar, caulked and cambered and building in by bricklayer.
3 0 1 2		2½-in. York tooled hearth, edges jointed, and bedding in mortar. *Back.*
4 6 1 6		2½-in. ditto, rubbed ditto. *Front.*
4 6 1 8		Half-brick in cement trimmer arch, and levelling in fine concrete for hearth, and centring trimmer arches.
4 6		Skewback cutting.
4 6		4½-in. by 2½-in. deal feather-edged springer.
No. 1		Filleting soffit of trimmer arch for lathing to.
No. 1		Slow-combustion stove, p.c. £3, and add setting same with the requisite bricks in mortar, firebricks, and fireclay.
No. 1		Rendering in lime and hair mortar to backs of fireplaces.
No. 1		Flue 30 ft. long, parged with cow-dung parge, and cored out at completion.
No. 1		Red terra-cotta chimney-pot, 2 ft. 6 in. high, and setting and flaunching in cement.
No. 1		Chimney-piece, p.c. £4, and add fixing in best manner with the necessary galvanised iron cramps, dowels, and cement, etc.
No. 2		Notching 2½-in. York hearth for jambs of chimney-piece.
4 0 3 6		Deduct render float and set walls, and Deduct paper at 3s. per piece.
No. 1		Making good in Parian cement to plastering around chimney-piece.

The void in the case of flues (up to 14 in. by 14 in.) is not deducted. It is left to pay for the forming of the flue.

Ventilation. Take, first, all the foul-air extracts, and then the fresh air inlets. Number the gratings, etc., and fixing, taking the descriptions from the specification.

No. 1. 14 in. by 9 in. cast iron galvanised air grating of approved pattern and building in, including forming opening in 1½ B wall, finished all round with ¾ in. Portland cement trowelled smooth, also the requisite 3 in. tooled York lintel.

The ventilators in the roof are usually taken with the roof.

External Openings. First deduct the brickwork, then take the work on the inside and afterwards that on the outside of the wall.

Example :

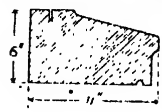
2/	4 6	1 B deduct.
2/	6 3	
		Night nursery windows (2).
2/	3 9 6 0	½ B deduct
2/	5 3 9	1 B deduct *For lintel.*
2/	5 3	9 in. by 9 in. concrete lintel, etc., a. b.
2/ 2/	No 4	Concrete fixing bricks a. b. 2/4 6 – 9 0 2/6 3 – 12 6 21 6
2/	No. 1	Window frame 21 ft. 6 in., around bedded in lime and hair and pointed in cement, the sill bedded in white lead.
2/	3 11	Centring to 4½ in. segmental soffit.
2/	3 11 4	Extra on brickwork for red rubbed and gauged arch in T.L.B., rubbers set in cement and raked out and pointed to match the general facings.
2/	4 2	Ditto, and deduct red facings a. b.
2/ 2/	9	Skewback cutting to facings (at ends of arch).
2/	4 4	Circular cutting to facings (over arch).
2/	4 2	11 in. by 6 in. rubbed Portland stone window-sill, sunk, weathered moulded, throated, and grooved for iron tongue, and setting in cement (as sketch in next column).
2/	No. 2	Fair ends with moulding returned and mitred and stoppings to weathering, etc.
2/	No. 2	Ends of sill cut and pinned to facings.
2/	No. 1	Sill bedded hollow and made up and pointed at completion.

2/ 2/	4½	Red facings as before. *Reveals* 6 3 6
2/		Deduct facings as before. 6 9

Some surveyors here follow with the joiners' work, etc., of the window.

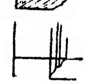
The external openings should be taken floor by floor, beginning at the bottom and sometimes front by front.

Measurement of Stonework. In the foregoing instance the facings are assumed to face of brick. When, however, the facings of the



front or the dressings of the openings are of stone, the measurement of the work on the outside is modified accordingly. It may be convenient at this point, therefore, to deal with the mode of measuring stonework, of which some general account may here be given, though the matter is too complicated to be explained with completeness. All stones not more than 3 in. thick are measured "super." Copings, cornices, string courses, plinth courses, are commonly taken by the foot run, with a sketch of the section, the mitres, etc., being numbered. Sometimes the stones are "cubed up" and described, being classified under several heads, as "cube Portland stone and all labours in plain string courses"; "Do. in moulded do. and cornices"; "Do. in moulded and rebated jambs of doors and windows," etc., accompanied by sketches illustrating the character of the work.

The most scientific mode, however, is to take the stone and the labours upon it separately. The only labour included in the price per foot cube is that needed to saw or draft it to its size, and to hoist and set it. First the size is taken as the smallest imaginary rectangular cube that would contain the finished stone, and if any *particular stone* is longer than is usual (generally 6 ft. and over), it is kept separate and called "scantling." The heading of the mason's bill should state that "the stone is measured net as set, including preliminary labours." The following are recognised labours taken by the foot super. "Back," the labour on the back of the stone, where it comes into contact with other material—as brickwork; "bed," the labour on the horizontal surfaces above and below coming in contact with stone or other material; "joint," that on the similar vertical faces at right angles to the front face (these are usually added together, the quantity halved, and described as "one face measured for two"); "sunk bed and joint," similar labour to bed and joint, but not rectangular with the adjacent faces, or rebated—as the joints of the voussoir of an arch or the sinking for a door frame (the last-named labour is sometimes kept *separate*); "circular bed and joint," the labour when convex as at the top of a voussoir; "circular sunk bed and joint," that where concave, as at the bottom of a voussoir when not exposed; "plain work," the labour on the exposed plain surface; "sunk work," that similar to sunk joint, but exposed, as the weathering on the top of a sill. Where the sinking cannot be worked without impediment (or worked "through"), as in a rebate on the outside of a window head, it is



termed "sunk work stopped." This applies also to other labours. "Circular work" is the face labour to convex surfaces—as to the shafts of columns: "circular sunk work," the like to concave surfaces as to the soffits of arch stones; "circular circular work," the labour to the face when circular both ways, as to the outside of a dome; "sunk work circular circular," that to the inside of a dome: "moulded work" is measured over the whole surface as by a fine string: "moulded work circular continuous," as to the moulded base of a column; The following are taken by the foot run: chamfers up to 3 in. wide, mouldings up to 6 in. girth, groove, throat (*i.e.*, hollow groove), joggle, and the like; stopped ends, mitres, mortises, perforations, etc., are numbered. Examples:

2/	1 2 10 5 2	Cube Portland stone and hoisting and setting as described. (*Six stones.*) *Jambs of window, south of library.* [See sketch.]	
2/6/	1 2 10	Bed (one face measured for two).	1 2
2/	2 0 5 2	Half joint.	10 2 0
2/	1 11 5 2	Plain work	10 6 1 4
2/	1 5 5 2	Moulded work.	
2/	5 2	Moulding 4 in. girth.	
2/	5 2	Groove for iron casement.	
	12 0 1 8 1 0	Cube Portland stone a. b. *Cornice of bay window adjoining.* [See sketch below.]	
	12 0 1 8	Bed.	
5/	1 8 1 0	Joint.	
5/	1 8	Cement joggle.	
4/	1 8 1 0	Sunk joint (all measured).	
	No. 6	Lead cramps and mortises as described.	
	12 0 11	Sunk work.	
	No. 8	Mitres to 11 in. splay.	
	3 0 1 9	Moulded work.	
	9 0 1 9	Moulded work stopped.	
	No. 4	Mitres to moulding 1 ft. 9 in. girth.	
	No. 4	Irregular do. do.	
	12 0	Labour carving egg and tongue enrichment p.c. per foot run, and attend carver to same.	

Floors. First take the "hard" floors, then the timber floors. Begin with the basement. Take any requisite hard core (super) describing the thickness, "well rammed and levelled for pavings," the concrete bed, the cement floating, and the tile or other pavings, to the last-named of which, if the plan be irregular, take a "run" of "raking cutting and waste." To the upper floors take any cast-iron or steel columns or stanchions, girders and steel joists. Cast-iron columns are measured up in detail (super) as metal of such and such thickness, weighted out, 5 per cent. being added for featherings, and billed as:

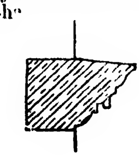
Cwt.	qrs.	lb.	
128	2	14	In No. 6 cast-iron columns and hoisting and fixing by bricklayer at first floor level.
			No. 1 pattern to cast-iron column $9\frac{1}{4}$ in. mean diameter, 13 ft. high, $1\frac{1}{4}$ in. metal, with moulded and bracketed cap and base and moulded necking.

Cast-iron stanchions are taken similarly. Steel joists are taken by the foot run, and weighted out, those 12 in. deep and over being kept separate. Compound girders are measured up in detail, and kept separate with description; this is also the case with riveted plate girders. In the last-mentioned case a percentage is usually added for rivet heads (from 2 per cent. to 5 per cent.). The shanks of the rivets take the place of the holes in the metal.

Connections of girders should be numbered and described. The steel work of a floor having been taken, next measure the flat-boarded centering, the concrete—giving the thickness—the cement floating, etc., as before described. The timber floors now follow, beginning with the sleeper walls, etc., and the sleepers, plates, and ground joists (cubed up and described as "fir and labour in sleepers and ground joists"). To the upper floors, take any steel girders, and then similarly measure the joists as "fir framed in floors." Take the ends built in, and any stone or iron corbels next flues. Take the herring-bone strutting by the foot run. Measure any sound boarding and pugging over the whole area of the floors, and add to this description "joists measured in."

Quarter Partitions. Take each piece of timber by the foot cube and describe as "fir framed in quarter partitions." Keep separate any that are "trussed," and describe the latter as "fir framed in trussed partitions." Measure the horizontal timbers first, then the vertical, then the raking. Measure the straps by the foot run, and describe as "wrought iron in straps, forged as required, including perforations and fixing by carpenter." Number the bolts.

Staircases. Here follow the stone or concrete stairs, the steps being taken by the foot run by 14 in. by 7 in., or whatever may be the extreme size, and the material, finish, and form—as whether square or spandril—stated. The labour to the ends is numbered, as "fair ends," or "fair ends with moulding returned and mitred." The ends cut and pinned are also numbered. Winders are numbered and described, the extreme dimensions being given, with sketches. Next take the landings by the foot super; similarly, the labour on the edges by the foot run, as also the "edge cut and pinned."



Number the newels and balusters, and the mortises and lead for them. Take also here the handrails, whether of metal or of wood, by the foot run, stating if "ramped" (curved in a vertical plane), "circular level" (curved on the horizontal plane), or "wreathed" (curved in two planes, as at the turn round a well hole). If the handrail be of wood, take at each joint a "heading joint and wrought-iron handrail screw, the heads, etc., let in and pelleted"—that is, concealed with wood pellets let in.

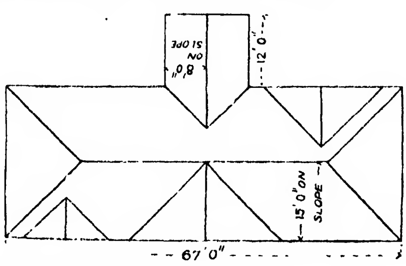
Roofs. If the architect does not supply a roof plan, it is worth while to make one yourself, or get one made. First, take the roof trusses, measuring by the foot cube each timber separately, thus: tie-beam, principals, king-post, struts; and describing as "fir-framed in roof trusses." Number the cleats for purlins, also the cast-iron shoes and heads, giving the weights and stating how many patterns will be required. Take the straps and bolts as already directed for partitions, and number the wedges and cotters, giving the weight. Take also the stone templates and heels of roof truss cut and pinned.

If the trusses be of steel, each piece should be measured in detail, and the whole reduced to weight. The item would then appear in the bill somewhat as follows:

Cwt. qrs. lb.

244 1 7 In No. 7 steel riveted roof trusses, 59 ft. span, 15 ft. rise, of 4 in. × 4 in. angle as principals, $1\frac{1}{4}$ in. and $2\frac{1}{8}$ in. diameter tie rods, $2\frac{1}{2}$ in. × $\frac{1}{2}$ in., $3\frac{1}{2}$ in. × $\frac{1}{2}$ in., and 1 in. diameter bar as struts, etc., $\frac{5}{8}$ in. connecting plates, and all fitting, forgings, and cutting, rivets and bolts and holes, and hoisting and fixing by bricklayer, the apex 54 ft. above ground-floor level.

Measure the superficial area of the slating (or tiling) with the deal battens for same, and roof boarding and felt. If all the slopes are of the same pitch, the hips and valleys do not affect the area.



The area of this roof is taken in two dimensions, thus:

2/ 67 0 15 0		Slating as described, and
12 0 8 0		2 in. × $\frac{3}{4}$ in. deal battens spaced for countess slating and well nailed; and $\frac{3}{4}$ in. deal roof boarding, English cut, closely jointed, and all splays, notchings, etc., and well nailing, and felt as described, well nailed with clouts, and including laps (measured net, as seen).

Collect the total length of the eaves thus:

2/ 25 6 =	51 0
	27 0
2/ 12 0 =	24 0
	2 6
	3 6
	20 6
	3 6
	3 3
	135 3

135 3 | Extra labour and materials to slating at eaves

From the length of the eaves may now be taken the eaves fillet at eaves (run), or eaves board (super.), and the plate may be calculated: the roof plate (cube) next, and other horizontal timbers should be taken, as purlins, ridge-rafters, and slate or other ridges; then the rafters and the ceiling joists (cube), the extra labour and material to slate verge (run), and the deal tilter thereto, the deal tilter next gable walls, etc., and the lead soakers and flashings to make watertight connection between the edge of the slate roof and the wall. Lead soakers (super and weighted) are of 4 lb. lead, one to each course of slates (or tiles), lying 4 in. under same, and going 4 in. up the walls; the length should equal the gauge of the slating, plus the lap, plus 1 in.

Number them for fixing by the slater. For secret [illegible] ab[illegible] 13 i[illegible] of [illegible] lead [illegible]qu[illegible]ed. Ne[illegible] 5-lb. lead stepped flashings, 6 in. wide, as cover (super and weighted). Lastly, the running length for lead wedging and for raking out joints of brickwork and pointing in cement to stepped flashings. All lead work is measured strictly net, with no allowance whatever for waste.

To chimney stacks take the deduction of rafters and the addition of the trimmers, etc., also the deduction of the slating, etc. Measure a 6-in. width of slating down the slopes for cuttings, and the lead work, etc., as to gables; at bottom a 5-lb. lead apron, 12 in. wide, and at top a lead gutter 8 in. wide. Let us assume that the stack is three bricks thick, etc., the gutter would then be measured thus:

2 3 8		$1\frac{1}{4}$ in. deal gutter boards and framed bearers.
No. 1		Short length of 2 in. deal rounded roll (across the gutter in the middle).
No. 2		Small 1 in. deal gussets, prepared one side for lead, and fitted and fixed at ends of gutters.
		ft. in. 2 3 Extra for roll 8 At each end 2/.9 = 1 6 4 5
		ft. in. 8 Against brickwork 6 Up slope 1 0 2 2
4 5 2 2		6-lb. lead and labour laying in gutters.

No. 2		Ends of roll bossed	2 3
		2/.6 =	1 0
			3 3
	3 6	5 lb. lead and labour laying as flashings.	
	3 3	Lead wedging to flashings, and Rake out and point flashings.	
2/	2 3	Large feather-edged eaves fillet, and Extra to slate eaves a.b.	

Next, take the hips and valleys, first the timbers (cube), then the length by 6 in. of roof boarding for cuttings, and by 1 ft. of slating for cuttings, also the length for the slate hips. Number the labours at the ends of the hips and the hip hooks at the foot. For a lead valley, super up the $1\frac{1}{4}$ in. valley board, "splayed and fitted," run the tilter on each side, and super up the lead, the length plus 6 in. at each end, and 6 in. for each lap, by (say) 1 ft. 6 in. wide.

Take the gutters next parapets, etc., in the manner already described, but measure the rolls and drips by the foot run, and at each 2 in. drip, allow 8 in. extra of lead. Take the cesspools thus:

No. 1	$1\frac{1}{4}$ in. deal dovetailed cesspool, 10 in. × 10 in., and 5 in. deep (all in clear), holed, fitted, and rebated for cover.

Super up the lead lining, and number the "extra labour, etc., dressing and copper nailing lead in cesspool," the copper cover, the lead socket pipe to carry the water to the rain-water head outside, and the hole through the wall. All the cube timber in the foregoing is described as "fir-framed in roofs." Another way is first to measure all the timbers, boarding, etc., as above, and afterwards the slating and lead work. Note particularly that the lead work of a gutter should always be carried up the slope of the roof to a vertical height of 6 in. above the sole of the gutter.

Eaves Gutters, and Rain-water Pipes. These are taken by the foot run, now generally measured net, excepting to small breaks, and around pilasters, etc. (which are numbered), the size and description and mode of fixing being given, as thus:

98 0 5 in. by 4 in. cast iron moulded eaves gutter (No. 20 in So and So's list), with rebated joints made up in red lead and two bolts to each joint, and strongly screwing to deal fascia and bedding and pointing in cement on brick cornice, including all cuttings and waste (measured net). The stopped ends, angles, outlets, and covers for same are numbered. In the case of rain water pipes the swan-neck bends should be numbered, the girth given, and the number of patterns required stated.

Internal Plumbing and Water Supply. It is convenient to include in the heading of this bill a table of the weights per yard run of the lead pipes, the pipes being classified as "waste," "service," and "main." The size of a pipe is the diameter of its bore. The price per foot run fixed includes running joints, wall-hooks or tacks, also bends, unless the pipe is 2 in. or over, in which case the bends must be numbered in addition. Number the soldered ends, also the "branch" joints, stating the size of the pipe—as in the following example:

No. 2	Extra soldered joints to 1 in. lead pipe, or,
No. 2	Soldered joints of $\frac{3}{4}$ in. and 1 in. lead pipes.

The joints to taps and unions are included with them. Lengths of pipe under 2ft. 6 in. are numbered, the number of bends in each being stated.

Fittings and Wastes, Etc. Begin with the w.c. on the top floor. Number the apparatus, giving description and including fixing and all unions and joints. Next take the soil pipe down to the drain and connect thereto, also up, as ventilator, and finish with cap, and take the hole through the wall. Take the water-waste preventer, the overflow pipe, and the hole through the wall, the flushing pipe and connection to pan. Similarly, take all other w.c.'s, urinals, etc., discharging into this soil pipe. Take the anti-syphonage pipes. Sinks, urinals, lavatories, and baths, and their wastes are measured similarly. Care should be used to take the traps if they are not included in the description of the fittings—for instance, to the lavatories. With the fittings it is convenient to measure any draining-boards, cupboards, etc., connected therewith.

Cisterns and Pipes. Cisterns are usually of galvanised wrought iron. Describe the capacity—*e.g.*, 300 gallons—the thickness of the metal, and the height to which hoisted. If the situation will not allow of a stock size being used, give the exact dimensions. Take any fir or steel bearers, the lead or zinc safe under and waste pipe from same, and the deal cover. Next, take the "warning pipe." If this passes through the roof, take a slater's number item of "perforation" through slated roof for pipe passing through, and making good, and plumber's item for a set of 5-lb. lead flashings soldered on. With each pipe that leaves the cistern take the connection thereto—as:

No.	Perforation in galvanised iron cistern for $1\frac{1}{2}$-in. union.
No.	$1\frac{1}{2}$-in. brass boiler-screw union and fly nuts and 7-lb. lead washers to iron cistern, and soldered joint to lead pipe.

From the cistern take the service pipes to the various fittings (except, perhaps, the sinks, which are now usually supplied from the "rising main"). Measure the chief pipe from the cistern on to the point where it ends, and number the soldered end or tap which finishes it. If, in its course, the pipe diminishes—say, from $1\frac{1}{2}$ in. to $1\frac{1}{4}$ in.—take at that point a "$1\frac{1}{2}$ in. extra soldered joint." Next take the stopcock on it near the cistern; then the first pipe that branches from it to its end, with all its taps and branches, complete. That branch being exhausted, pass down the main pipe till you come to the next branch; exhaust that in like manner, and so on. Having completed the pipes from the cistern (termed "services"), take the "supply pipe"—that is, the pipe from the main in the road up to the cistern—and the ballcock at the end of it. Then the stopcock near the beginning, and next, any branches to sinks, etc. If there are two or more cisterns, take one and all the pipes from it before touching the other. If iron pipes are used, the mode of measurement is much the same as in the case of lead. With the pipes take all pipe-casings (run), also holes through walls and chases.

The hot-water supply, gasfitter, bellhanger, lifts, speaking-tubes, and electric lighting follow here, and are usually dealt with by provisional sums of money.

Drains. Begin with the gulley at the point of the drain farthest from the outfall, number and describe it, with the excavation and concrete and setting, and take the stone cover. Next take the drain therefrom to the first chamber, describing the size of the pipe, how jointed, and the average depth of the trench and any concrete under or around it. Count up all bends, junctions, etc. Complete the drains that go into this pipe and this chamber, and then take the chamber. Next take the pipe from this chamber into the next, and all branches, with their gulleys, etc., and so on. Finally the pipe from the last chamber up to the sewer in road and connection therewith.

Joiner's Work. Measure the floor-boards (super), describing the material, thickness, etc. If any edge of a floor is not square with the others, take the length by 3 in. for waste. With the skirtings, chair rails, dados, and wall-linings, take the grounds, separating those that are plugged or fixed with wall-hooks across flues. Number the mitres, etc., in skirtings, and chair rails, and to dados, etc., take them by the foot run.

Staircases. First take the newels (run), numbering the caps and pendants; next the wall-strings and outer-strings (run), separating the "ramped" and "wreathed," etc. [see page 6510], then the steps, for which take the length from left to right *plus* 1″ at each end (housing). This dimension, multiplied by the width of the tread and the height of the riser added together is the measurement of a step, and should be booked thus:

Tread	11
Riser	6
	1 5

3 3		$1\frac{1}{4}$ in. deal treads with moulded nosing and 1 in. risers, tongued together, glued, blocked and bracketed on and including two strong fir carriages and prepared for cut strings—(if the ends are visible, or for close strings if otherwise). Note that if *a* is the width of the tread and *b* the height of the riser, *a* plus 2*b* should usually equal 23 in.
1 5		

Winders are measured net, thus:

3		Ditto in winders and measured net	
		6	3
		1	3
10 9		—	3
7		7	
			10 9

If the bottom step is longer and with a semi-circular end measure it the extreme length and take in addition an item:

No. 1		Extra on treads and risers as before for semicircular end with solid block and veneered front to riser without heading joint (say) 4 ft. 6 in. girth.

Take housing or returned and mitred ends of the steps; the handrail [see page 6511], number and describe the balusters, stating how fixed at ends, and measure the lathing and plastering to the soffits. Super up and describe the landings, including bearers.

Windows. Measure sashes and cased frames, the extreme width by the extreme height, and give the description from the specification. If the head is (say) segmental, add the words "with segmental head, measured square." The price per foot for this work includes the usual splayed edge on the bottom rail and the splayed edges of the meeting rails. Any further labours are extra and must be taken by the foot run. Mention in the description if weighted for plate glass, also if in two or more lights, with cased mullions. Take the run of the galvanised iron tongue and groove in sill and number the sash fasteners and other ironmongery. Take the glass, bearing in mind that parts of inches are counted as full inches; thus, $11\frac{1}{4}$ in is 1 ft. If the glass is of irregular shape, measure the extreme size and describe as "cut to shapes." Take the linings, whether of wood or cement (super if over 4 in. wide), architraves and grounds (run) the window board (super) and the deduction of plastering and paper. Casements and solid frames are taken similarly but in detail, the casements being supered and described as "fixed," "hung at side," or as the case may be, and each piece composing the frame taken by the foot run and the labours on it described.

Doors are measured by the foot super, the width by the height, and described as:

3 0		2 in. deal four panel moulded both sides door.
7 0		

"Moulded and square" means moulded one side and square the other. If a door is glazed, describe it as (say) "rebated and moulded on solid, and prepared for glass," take the run of the small beads as stop for glass (including mitres) and measure the glass.

Next take the linings (super) or the solid frames (run) and the hinges, locks and other ironmongery and architraves. Deduct the plastering and paper. In the case of swing doors measure the run of the rounded edges similarly. Space does not permit of entering into the measurement of screens and cupboards and other fittings, but the student will find little difficulty in adapting the information given above to joiner's work of this kind.

Plastering. Measure the ceilings (super), taking the description from the specification, and mentioning if panelled or coved. Take any ceiling mouldings (run), giving the girth and numbering all mitres, etc. Next the cornices, super if 12 in. girth or over, if not, by the foot run, giving the girth. Number all mitres, etc., giving the average girth of the moulding to which they belong. Bear in mind the "core" for the cornices. The smaller cornices may be in solid plaster, but for the larger ones some "bringing-out" is required, over-sailed courses of brickwork, if practicable, and, failing these, deal framed bracketing (super) of about one-third the girth of the cornice. Wall surfaces are taken super, the same dimension serving for the plastering and for the papering.

Painting. Painting is usually measured for the most part from the sheets of dimensions after the abstracting and checking have been done. This system has the advantage of giving the surveyor a final look through his dimensions, often invaluable. Measurements in painting are taken (super) "wherever the brush goes," and are classified according to the number of coats, kind of finish, whether in two or more tints, etc. Any work that will have to be done off ladders should be given separately.

The measurement of executed work follows the lines of the "taking-off" from drawings.

THE MODERN LOCOMOTIVE

The Boiler. Engines—Simple and Compound. Methods of Propulsion. Adhesion and Tractive Force

By JOSEPH G. HORNER

THE modern locomotive is wholly an evolutionary product, the end of which is not yet in sight. The elements of the locomotive are the steam generator or boiler, the engines, and the methods of propulsion.

The Boiler. The most essential feature of the boiler is the large number of tubes (multitubular) which traverse its barrel, and through which the flame and hot gases pass from the fire-box on their way to the smoke-box. The locomotive type of boiler is standardised on these lines—fire-box, muiltitubular barrel, and smoke-box. Though the heating surface comprises fire-box area and tube area, the first, though smaller, is much more efficient than the second. Experiments have proved that beyond a very moderate length, there is no advantage in extension of the tubes. Hence modern locomotives—that is, those of the past decade—differ from earlier ones in enlarged dimensions of fire-box, comprising a larger grate area. As the width is limited, the extension is made in length. The limit to length is that at which efficient stoking can be done. There is a type of fire-box in which increased width is obtained (the wide fire-box) by making the sides rest on the frames instead of fitting down between them. But though the heating effect of tubes is an almost negligible quantity at and near the smoke-box end, they are nearly or quite as efficient as fire-box surface close to, and for a few inches away from the fire-box. Hence the practice adopted in American locomotives and on the Great Western Railway [see **76** to **80**] of enlarging the barrel towards the fire-box end (extended waggon top). These boilers are about 7 in. larger in diameter at this end than they are next the smoke-box.

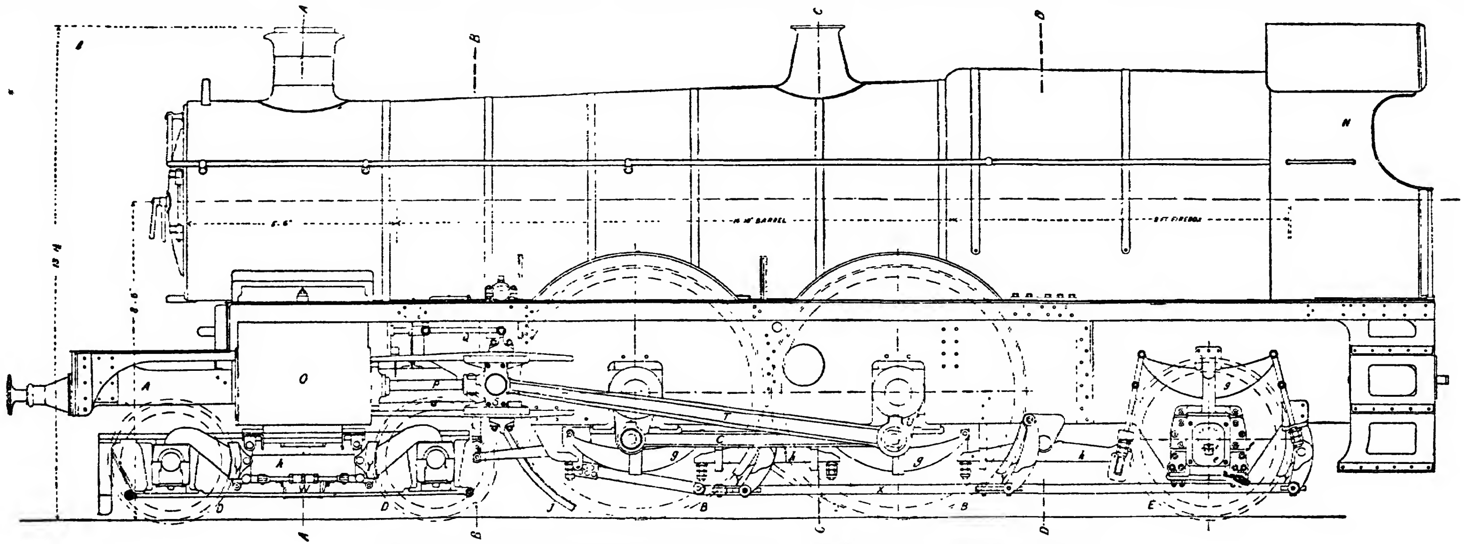
Boiler Tubes. The tubes vary in diameter and number, and barrels and tubes vary in length, and all these are variables in locomotive design. Those of all the railways have their own well-marked characteristic designs, which vary with the ideas of different superintendents. Barrels range from 4 ft. 10 in. in diameter to 5 ft. 6 in., and in length from 14 ft. to 21 ft. Tubes range from 1¼ in. to 2 in. external diameter, and number about 200. Small tubes, packed closely together, interfere with circulation, hence larger tubes and freer spacing is now adopted than formerly. The grate area of the fire-box ranges from 20 sq. ft. to 30 sq. ft. in English practice, but in the United States these areas are nearly doubled in the large freight engines and express locomotives. The total heating surface in English practice ranges from 1,500 sq. ft. to 2,500 sq. ft., which also are nearly doubled in American practice. The weight of a main line locomotive equals from 60 tons to 75 tons, and the tender another 50 tons. Some American engines weigh from 80 tons to 100 tons.

As there is no tall chimney to a locomotive boiler, there is no natural draught available to supply air to the fuel. The early locomotives had taller chimneys than the present ones. The place of the chimney, or the fan or blower, of other boilers, is taken in locomotives by the blast pipe. This is situated in the smoke-box, and enters the lower part of the chimney. The steam exhausting from the cylinders passes through the blast pipe at a high velocity, and draws after it a large volume of air. The air can come only through the fire-box and tubes. It is sufficient in volume to create a very strong draught, as efficient as that of a fan. In its simplest form, the blast pipe has a plain conical nozzle. But most are more elaborated than this, combining provision for producing variable degrees of blast, sharper or quieter, according to the rate at which it is desired to consume the fuel.

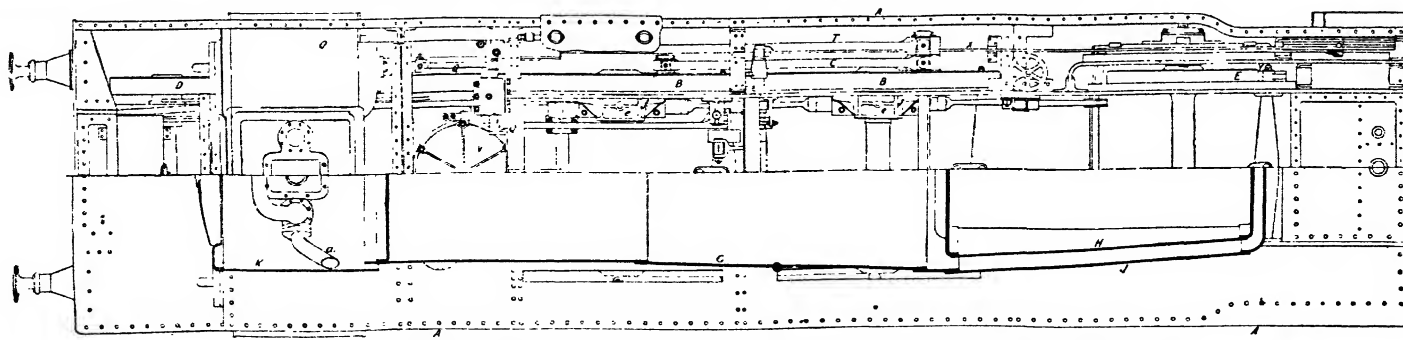
The fire-box is of approximately rectangular outlines, and comprises inner and outer portions. The inner contains the fuel, the outer is a continuation of the water and steam space. It is attached partly to the end of the cylindrical barrel, but mainly to the inner fire-box. The rectangular shape with plane faces is the weakest possible form. Yet it is the only one practicable, because of the limitations of space. The steam pressures, therefore, from 150 lb. to 180 lb. or 200 lb. per square inch, are resisted by stay bolts, which are disposed—at about 4 in. centres—so as to take the stress, and leave only as much plane plate between as will be able to resist bending. These bolts are a most important element in this type of boiler, and have been the subject of a vast number of experiments. Generally, they are screwed into adjacent plates and riveted over on the outsides. The central part is turned down as small as the roots of the threads, and with a radius, and the stress is calculated on this diameter. The roof of the fire-box is stayed with similar bolts, or more often with bridge or girder stays, of which there are numerous types in cast and wrought steel. The inner and outer fire-boxes are united through the foundation ring, and the fire-hole ring. These are forgings, or steel castings. The rivets pass through them. The smoke-box, not being subject to pressure, is made of thin sheet steel, and is riveted to the end of the barrel. It has a doorway in front, through which the tubes are exposed for cleaning. It receives the blast pipe and chimney.

The Materials of the Boiler. Formerly, all boiler barrels were made of wrought iron. This is now discarded in favour of steel. Fire-boxes are mostly made of copper. In the United States steel is commonly used. The tubes are variously made of wrought iron, steel, copper, brass, and Muntz metal, the last two being usually employed in Britain. The tubes are fixed by expanding their ends into holes drilled in the plates, which form the terminations of the boiler barrel (tube plates). The one at the front is the smoke-box tube plate, the other is the fire-box tube plate. These are about ¼ in. thicker than the ordinary shell plates, in order to give sufficient surface for holding the tubes.

The Engines. Until a comparatively recent period in the history of the locomotive, simple engines have been universal. Even after compounds were designed and tried, they made but slow headway. At present the compound engine is having its triumph on the Continent, but with various and



76. GREAT WESTERN RAILWAY ENGINE. 4—4—2 CLASS (ELEVATION)

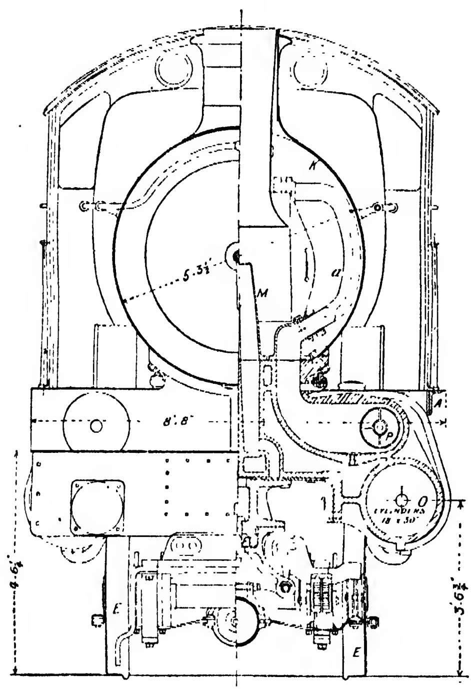


77. GREAT WESTERN RAILWAY ENGINE. 4—4—2 CLASS (BOILER SECTION AND FRAME PLAN)

diverse arrangements, and in a lesser degree, in England and America.

The Simple Engine. Not so long ago, increased engine power was sought by increase in dimensions of cylinders to the neglect of boiler power. It was not thought possible to increase the latter much, as has been now done. But at present the view taken is that ample boiler power—obtained chiefly in the enlarged fire-box and boiler end adjacent thereto—gives more than enlarged cylinders without such powers. The diameter of cylinders is limited by the conditions of the gauge. Cylinders of 18-in. or 19-in. bore are the maximum. Length of stroke is rather variable. It is usually about 26 in., but the recent Great Western engines, illustrated, have a 30-in. stroke, which gives correspondingly greater capacity.

The usual position for the cylinders in English practice is inside the frames, but in America and on



78. FRONT ELEVATION SECTION ON A-A

the Continent, outside. This affects the position of the valve gears, which must be adjacent to the cylinders, hence it seems odd to us to see the valve gears outside the frames in Continental engines. In favour of inside cylinders and gears it has been claimed that they are less liable to receive damage, and that they run more steadily than outside ones. For the latter the claim is that they are more readily examined and repaired than if located inside. There is little, if any, basis for the first, while the advantages of accessibility are unquestionable. A real objection to the inside arrangement is that dip cranks must be used, and these are liable to fracture, and numbers of failures and some fatal accidents have been traceable to these. With outside cylinders, the crank axle is straight, and the crank pins are on the driving wheels.

Simplicity is studied in locomotive engine details. The cylinders are not jacketed, but they are enclosed in the smoke-box in inside types. The cross-head guides are flat bars. The valves are of the common D type, and are main valves only, cut-off, and expansive working being controlled by link motion arrangements. There are only two types used generally, the Stephenson and the Walschäert, the first in England and in America, the second on the Continent chiefly. The Walschäert gear is, however, being taken up on some of the English lines lately. Other rivals, as the Gooch and the Allan gears, and others less known, have fallen into disuse.

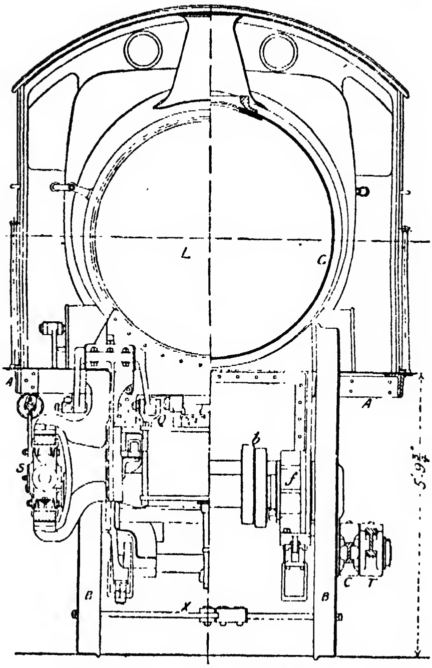
Compound Engines. All locomotive engines are of non-condensing type, because there is no room for condensing apparatus. A certain measure of economy is thus sacrificed. It seems a pity to generate steam, and, after using it once, to dissipate it into the atmosphere. Hence the fascination which compounding has had ever since it was proposed by Mallett in 1874. His was the only compound in the Paris Exhibition of 1889. The full story of the growth of the compound, if written by a qualified man, would be one of the most fascinating in the story of engineering practice. Invented in France, it has been developed in every country in Europe, and in America. In England the late Mr. Webb will be remembered as the persistent advocate of the system in the teeth of much opposition. There are now at least a dozen fairly distinct types of compound locomotives in regular use on the railways of the world, differing in arrangements of the cylinders and valves, to describe which is not possible here, and they would be bewildering apart from illustrations. The most familiar names are the Mallett, the Webb, the Henry, the De Glehn, and the Plancher. Tandem compounds, though in existence, are in a great minority, most designs having cylinders in parallel relations. There are two, three, and four cylinder compounds. Generally, engines can be worked as simple or compound. Piston valves are adopted in some recent engines. Coal economy ranges from 12 to 20 per cent.

Methods of Propulsion. These involve problems concerned with diameter of driving wheels, of the loads on them, and of tractive force. In these, as in other details, the evolutionary processes are writ large in the ever fascinating history of the locomotive. The influence of the old Watt idea that piston speed should not exceed 200 ft. per minute long affected locomotive practice. The idea held was that the velocity of the pistons should be kept down to moderate limits, or from 500 ft. to 600 ft. per minute, and speed obtained by having driving wheels of large diameter, say of from 8 ft. to 8 ft. 6 in. That explains why the older express engines drawing comparatively light loads often had large single drivers—that is, uncoupled; and the goods engine drawing heavy loads had small coupled wheels. The idea still lingers, notwithstanding some of the fastest expresses are now drawn by coupled engines with piston speeds of considerably over 1,000 ft. per minute. This also explains why, with increase in tractive force, the diameters of cylinders have not been much increased.

Increasing piston speed is as efficient as increasing diameter to an equivalent amount. If, for example, a given piston speed were increased by 50 per cent., the engine power would be augmented by 50 per cent. for the same steam pressure. But steam pressures have also grown largely. Compounding is also a source of gain. Larger boilers supply larger volumes of steam, and all these things have produced engines of greater power, so that one engine now hauls loads that required the services of two engines a few years since.

Adhesion. The two essentials which render a locomotive capable of hauling a load on smooth rails are its adhesion and its tractive force. Everyone is familiar with the slipping of locomotive wheels when starting on slippery or wet rails. This means that the greasy state of the rails overcomes for the moment the adhesion of the wheels thereto. In the early inception of locomotive engineering it was not believed that engines could haul coaches on smooth rails, and rack rails much like those employed on mountain railways were used. It was found that adhesion is secured by putting enough weight on the driving wheels, hence the advantage of the employment of big, heavy engines. The adhesion of an engine is not the same as the weight of the engine. It is less because of the slip. About one-fourth of the total weight on the driving wheels is available for adhesion on dry rails. On wet rails it may be as low as one-tenth. One-sixth is about the average proportion for ordinary conditions. Because of this loss of adhesion, the practice of sanding is necessary when starting, and when climbing inclines in wet, foggy, and frosty weather.

The weight which can be imposed on the driving wheels is obviously limited, and, therefore, with increase in weight of engine, coupling becomes necessary. But the weights on a single axle have increased largely. In 1850, six tons was the maximum load considered permissible on a single wheel, now 16 tons and 18 tons are carried. This is largely due to the substitution of steel tyres and steel rails for those of iron. But even with these loads, the increasing weight of engines has had to be distributed over more wheels, and the old types with single drivers are rapidly passing out of existence. Four, six, and eight wheels coupled are common types, and even ten wheels in some American designs. Coupling



79. SECTION ON B-B SECTION ON C-C

wheels means that each wheel must take its proportion of the load whatever that may be.

Tractive Force. In order that the engine shall pull its load, its friction on the rails must be at least equal to the effective pull or tractive force. If the engine wheels do not slip, then obviously any movement of the engine must draw its load along. If they slip then the adhesion is not equal to the tractive force. The driving wheels are levers, and their point of contact with the rails is their fulcrum. The tractive force is calculated thus:

$$\frac{(\text{Diam. of cylinder in in.})^2 \times \text{stroke in in.}}{\text{Diameter of driving wheel in inches}} = \begin{array}{l}\text{Tractive force in lb. for each lb. of effective}\\ \text{steam pressure upon the piston.}\end{array}$$

An important element in smooth running at high speeds is the balancing of the reciprocating and revolving parts. These include the piston and connecting rods and the cranks. They are counterbalanced in the driving wheels by the addition of weights. Many rules have been given for these, but the most exact results are obtained by trials.

The illustrations, [76 to 80] give various views of an Atlantic type, 4-4-2 class of Great Western Railway engine, designed by Mr. J. G. Churchward. The appended list of parts may be compared with the drawings which are lettered correspondingly. A, frames; B, driving wheels; C, coupling rod; D, bogie wheels; E, trailing wheels; F, bogie pivot; G, boiler barrel; H, inner fire-box; J, outer fire-box; K, smoke-box; L, tube space; M, blast pipe; N, cab; O, cylinders; P, piston, valves; Q, valve gear; R, piston rods; S, cross-heads; T, connecting rod; U, cranks; V, vacuum brake cylinder; W, ditto for bogie; X, brake rods; Y, brakes; Z, draw bar; *a*, steam pipe; *b*, eccentrics; *c*, reversing lever; *d*, regulator; *e*, axle boxes; *f*, horn blocks; *g*, axle springs; *h*, compensating levers; *j*, sanding pipe.

Group 26 **BUSINESS MANAGEMENT** 2 Continued from page 6351	**FACTORY AND OFFICE SYSTEM** Relations Between Employers and Employes. Card Index and Loose-leaf Book Systems in Office Work

By D. N. DUNLOP

THE growth of a business is primarily a matter of organisation; organisation is primarily a matter of system; and the foundation of system is energy applied with intelligence. Many business and professional men would install systems if it were not for the false impression that they entail extra work. This error needs no other refutation than the fact that no good system is ever discarded after having been installed, but is extended and modified as business requirements demand.

What is System? System means a thorough knowledge of the smallest details of one's business, secured not by the process of doing everything oneself—there are too many details—but automatically as the result of well-directed effort and organisation. Well-directed effort on the part of each member of the staff means that each worker must know or be taught to know how and where to apply his labour with the best and quickest results. The power of executive, or of organising a business, means the power to make all the small processes of the business dovetail into each other, and work with smoothness and efficiency. Knowledge of the details can come only from a system which brings them regularly to the attention of the manager. The best system is that which enables a man to do most work with the least expenditure of time, energy, and money.

The principle underlying modern system is the elaboration of the idea of *movable units*, as exemplified in the card and loose-leaf systems, which we shall reach later in this course. The old methods differ from the new in many respects, but none is of more fundamental importance than the treatment of ledgers, books, and records of all kinds in which every leaf was a fixture, and every item on each leaf immovable. The idea of the unit, complete in itself and movable, has led to the keeping of a book of records which would have been impossible under the old order, and which enable the manager to keep in touch with the whole of the working plant and staff of his business. Daily, weekly, and monthly statements are brought to his desk to enable him to probe the efficiency of men and machines in a manner unknown in bygone days, and to trace and stop leakages in every department. Numerous labour-saving appliances and devices double or treble the output of the staff in work of all kinds, while some employes are dispensed with altogether.

Supervision. Supervision is another feature of the modern system; no officer is allowed to dodge the responsibility for misconduct or failure on the part of a subordinate whom he is in duty bound to keep up to a high standard of efficiency. Supervision must be close, constant, inexorable, but always fair, and must extend throughout the whole organisation, binding all parts together. The result is that when an order is issued by the general manager, it works its way from the centre to the most distant part of the establishment automatically, just as in a system of electric distribution when the switch is turned on. From the manager to the office-boy each employe has someone above him who knows what work he is doing, and who comes periodically to demand results.

The Dwindling of Profits. Not so long ago, within the memory of middle-aged men, the margin of profit to the middleman was so large that there was no need to institute careful methods of conducting business; guessing was near enough. But with increasing competition, large profits had to give way, and the margin became narrower and narrower. The balance-sheet still shows large gross profits in many cases, but the volume of business has expanded, and the concerns have developed and assumed enormous proportions, while the working expenses have grown simultaneously, with the result that *net* profits have proportionately decreased.

The result has been a new rivalry among business men—the pursuit and cult of economy.

The Cult of Economy. The first lesson learnt was that economy does not mean cheapness or a purely arbitrary reduction of expenses, but, on the contrary, intelligent and far-seeing expenditure and the elimination of all waste and leakage.

New methods had to be sought for reducing the outlay, while still accomplishing the end in view. Industrial and mercantile transactions involve the manipulation of material by manual, mechanical, and mental labour in order to produce a marketable commodity. Of these two factors labour is the more costly and also the more variable. Great prejudice exists in many workshops against labour-saving machinery, which is said to be a menace to the working man. This is altogether false; the effect of labour-saving machinery is entirely beneficial; it tends to lessen the cost of products and to raise the price of labour.

Cost. The business man must know to a fraction of a penny what everything costs him. A cost system should provide:

1. Efficient means of collecting all the data necessary for drawing up statements of detailed and total cost.
2. Means of affording comparisons on all manufactured products, in order that the manager may have the opportunity of analysing the comparative cost of any given job with that of previously executed jobs, and with the estimates and tenders for contracts.
3. An exact account of the work performed by every employe on the pay-roll during every hour charged therein.

By means of these records, collected on separate cards, the general manager obtains incontrovertible testimony as to the efficiency of man and plant.

A modern cost system should keep the following aims in view:

1. To lessen the cost of production.
2. To determine the cost of products collectively and in detal.
3. To fix the sale price of every article on an absolutely safe basis.

The Factor of Labour. The following are some of the means of promoting this special quality of labour.

1. Discipline and justice.
2. Cultivation of good relations between employer and men.
3. Promotion of moral and physical well-being.
4. Co-operation in the business management.
5. Participation in the profits.
6. The encouragement of *esprit de corps.*
7. Offering facilities for the acquisition of technical and scientific knowledge.
8 Inviting suggestions for improvements in machinery or processes.

It must be remembered that the employer who gives his men nothing but bare wages can expect nothing from them but so many hours' work put in. The manager must find the secret of enlisting intelligent and sympathetic co-operation.

Co-operation is effected by means of committees formed in all departments from superintendents and foremen and from employes drawn from the ranks, on account of their fitness to serve on the committee, their sense of fairness and the esteem with which they are regarded by their fellow-workmen. The meetings of the committee are held daily or weekly during the lunch hour, or at the close of the working day at the expense of the firm; their business is to report on the work and organisation of their department, and to make suggestions and discuss complaints and grievances. Committees are formed to look after sanitation and cleanliness, advertising sales, shipping, repairs, office details, etc. The employes get to feel that the business is "ours," and they become imbued with a strong feeling of *esprit de corps*, or common spirit of devotion, sympathy and enthusiasm combined with jealousy for the honour of the body as a whole. Many firms provide suggestion and grievance boxes kept locked, into which the men drop slips of paper, duly signed, containing suggestions, and these are daily collected by the manager's secretary and taken direct to the chief's office where they receive immediate attention.

Many employers have found that the encouragement of personal cleanliness and neatness at the works by providing baths, spacious lavatories, and clothes lockers for the men had a beneficial, effect on the workmen's homes and family life, for the self-respect thus engendered at the works refuses to tolerate slovenly habits and dirty, untidy homes. The sound discipline and high moral tone, too, is likewise reflected in the home life of the workmen. The cost entailed by these methods of management is a sound investment which is more effectual than many bonus and premium systems, and appeals to man's nobler nature.

The Labour Department. One of the most difficult problems which confront the business manager is the organisation of labour on a basis fair to master and men. The system adopted cannot be too simple in its working, but once installed it must be rigidly enforced.

The system we would here suggest to managers who wish to improve their organisation falls into three sections:

(*a*) The labour department.
(*b*) The timekeeping system.
(*c*) The routine.

In a large factory employing a large number of hands it is essential that labour should form a separate department under the direction of a special manager. His duties are to organise this department, to create a labour policy for the firm, to study labour questions, treat with trade unions, act as court of appeal in all labour troubles in the works, to frame rules and regulations, to impose fines and award prizes.

The Executive. His executive comprises employment agents for office, factory, and sales department, who devote their time to the selection of employes, to their training, discipline, promotion and dismissal. His right-hand man, the superintendent or buffer, plays the part of mediator between chief and men; he wins the confidence of the men, having no authority to promote or dismiss; he hears complaints and suggestions, looks after the well-being of the men. organises clubs, co-operative schemes, and recreations and fosters *esprit de corps.* The labour manager receives all data dealing with labour and the cost of production, from which he is able to study the efficiency of his army of workers, and to note the individuals who distinguish themselves and are fit subjects for promotion.

The employment agent prepares the personal records of employes, indexed by names, which comprise essential information concerning physique, character, ability, previous berths and records, reason for leaving, rate of pay, increase, promotion, quality of workmanship, complaints duly substantiated after full inquiry, special services rendered.

Three Classes of Industrial Labour. Industrial labour is divided into three classes:

1. *Productive labour*, which converts raw material into a finished product.
2. *Department non-productive labour*, essential to the productive labour, while not producing anything itself, such as foremen, oilers, sweepers, truckers, etc.
3. *General non-productive labour* necessary for the operation of the producing department, but entirely outside its jurisdiction, such as labour of the office, the sale, advertising and shipping departments, timekeeper, engineers, firemen, etc.

All three kinds of labour must figure in the cost, the sum total corresponding to the pay-roll for the same period. Every product must be made to bear its own share not only of productive labour, but also of both classes of non-productive labour.

Timekeeping System. The first aim of a modern timekeeping system is to account in detail for every minute of time charged in the pay-roll, and to see that this is accurately distributed among the articles produced; second in importance is the elimination of all clerical work from the factory departments.

The workman has two kinds of records to keep, for which cards are provided: (1) The *attendance* or *day* time card, showing the time at which he enters and leaves the works; and (2) the *job cards*, showing the exact time spent over each operation in the workshops throughout the day.

Mechanical Recorders. Mechanical recorders are used as substitutes for clerical work. On entering the works, the workman drops his card into a slot, presses a lever and picks his card out of a receptacle. The exact time in hours and minutes according to the clock on the face of the recorder is found registered in the space on the card allotted to him for the morning or afternoon of the proper day of the week; on leaving the works for the dinner hour, and finally at the end of the day, the simple action is repeated. The men, who are at once made to understand that they are paid solely for the time thus recorded on their cards, take care not to omit to register on entering and leaving the works. An automatic recorder or a calculagraph is placed in every workshop under the new regime, and the

foreman on receiving a completed job sees that the workman registers on his job card before he hands him the new work.

Keeping Records. In every business there are innumerable records of transactions, documents, lists, etc., which must be kept for constant reference; the problem is how to file and index them so that they are easily found when wanted. Experience teaches that any method which involves turning over the folios of ledgers, untying tapes, unfolding wrappers, extracting from envelopes, all tend to limit the utility of the data in question. The card system of filing and indexing solves the problem. Its watchwords are *mobility* and *get-at-ability*; it is based upon the rise of one or many series of cards, uniform in size, ruled, and printed according to the nature of the matter to be indexed, and arranged vertically on edge in trays or drawers. The cards are kept from slipping by an adjustable sliding block or follower, and are secured by means of a rod passing through a perforation in each card which, when bolted or fastened, prevents their removal. Guide cards of various colours, having indexed projections, are distributed among the cards to define certain sections and facilitate identification, while for sub-indexing, the smaller tabs on the cards give various clues alphabetical or numerical. The trays and drawers can be obtained singly or in an infinite variety of combination, in cabinets to suit the requirements of all. Expansion, which is one of the most valuable features of the system, is provided for by building up the cabinets in sections, which can be added as they are required. The essence of the whole system is that each card forms an independent unit, devoted to one name only; it can be removed to another series at any moment, according to its special significance, without leaving a gap or being considered an intruder in its new position, where it may be as readily found as before.

Decimal System of Indexing. For the purposes of an index, with its innumerable divisions and subdivisions, a numerical application of the card system has been found to save much time, as, for instance, in collecting and classifying the material for illustrated catalogues, in filing technical literature, photographs, cuts, blue prints, etc. The decimal system is the only one capable of keeping pace with proclivities for expansion of the card index, while remaining intelligible and self-evident.

As an illustration, let us take electrical engineering, which is classified among the useful arts, 600. To mechanical engineering is assigned 621; to electrical engineering No. 621·3. In group 621, the three after the point is given up entirely to electrical engineering, and may be extended indefinitely as occasion demands; 621·331 stands for electric railways. The whole system is worked out in Dewey's book, and a very complete index gives a clue to the corresponding numbers. Any firm, however, can form its own numerical sub-sections. For instance, the electrical railway section might be worked out thus: underground and elevated railways, 621·3311; three-phase, 621·3312; single-phase, 621·3313; mono-rail, 621·3314, etc. Or, again, by analogy, the decimal system can be employed in its entirety for any one business. It is evident that the use of the decimal system in indexing necessitates a key made alphabetically by an intelligent and responsible member of the establishment. With the key at hand, a moderately sharp office-boy can find the reference required in a moment. Guide cards and alphabetical tab-cards can, of course, be used in combination with the decimal system for subdivisions.

Adaptation of Decimal System in Engineering Works. In engineering and other industrial works this system may be adapted with excellent results to the nomenclature and classification of machines made, used, or of other products of the factory. It is a good plan, in grouping them, to allot 100 for each group, whether there be few or many machines in the group; memory is thereby assisted and expansion made possible without re-classification. For example:

1 to 99, planes, milling machines, etc.
100 to 199, drill presses, boring mills, etc.
200 to 299, turning and turret lathes, etc.
300 to 399, slotters, fixing machines, etc.
400 to 499, saws, cutting machines, etc.
500 to 599, oil separators, scales, electric cranes.
600 to 699, engines, motors, air compressors.

By adding a point and figures to the right, numbers can be assigned to parts, tools, and accessories of each machine.

The same system applies to the machines of the workshops for keeping machine records, and computing the machine rate.

The numbers, once allotted, follow the machines or products throughout their life in the factory, and represent them on all records. If the classification be used for the manufactured products, each drawing, pattern, casting, and, later, the part itself, should bear this number stamped upon it for the purpose of identification. Each number has a card on which all information respecting the part, such as specification, cost, percentage of floor space, insurance, interest, depreciation, the hourly machine rate, etc., is compiled and kept for reference.

Endless applications of the system will suggest themselves to those who have once tried it. For business houses, the decimal system recommends itself more especially for indexing the literature, correspondence, drawings, plans, photographs, etc.

Vertical System for Correspondence. The vertical is the ideal system of filing correspondence, enabling any subject or name to be referred to without delay, and preserving documents in perfect condition. It is nothing but the card system applied to letters by substituting folders for cards. Guide cards with index tabs project above the folders (made of strongest manilla), and may be filled in alphabetically, numerically, or geographically. By means of these guide cards, the folders can also be subdivided into subjects. A separate card index is required when the numerical system is used, to act as key to the numbered folders. Each card may bear entries of the dates of letters received and written, which often saves time in reference, rendering unnecessary any further quest in the correspondence cabinet. Separate facts, which it is desirable to record for the sake of their own importance, can be picked out of the correspondence by a boy or girl after they have been underlined in blue pencil by the chief of the department, and filed in other card indexes for reference under different heads, such as: quotations, complaints, orders, inquiries for articles not in stock, etc. Carbon copies of replies should, of course, be filed in the same folders as the original letters to save time in reference.

With a wider experience of the card system has come an extension of its scope, and many ingenious little devices are added from time to time, which considerably increase its utility. Movable tabs, mounted on a clip, are extensively used for the purpose of rapid identification, or for sub-indexing.

It is frequently necessary to keep several kinds of records in one tray or drawer. In order to distinguish them, a code of signals may be used which renders each set quite distinct. There are several ways of doing this besides the above:

1. By using cards of different colours.

2. Another method of coding the cards is to stain the top edges with coloured inks, or to make rows of dots along the edge at regular intervals, the same for all cards. As the ink can be easily scratched off, re-classification does not entail re-writing on new cards.

3. Similar notches can be cut on the top edges of the cards. When they are in place in the drawer, a line is ruled along the tops from front to back at certain intervals. Each of these lines produces on each card edge a dot, so that the edge of each card has on it the same number of dots at equal distances apart. Notches can be cut at any one of these dots to denote a certain thing.

The Memory Tickler. This is another instance of the utility of the card system. Every business or professional man, whether his place is at the top or the bottom of the ladder, needs some means for keeping him in touch with matters which require his attention punctually at definite times, or which may have to be postponed. A drawer or tray with guide cards for every day in the month, and every month in the year, is the best reminder. In front of the guide, cards may be used, folders or cards only; into the folder may be dropped slips of paper, visiting cards—anything that will serve to call up the matter which must be attended to. If any important function be postponed, the memorandum is filed on ahead, with the certainty that on the proper day it will receive attention. Every morning, the first duty after opening the mail (or perhaps even before) is to look through the *tickler* for the day, and lay out the day's work in accordance with its records. When making a promise, the date should at once be *tickled* one or two days before the fulfilment; it is a sure reminder. Manufacturers use the tickler with admirable results in turning inquiries into orders by automatically indicating the proper date at which an inquiry should be followed up if no order has come.

The Information Drawer. Business and professional men are for ever coming across useful scraps which they collect and store up for future emergencies. These scraps, valuable as they may be in themselves, are worse than useless unless you can put your hand upon them at once.

The information drawer is a catch-all for jottings, slips, cuttings, memos, etc., and is worth its weight in gold. Here, all transient, fleeting ideas are instantly anchored. The filing may be done in front of guide cards, indexed with a subject, and containing on its face and reverse a list of the records filed; or else folders may be used for each letter of the alphabet or for any subdivision that may be desirable, and they can then be filed in the usual way. The latter is the simpler system, and the best adapted to small needs.

Revolution in Office Methods. A complete revolution has indeed taken place in office methods since the advent of the card and loose-leaf systems. The introduction of the loose-leaf into business is no fad which will presently give place to some other; its wonderful possibilities have already obtained wide recognition all over the world. The basis of both card and loose-leaf systems is the ingenious principle of the independent mobile unit, each leaf or card being allotted to one person or account alone.

Advantages of the Loose-leaf Ledger. Here are a few of the reasons why this system is rapidly supplanting all others:

1. The loose-leaf is the only known device for preserving a perfectly independent record.

2. It allows all extraneous matter or dead accounts to be removed to the transfer file.

3. It renders the accounts elastic, obviating all difficulties about giving a customer a quarter-page when he should have had a half, doing away with *double double* to utilise space. The loose-leaf adjusts itself to every kind of account book and ledger: it is immaterial whether there be one item or a thousand.

4. The loose-leaf ledger is perpetual; once opened it remains open. When business dealings with a customer cease his account leaf is removed to the transfer ledger; should the business relations be resumed, all there is to be done is to return the account leaf to the current ledger. There is no need to hunt for old accounts through four or five ledgers, and perhaps five or six folios in each ledger. All the accounts are found together in the file.

5. Both sides of the loose-leaf can be filled up to the last line, while with bound books about 25 per cent. of the space is wasted.

6. The use of the loose-leaf ledger saves no less than $33\frac{1}{3}$ per cent. of the bookkeeper's time. At regular periods, the file pages and balanced accounts are removed to the transfer ledger. The dead accounts having been eliminated, striking a balance is an easy matter, and there is no danger of overlooking an open account.

7. No written index is needed, for the loose-leaf ledger provides an automatic indexing arrangement, the pages being filed in alphabetical order, as they would be in a directory, with tabs indicating the subdivisions of the alphabet. The most difficult of all bookkeeping errors to detect is that of posting items to a wrong account; but as the accounts in the loose-leaf ledger follow one another in alphabetical order there is less liability of falling into errors of any kind.

The Transfer Ledger. A characteristic of loose-ledgers is the separation of active and dead accounts. The current ledger contains all active, and the transfer ledger the suspended or closed (dead) accounts, the latter, as well as all filled pages, being eliminated and transferred after the monthly or weekly balance, so that the bookkeeper has to deal with only current items, while the whole of his previous work is kept accessible and clearly indexed. This entirely obviates the bi-annual transfer, and keeps large accounts of several pages per month or year always together in one place, thereby reducing the labour of going over an old account.

At the time of the trial balance all congestion of work is avoided, and at the same time the results are rapidly arrived at by dividing the ledger among any number of clerks working simultaneously. A rule should be made in the office that no transfer of closed accounts or filled pages may be made from the current ledger until after the monthly or weekly balance has been made. Firms usually begin by drawing up monthly balances and statements, but they very soon adopt the plan of weekly or even daily balances when they find how easily the system works, more especially if they happen to have a tabulating or adding machine.

The best practice in accounting with loose-leaf ledger is to post from direct charges by what is known as the Bill and Charge system. A lad arranges the charges beforehand in strict alphabetical or numerical order in accordance with the

scheme of the ledger. As it is inadvisable to include more than 500 accounts in one ledger, the alphabet is divided into four or five sections, each in a binder. When posting, you begin at the beginning of the ledger, and work straight through to the end of the last ledger; you will then have come to the end of the charges and will not have had to consult the index once during the whole process. Bookkeepers and accountants will readily understand what a vast saving of time is thus effected; there is besides an economy in the cost of labour which is one of the valuable features of the new business methods—the accomplishment of part of the bookkeeper's work by lower-priced help.

In order to avoid interruption of work on the ledger and waste of time, a temporary holder with a spring back is provided, having a capacity of 50 sheets to 100 sheets for the reception of new accounts or transfers which come in during the day. The principle of the loose leaf applies equally well to all the other books used in accounting, such as the cash book, journals, cost books, bills receivable and bills payable; purchase, order, and invoice books.

Loose-leaf Cash Book. In the loose-leaf cash book the ruling of the leaves and distribution of the accounts can be made to conform to the practice of the firm. The advantage of this form of cash book lies in the fact that receipts and disbursements are handled separately on leaves of two different colours, every line of which can be utilised; there may be in a month or a week ten leaves for receipts and only two for disbursements or vice versâ. The question of safety, should it be raised against the loose-leaf cash book, may be thus disposed of: the loose-leaf cash book should be paged just the same as the bound book. The cashier uses the leaves consecutively, and if a leaf be spoiled or torn it must be left in its place as though it had been used. The cashier must be made responsible for every leaf of his book; any tampering with it by extracting leaves would, therefore, be easily detected. The current cash is carried in a spring-back holder and as soon as the balance has been brought forward and the posting completed, the leaves are removed to a permanent binder, and so arranged that the receipts follow each other from week to week and month to month. The disbursements are kept to themselves behind a division leaf tabbed "disbursements" or in a separate binder. This cash book proper is stored in the vault or safe, and is no longer accessible to any not authorised by signed requisition to consult it.

Loose-leaf Invoice and Purchase Book. These possess the unique advantage of never becoming filled. By means of a scheme of indexing, they may be made to serve as purchase ledgers, showing at all times the accounts payable. The bills of each firm are filed in succession, so that reference to old accounts is a simple matter. The invoice book, in spite of being permanent, does not become cumbersome, for as soon as accounts are paid, they are transferred to another binder kept for reference only. The bookkeeper can post from this book direct without additional entry, and the *accounts payable* need no other proof of accuracy than the Purchase Record.

A simple form of leaf for this book contains the following columns—date, number, from whom purchased, amount of bill, discount, department, rebates, O.K.'s, date received, date paid, amount, remarks

The Price Book. The loose-leaf system has sounded the knell of the consecutively printed price book. The prices of goods are printed on one side of the paper and well spaced out, so that each item can be cut out, dated, and pasted in the loose-leaf price book. As each entry, as well as each leaf is independent, any line of prices may be charged without affecting the balance of the book, or necessitating revision and reprinting; the new entry is simply pasted over or at the side of the old one. For goods which fluctuate in price, the system is invaluable, as changes in price can be compared *on the same sheet*, each line of goods in this case having a page to itself.

Revolution in Rulings. The facilities afforded by the system for special rulings in loose leaves has led to a number of changes in ruling. The most notable and practical is the centre ruling for debit and credit columns divided by a balance column. The advantage of this balance column in the ledger lies in the possibility it affords of bringing down the balances in pencil at the end of the month or calling them out to the adding clerk, if the firm possess an adding or tabulating machine. It frequently happens that balances are obtained without duplicating the figures. Balancing in sections is also extensively practised and many bookkeepers handle their work so that they are practically always in a state of balance.

Double-double Abandoned. It does not seem practical to use a *double-double* ruling in loose-leaf books under any circumstances. The argument adduced in favour of its use—which is, to avoid more frequent carrying forward of totals or balances—is a fallacy in the case of the loose-leaf ledger, for it is no more troublesome to carry forward a balance to the succeeding page on a single leaf than to the second section of a double-double page. The use of double-double ruling either necessitates a very wide page and cumbersome ledger or very narrow columns for posting, both of which are inconvenient. With the loose-leaf accounting books as many leaves as are necessary for an account may be provided without trouble or reindexing; there is, therefore, no longer any advantage in using double-double in order to provide extra posting space on one page. It is no longer necessary either to have such long ledgers, running sometimes from 24 in. to 30 in.; with the loose-leaf ledger the $9\frac{1}{4}$ in. by 11 in. page or the 11 in. by 11 in., which allows a line for each day of the month and a few extra lines, is found to be sufficient even with large business houses.

The Binders. As the loose-leaf books do not need to be renewed like the bound books, new leaves alone being required, the binders are made very durable and strong with a capacity of from 500 to 1,000 leaves (2,000 pages). The leaves are punched with slit holes to allow of the leaves springing or slipping round the posts at any point; the book can thus be opened wide, lying quite flat so that the leaves are easily manipulated. It is impossible to extract a leaf without tearing it, unless the binder is unlocked. Leaves are just as securely held whether there be few or many. The binders can, therefore, be enlarged by the bookkeeper up to about 6 in., which accommodates 1,000 leaves, and makes as bulky a volume as can be conveniently used. So-called self-indexing features have been devised for the improvement of the bound ledger, but their utility is always restricted by their finite nature and inelastic limitations; they cannot compare with the loose-leaf book, *the only ledger which will index alphabetically in correct sequence for different terms* by means of its interchangeable leaves.

VERBS

The Subjunctive in Principal Propositions. In addition to what has been said as to the use of the subjunctive in subordinate propositions, it must be observed that this mood is also used in principal propositions, with the following meanings:

1. Command and exhortation; in this case those persons are used which are wanting in the imperative, as: *Venga, venga colui, so io come ricèverlo,* Let the man come, I know how to receive him.

2. Wish or imprecation, as: *Iddio ti guidi e la benedizione di tuo padre t'accompagni,* May God guide thee, and may the blessing of thy father accompany thee.

3. Supposition, as: *O fosse perfidia, o fosse puro caso, il fatto sta che per seguire il suo consiglio ci trovammo ridotti a mal partito,* Whether it was perfidy or mere chance, the fact is that, in consequence of following his advice, we found ourselves in a bad position.

4. Doubt, as: *Che ábbia torto io!* It may be that I am wrong!

5. Condition, regret, reproach, as: *T'avessi incontrato prima! quanto tempo avrei risparmiato,* Had I met you before, how much time I would have saved.

6. Concession, as: *Abbia tutti i difetti di questo mondo, per me è un galantuomo,* He may have all the faults in the world, for me he is an honest man.

Tenses and their Use. The present tense represents a fact or an action as happening at the very moment of speaking, as: *Cammino,* I walk, or I am walking; *piove,* it rains, or it is raining.

The present is also used:

1. To indicate anything that happens in a period of time not entirely elapsed, as: *Questo mese tutto mi va male,* This month everything goes badly with me.

2. To indicate facts which are always true, as in general statements and proverbs, as: *Dimmi con chi vai, e ti dirò chi sei,* Tell me what company you frequent, and I will tell you who you are.

3. Instead of the past tense, in animated narration, and it is then called the Historical Present, as: *Il giorno dopo entra in càmera, ma non vede nessuno,* The next day he enters the room, but he sees no one.

NOTE. Instead of the historical present, an historical infinitive is sometimes used, as: *Ed ecco verso noi venir per nave—un vècchio bianco* (Dante), And lo! there comes towards us a hoary old man in a boat.

4. Instead of the future, when we wish to express a fact with emphasis or resolution, as: *Se torno a nàscere!* If I am born again!

The imperfect represents a past action, but as a continuous one. It is used:

1. To indicate something not yet entirely accomplished, when something else happens, as: *Quando egli entrò io scrivevo,* When he entered, I was writing.

2. Instead of the past, and it is then called the historical imperfect, as: *Un mese dopo, la poveretta moriva* (for *morì*), A month after, the poor woman died.

3. Instead of the present, as a slightly less direct form, used for the sake of courtesy, as: *Arriva in tempo, volevo domandarle una cosa,* You arrive in time, I wish to ask you something.

The present of the conditional is similarly used, as in English: *Vorrei domandarle,* I should like to ask you, instead of *voglio domandarle,* I want to ask you. So also *non saprei,* resembling the English "I could not tell you," instead of *non so,* I do not know.

4. Instead of the perfect of the conditional, especially with the verbs *potère, dovère, bisognare,* as: *Potevate dìrmelo* (*avreste potuto dìrmelo*), You could have told me; *Non dovevate farlo partire* (*non avreste dovuto*), You ought not to have let him go.

The past definite (*passato remoto*) indicates a fact that happened in the past, having no relation with present time, as: *Quando ci vide, fuggì,* When he saw us, he ran away.

The past indefinite (*passato pròssimo*) represents a fact not long ago passed, or having some relation to the present, as: *Perchè non siete venuto stamattina?* Why did you not come this morning? *Non vi ho visto tutta la settimana. Dove siete stato?* I have not seen you all the week. Where have you been?

NOTE. The student should observe that the Italian *passato pròssimo* can be used to represent a more distinct past time than the English perfect compounded with "have"; as: *L'ho veduto l'altro giorno,* lit. I have seen him the other day.

The pluperfect indicates a past action anterior to another action also passed, as: *Non seppe repètere una parola di quanto gli avevo detto,* He was not able to repeat a word of what I had been telling him.

The future tense indicates an action that is yet to take place, as: *Ti scriverò,* I will write to you. It is also used:

1. To express a command or an exhortation, as *Domani vi leverete alle sette,* To-morrow you shall get up at seven; *Lei mi permetterà,* You will allow me.

2. To express a supposition or a probability, as: *Chi è? Sarà mio fratello,* Who is it? It will be my brother (more usually, It may be, etc.).

3. To represent a shade of uncertainty, as: *Avrò torto, ma non posso fare altrimenti,* I may be wrong, but I cannot do otherwise.

The future perfect (*futuro anteriore*) indicates that something takes place previously to a future event, as: *Quando avrò finito glielo mostrerò,* When I (shall) have finished, I will show it to you.

Like the simple future, the perfect future may also be used to express a conjecture, as: *Come va che il suo amico non viene? Avrà perduto il treno,* How is it that your friend does not come? It may be that he has lost the train.

INTERJECTIONS

Interjections, strictly speaking, are not real words, but only sounds, expressing a sudden emotion, as joy, grief, surprise, contempt, etc. The number of real interjections being very limited, contrary emotions are often expressed by the same sound, the meaning of which is modified by a mere inflection of the voice, or by a gesture accompanying it.

Certain verbs, adverbs, and nouns are also used as interjections, as: *sta! bene! bravo!*

The following are the interjections most frequently used, with the meaning they generally have:

Calling: *ehi! ohe! olà! 'ss!*
Doubt: *mah!*
Grief: *ahi! ohi! ah! oimè!*
Incertitude: *uhm!*
Negation and disdain: *oibò! poh!*
Surprise or wonder: *ah! eh! oh!*
Threatening: *ehm!*
Vexation or irritation: *ih! ah!*
Weariness or impatience: *uh! aùff!*
Wish, desire: *magàri! deh!*

Of the verbs, adverbs, nouns, and other expressions used as interjections, the commonest are:

abbasso . . . ! down with . . . !
addio! good-bye!
aiuto! help!
al fuoco! fire!
all'armi! to arms!
animo! cheer up!
arrivederci is the French *au revoir*
badate! take care!
bella! capital!
bene! well!
bravo! bravo!
buono! good!
che! what!
che peccato! what a pity!
chi va là? who goes there?
davvero! indeed!
diavolo! diamine! per dince! the deuce!
dio mio! dear me!
eccomi! I am coming; yes, here I am
evviva! hurrah!
evviva . . . ! viva . . . ! long live . . . !
fuori! be gone!
guai! woe!
guardate! behold!
orsù! come on! courage!
piano! gently!
possibile! veramente! good gracious!
su! su! come along!
vergogna! shame!
via! eh via! nonsense!
zitto! silence! hush! etc., etc.

Adjectives, as *bello, buono, bravo, zitto,* also when used as interjections, agree in gender and number with the person to whom they are referred, as: *brava!* (to a lady), *brave!* (to several ladies), *zitti* (to several gentlemen or to gentlemen and ladies), *belli!* (admiring pictures, for instance), etc.

Exercise LVI.

1. Vergogna! alla vostra età fare una cosa simile. 2. Ehi! facchino, qual'è il treno per Nàpoli? 3. Viva il Re! viva la Regina! 4. Che peccato! hanno rovinato tutti i fiori. 5. Piano! piano! non vedete che in questo modo romperete tutto? 6. Ahimè! sono rovinato; non so che cosa fare. 7. Badate! c'è un gran fosso nel mezzo del giardino. 8. Che bella mùsica e che buoni artisti! Bravi! bis! 9. Su! non bisogna pèrdersi d'ànimo; il diàvolo non è così nero come si dipinge. 10. Dio mio, con questi ragazzi c'è da pèrdere la testa! 11. Aiuto! al fuoco! le fiamme minàcciano un depòsito di petròlio. 12. Ehi di casa! buona gente, dàtemi allòggio per questa notte. 13. Bella questa! voi avete rotto lo spècchio, e volete ch' io lo paghi. 14. Ih! che fracasso! non è possibile dormire. 15. Auff! che noia; andiamo via.

Key to Exercise LVI.

1. Shame! at your age to do such a thing. 2. Hi! porter, which is the train for Naples? 3. Long live the King! Long live the Queen! 4. What a pity! they have spoiled all the flowers. 5. Gently! gently! don't you see that in this way you will break everything? 6. Alas! I am ruined; I do not know what to do. 7. Take care! there is a large ditch in the middle of the garden. 8. What good music, and what good artists! Bravo! Encore! 9. Cheer up! one must not lose courage; the devil is not so black as he is painted. 10. Dear me! these boys are enough to drive one mad. 11. Help! fire! the flames are threatening an oil warehouse. 12. Hulloa! good people, give me a shelter for to-night. 13. This is capital! you have broken the looking-glass, and you want me to pay for it. 14. What a noise! it is not possible to sleep. 15. What a nuisance! let us go away.

Formole di Lettere

Mr. N. N., N. N., Esq., *Signor N. N.*
Mrs. N. N., *Signora N. N., Distintissima signora N. N.*
Miss N. N., *Signorina N. N.*
Sir, *Signore*; Dear Sir, *Egregio signore.*
Gentlemen, *Signori.*
My dear friend, *Carissimo amico.*
Dear Mrs. N., *Gentilissima signora* (*N.*).
Dear Miss N., *Gentilissima signorina* (*N.*).
I am, I remain, *Mi creda.*
Yours truly, *Suo devotissimo.*
Yours affectionately, *Suo affezionatissimo.*

Note. The student is advised to use a good English-Italian and Italian-English dictionary, such as that by Melzi, 6s. net, Hirschfeld Bros., Ltd., 13, Furnival Street, E.C.

ESPERANTO

By Harald Clegg

Suffixes

EDZ denotes a married person.

Examples: *Edzo,* husband; *edzino,* wife. *Doktoro,* doctor; *doktoredzino,* doctor's wife. *Poetino,* poetess; *poetinedzo,* poetess' husband.

EJ denotes a place where an action occurs.

Examples: *Dormi,* sleep; *dormejo,* dormitory. *Kuiri,* cook; *kuirejo,* kitchen. *Preĝi,* pray; *preĝejo,* church.

This suffix is sometimes applied to noun-roots, in which case it indicates place of origin. Thus, *orejo* would be "gold-field" and *fruktarbejo* "orchard."

EM denotes propensity or disposition.

Examples: *Kredi,* believe; *kredema,* credulous. *Labori,* work; *laborema,* laborious. *Ŝpari,* spare; *ŝparema,* frugal.

ING denotes a holder; that into which a *single* object is appropriately placed.

Examples: *Glavo,* sword; *glavingo,* scabbard. *Cigaredo,* cigarette; *cigaredingo,* cigarette-holder. *Violono,* violin; *violoningo,* violin-case.

UJ denotes that which bears or contains.

Examples: *Mono*, money; *monujo*, purse. *Anglo*, Englishman; *Anglujo*, England. *Piro*, pear; *pirujo*, pear-tree.

In naming a country the word *lando* is very often substituted for this suffix.

Examples: *Belgo*, a Belgian; *Belgolando*, Belgium. *Ruso*, a Russian; *Ruslando*, Russia.

And in place of UJ, when trees are indicated, the word *arbo* is very often used.

Examples: *Pomo*, apple; *pomarbo*, apple-tree. *Ĉerizo*, cherry; *ĉerizarbo*, cherry-tree.

Subordinate Clauses

The tense of a simple or compound Esperanto verb in a subordinate clause must always adhere logically to the idea to be rendered, and must never, as often occurs in English, suffer itself to be influenced by a verb in the principal sentence. In English we should say: "I asked him whether he *had* a son," whereas the question asked was whether he *has* a son, this being the original terse of the verb used by the speaker. In Esperanto sentences of this kind the tense of the subordinate verb must remain that which it was when first spoken. Thus, the above sentence would be translated:

"*Mi demandis al li, ĉu li havas filon.*"

A few further examples will help to explain this principle.

My brother said that he would consent, *Mia frato diris ke li konsentos.* The prince asked who she was, *La princo demandis kiu ŝi estas.* My father asked me when I was going to visit him, *Mia patro demandis al mi kiam mi vizitos lin.* She told me that she had sold the house, *Ŝi diris al mi ke ŝi estas vendinta la domon.*

In simple sentences, and principal sentences of complex sentences, too, the student must be careful to guard himself against misuse in English.

Examples: When I am dead you will be sorry, *Kiam mi estos mortinta, vi estos malfeliĉa*; To-morrow is Sunday, *Morgaŭ estos Dimanĉo*; If you loved me I would love you, *Se vi amus min, mi amus vin.*

Vocabulary

afrank', frank or prepay a letter
balanc', sway, swing
balbut', stammer, stutter
dediĉ', dedicate
eks', ex, late
fabel', story, tale
font', source
funebr', funereal
garanti', guarantee
gros', gooseberry
haven', port, harbour
kav', cave, hollow
kel', cellar
kruĉ', jug, pitcher
legom', vegetable
magi', magic
mien', mien, air
milit', war
mov', move (v.t.)
nuks', nut
ofer', sacrifice, offer
ofic', office (duty)
pilk', play-ball
pipr', pepper
prun', plum
pugn', fist
rad', wheel
rem', row (v.)
riproĉ', reproach
sal', salt
serur', lock (subst.)
simil', like, similar
solv', solve
staci', station (railway)
sup', soup
surtut', overcoat
ŝarĝ', load, burden
ŝink', ham
ŝtup', step, stair
ŝvel', swell (v.i.)
tajlor', tailor
taŭg', be fit for
tim', fear
traf', reach, fall in with
trakt', treat of
tren', drag, trail
turn', turn (v.a.)
tuŝ', touch (v.t.)
vast', wide, vast
vek', wake, arouse (v.t.)

Exercise XIX.

Note. The participles are to be used where possible.

He unexpectedly arrived in London last night. In the middle of my garden there grow pear-trees, plum-trees, and gooseberry bushes. Besides those you find all kinds of vegetables. The servant has just laid the covers on the table, but where are the soup-tureen, the salt-cellar, the pepper-box, and the bell? Having been aroused from sleep the tailor opened his (the) eyes and saw the locksmith standing by him. Being naturally very timorous, he stammers somewhat whenever (any) one approaches him. Running rapidly to the station, he just caught the train as it started. The letters were sent postage paid. What a strange swelling there is on your face! This work has been dedicated to my most loved friend. Here are the purse and the jewel-case which I found on the staircase near my office. Many thanks! This cigar-holder strongly resembles mine. In crossing the street the child suddenly fell under the wheels of a carriage. Having been loaded by the stevedores the ship went out of the harbour. The tailor guaranteed that this overcoat was made (out) of the best cloth. In rowing I broke one of the oars. The story of which he was treating is not altogether true. Turning my eyes to the wide sea, I saw the ship slowly moving away until it disappeared. Happily the terrible war between Russia and Japan is now over, but we shall always think of those dead warriors who needlessly offered their lives for their countries.

Key to Exercise XVII.

1. Servant (female), brood of chickens, physician, robber-chief, spinner, temptation, carpenter, butcher, service, nurse (female), duckling, explorer, shepherd, lady-artist, puppy, filly, sculptor, lady-doctor, preaching. The band of robbers were condemned by the judge. A writer (*verkisto*) writes books, and a writer (*skribisto*) simply transcribes papers. They heard the fusillade and the flying bullets. The clerk has confessed that he took the ring and now he is about to be tried (judged) by the judge. When the (female) spinner was ill, the physician visited her, but after some time she died. The iron was forged by the smith.

2. Tiu ĉi estas la rimedo, kiu estas rekomendata de la maristo. La pordo estis alriglita kontraŭ la rabisto. La suspektato estas denuncita de la komizo, kaj li certe estos severe punata. Tiuj ĉi versoj estas elĉerpitaj de la tradukisto, el la verkoj de la plej bonaj verkistoj. Iuj staris sur seĝoj kaj benkoj por pli bone vidi, sed la parolisto ne povis esti aŭdata. Ne estas eble vidi flugantan kuglon. Li estis sonĝanta pri sia malproksima hejmo, kiun eble li neniam vidos plu. Neniu havas la rajton juĝi. Memoru, ke kiu juĝas, tiu estos juĝata. Nun estas nokto, kaj ni povas vidi la brilantajn stelojn super la saŭmanta maro. Amikoj, malofte vidataj, estas amikoj forgesitaj.

Key to Exercise XVIII.

Mi pafis sagon en la aeron, sed perdinte ĝin, mi konkludas ke mi ne estas spertulo. Tiu ĉi ekzercaro, presite per linotipa maŝino, estas nun preta. Pentrante tiun pentraĵon, kaj desegnante ĉi-tiun desegnaĵon, li altiris multe da atento. Vi estas parolinta sensencaĵon. Admirinte la belecon de la meblaro kaj ornamaĵoj, ili prezentis arĝentan moneron al la pordisto. Ŝtalo estas fleksebla, sed fero ne estas fleksebla. Ĉiuj elmigrantoj malŝparis sian monon, kaj alveninte en kompatinda stato, ili ekscitite plendis

pri sia malfeliĉo. Tiu kantanto estas nek aŭdinda, nek vidinda. La skribinto de tiu ĉi letero estas la unua atestanto. Fininte sian manĝadon, li sonoris. Jen estas la rostita bovaĵo. Ĉu vi preferas bovidaĵon, ŝafaĵon aŭ ŝafidaĵon, sinjoro? Tia spriteco nenion signifas. Forprenu ĉi-tiun acidaĵon. Kiam la masonisto estis mortonta, liaj heredontoj venis por ricevi lian benon, kaj dividi lian riĉaĵon. Ilia rapideco poste pikis al ili la konsciencon. Estas pli bone morti malriĉa, ol neamata. La propono estis zorge preparita kaj poste prezentata al la societanaro. Vi estus multe embarasata, se vi scius kiel malprudenta li estas. La arbo estas fendita de la arbaristo per hakilo. Mi povas konscience atesti tion.

GREEK

By G. K. Hibbert, M.A.

ACCIDENCE. VERBS—continued

Regular Verbs in -μι. Hitherto, with the exception of the two verbs εἰμί, be, and εἶμι, go, we have given the conjugation only of verbs in -ω. We now come to the second class, verbs in -μι. These are distinguished in their inflection from the verbs in -ω almost exclusively in the tenses formed from the present and second (or strong) aorist stems. In the other tenses they agree with verbs in -ω. The following is the conjugation of the present, imperfect and second aorist tenses of the four typical verbs ἵστημι, set; τίθημι, put; δίδωμι, give; δείκνυμι, show:

Active Voice

Present Indicative

ἵστημι	τίθημι	δίδωμι	δείκνυμι
ἵστης	τίθης	δίδως	δείκνυς
ἵστησι	τίθησι	δίδωσι	δείκνυσι
ἵστατον	τίθετον	δίδοτον	δείκνυτον
ἵστατον	τίθετον	δίδοτον	δείκνυτον
ἵσταμεν	τίθεμεν	δίδομεν	δείκνυμεν
ἵστατε	τίθετε	δίδοτε	δείκνυτε
ἱστᾶσι	τιθέασι	διδόασι	δεικνύασι

Imperfect Indicative

ἵστην	ἐτίθην	ἐδίδουν	ἐδείκνυν
ἵστης	ἐτίθεις	ἐδίδους	ἐδείκνυς
ἵστη	ἐτίθει	ἐδίδου	ἐδείκνυ
ἵστατον	ἐτίθετον	ἐδίδοτον	ἐδείκνυτον
ἱστάτην	ἐτιθέτην	ἐδιδότην	ἐδεικνύτην
ἵσταμεν	ἐτίθεμεν	ἐδίδομεν	ἐδείκνυμεν
ἵστατε	ἐτίθετε	ἐδίδοτε	ἐδείκνυτε
ἵστασαν	ἐτίθεσαν	ἐδίδοσαν	ἐδείκνυσαν

Second Aorist Indicative

ἔστην	[ἔθην]	[ἔδων]	None
ἔστης	[ἔθης]	[ἔδως]	
ἔστη	[ἔθη]	[ἔδω]	
ἔστητον	ἔθετον	ἔδοτον	
ἐστήτην	ἐθέτην	ἐδότην	
ἔστημεν	ἔθεμεν	ἔδομεν	
ἔστητε	ἔθετε	ἔδοτε	
ἔστησαν	ἔθεσαν	ἔδοσαν	

NOTE. ἔστην is intransitive, I stood, not I set. The first aorist ἔστησα has the transitive sense, *I set, I made to stand.* The forms in square brackets, ἔθην, ἔδων, etc., are never used: for the singular forms of the second aorist the forms of the first aorist are borrowed—ἔθηκα, ἔθηκας, ἔθηκε, and ἔδωκα, ἔδωκας, ἔδωκε.

Present Subjunctive

ἱστῶ	τιθῶ	διδῶ	δεικνύω
ἱστῇς	τιθῇς	διδῷς	δεικνύῃς
ἱστῇ	τιθῇ	διδῷ	δεικνύῃ
ἱστῆτον	τιθῆτον	διδῶτον	δεικνύητον
ἱστῆτον	τιθῆτον	διδῶτον	δεικνύητον
ἱστῶμεν	τιθῶμεν	διδῶμεν	δεικνύωμεν
ἱστῆτε	τιθῆτε	διδῶτε	δεικνύητε
ἱστῶσι	τιθῶσι	διδῶσι	δεικνύωσι

Second Aorist Subjunctive

	θῶ	δῶ	None
στῇς	θῇς	δῷς	
etc.	etc.	etc.	

Present Optative

ἱσταίην	τιθείην	διδοίην	δεικνύοιμι
ἱσταίης	τιθείης	διδοίης	δεικνύοις
ἱσταίη	τιθείη	διδοίη	δεικνύοι
ἱσταίητον	τιθείητον	διδοίητον	etc.,
or ἱσταῖτον	or τιθεῖτον	or διδοῖτον	like verbs
ἱσταιήτην	τιθειήτην	διδοιήτην	in -ω
or ἱσταίτην	or τιθείτην	or διδοίτην	
ἱσταίημεν	τιθείημεν	διδοίημεν	
or ἱσταῖμεν	or τιθεῖμεν	or διδοῖμεν	
ἱσταίητε	τιθείητε	διδοίητε	
or ἱσταῖτε	or τιθεῖτε	or διδοῖτε	
ἱσταίησαν	τιθείησαν	διδοίησαν	
or ἱσταῖεν	or τιθεῖεν	or διδοῖεν	

Second Aorist Optative

σταίην	θείην	δοίην	None
σταίης	θείης	δοίης	
etc.	etc.	etc.	

Present Imperative

ἵστη	τίθει	δίδου	δείκνυ
ἱστάτω	τιθέτω	διδότω	δεικνύτω
etc.	etc.	etc.	et

Second Aorist Imperative

στῆθι	θές	δός	None
στήτω	θέτω	δότω	
στῆτον	θέτον	δότον	
στήτων	θέτων	δότων	
στῆτε	θέτε	δότε	
στήτωσαν	θέτωσαν	δότωσαν	
or στάντων	or θέντων	or δόντων	

Present Infinitive

ἱστάναι	τιθέναι	διδόναι	δεικνύναι

Second Aorist Infinitive

στῆναι	θεῖναι	δοῦναι	—

Present Participle

ἱστάς	τιθείς	διδούς	δεικνύς

Second Aorist Participle

στάς	θείς	δούς	—

NOTE. ἱστάς is declined like λύσας, and τιθείς like λυθείς. διδούς is declined like λύων, except in nominative and vocative singular :

Nom., Voc.	διδούς	διδοῦσα	διδόν
Gen.	διδόντος	διδούσης	διδόντος
	etc.	etc.	etc.

δεικνύς is thus declined :

Nom., Voc.	δεικνύς	δεικνῦσα	δεικνύν
Acc.	δεικνύντα	δεικνῦσαν	δεικνύν
Gen.	δεικνύντος	δεικνύσης	δεικνύντος
	etc.	etc.	etc.

PASSIVE AND MIDDLE VOICES

Present Indicative

ἵσταμαι	τίθεμαι	δίδομαι	δείκνυμαι
ἵστασαι	τίθεσαι	δίδοσαι	δείκνυσαι
ἵσταται	τίθεται	δίδοται	δείκνυται
ἵστασθον	τίθεσθον	δίδοσθον	δείκνυσθον
ἵστασθον	τίθεσθον	δίδοσθον	δείκνυσθον
ἱστάμεθα	τιθέμεθα	διδόμεθα	δεικνύμεθα
ἵστασθε	τίθεσθε	δίδοσθε	δείκνυσθε
ἵστανται	τίθενται	δίδονται	δείκνυνται

Imperfect Indicative

ἱστάμην	ἐτιθέμην	ἐδιδόμην	ἐδεικνύμην
ἵστασο	ἐτίθεσο	ἐδίδοσο	ἐδείκνυσο
ἵστατο	ἐτίθετο	ἐδίδοτο	ἐδείκνυτο
etc.	etc.	etc.	etc.

Second Aorist Indicative (Middle only)

None	ἐθέμην	ἐδόμην	None
	ἔθου	ἔδου	
	ἔθετο	ἔδοτο	
	etc.	etc.	

Present Subjunctive

ἱστῶμαι	τιθῶμαι	διδῶμαι	δεικνύωμαι
ἱστῇ	τιθῇ	διδῷ	δεικνύῃ
ἱστῆται	τιθῆται	διδῶται	δεικνύηται
etc.	etc.	etc.	etc.

Second Aorist Subjunctive (Middle only)

None	θῶμαι	δῶμαι	None
	θῇ	δῷ	
	θῆται	δῶται	
	etc.	etc.	

Present Optative

ἱσταίμην	τιθείμην	διδοίμην	δεικνυοίμην
ἱσταῖο	τιθεῖο	διδοῖο	δεικνύοιο
ἱσταῖτο	τιθεῖτο	διδοῖτο	δεικνύοιτο
etc.	etc.	etc.	etc.

Second Aorist Optative (Middle only)

None	θείμην	δοίμην	None
	θεῖο	δοῖο	
	θεῖτο	δοῖτο	
	etc.	etc.	

Present Imperative

ἵστασο	τίθεσο	δίδοσο	δείκνυσο
or ἵστω	or τίθου	or δίδου	
ἱστάσθω	τιθέσθω	διδόσθω	δεικνύσθω
etc.	etc.	etc.	etc.

Second Aorist Imperative (Middle only)

None	θοῦ	δοῦ	None
	θέσθω	δόσθω	
	etc.	etc.	

Present Infinitive

ἵστασθαι	τίθεσθαι	δίδοσθαι	δείκνυσθαι

Second Aorist Infinitive (Middle only)

None	θέσθαι	δόσθαι	None

Present Participle

ἱστάμενος	τιθέμενος	διδόμενος	δεικνύμενος

Second Aorist Participle (Middle only)

None	θέμενος	δόμενος	None

The other tenses of these verbs are conjugated like verbs in -ω. They are :

Future Indic.	στήσω	θήσω	δώσω	δείξω
First Aor. Indic.	ἔστησα	ἔθηκα	ἔδωκα	ἔδειξα
Perfect	ἕστηκα	τέθεικα	δέδωκα	δέδειχα

and Passive and Middle accordingly.

ἵστημι has also a second perfect form : infinitive ἑστάναι, participle ἑστώς. This is used only in dual and plural in the indicative : dual ἕστατον, ἕστατον ; plural ἕσταμεν, ἕστατε, ἑστᾶσι.

ἵημι, send, is conjugated like τίθημι, but the third plural present indicative is ἱᾶσι. It has future ἥσω, aorist ἧκα, perfect εἷκα, perfect passive εἷμαι, aorist passive εἵθην.

φημί, say, is conjugated almost like ἵστημι. It has imperfect ἔφην, and future φήσω. The second singular present indicative is φῄς—φημί, φῄς, φησί ; φατόν, φατόν ; φαμέν, φατέ, φασί.

SYNTAX. The Genitive Case

The Greek genitive is a "mixed case," standing both for the genitive proper and for the ablative. In Sanscrit there were eight cases—nominative, vocative, accusative, genitive, dative, ablative, locative, and instrumental. Latin has lost the last two as separate cases, and uses the ablative for both. Greek has lost the ablative as well, and makes the genitive include the old ablative, and the dative include the locative and instrumental.

A. **The Genitive Proper.** The genitive proper most often qualifies a noun, less often an adjective, adverb, or verb. It denotes 1 Origin. 2. Possession. 3. Object. 4. Quality. 5. Material. 6. Relation of whole and part.

1. ORIGIN, generally of paternity, as Διὸς Ἄρτεμις, Artemis (daughter) of Zeus. Under this head may be classed the "genitive of cause" and the "genitive of exclamation." The Genitive of Cause is common after verbs expressing emotions, as *wonder, pity, envy, revenge*, etc.—as : ζηλῶ σε τοῦ νοῦ, I envy you for your mind. It is also frequent in legal language after verbs of *accusing, acquitting, condemning, convicting*, etc.—as : διώκει με φόνου, He prosecutes me for murder ; φεύγειν φόνου, to be charged with murder. The Genitive of Exclamation gives the cause of the astonishment or grief —as : ὤμοι ἐμῆς ἄτης, Alas, for my infatuation !

2. POSSESSION, the chief noun being often omitted—as : τὰ τῶν Ἑλλήνων, the possessions of the Greeks. It may be used predicatively after a verb—as : ἐστιν ἀνδρὸς σοφοῦ κοσμίως βιοῦν, It is the part of a wise man to live discreetly. With this may be classed the "Subjective Genitive," denoting the subject of an action or feeling—as : ἡ τοῦ δήμου εὔνοια, the goodwill felt by the people. This is sharply contrasted with the next use.

3. OBJECT, often called the "Objective Genitive," denoting the direction or object of the action, or feeling. After a noun—as : ἕρκος πολέμου, a protection against war ; πεῖρα ἐχθρῶν, an attack on one's enemies ; τὸ Μεγαρέων ψήφισμα,

the decree concerning the Megareans (*not* proposed by them); ἡσυχία ἐχθρῶν, peace from foes. After an adverb—as: λάθρῃ Λαομέδοντος, unknown to Laomedon. After an adjective or participle—as: ἐπίστροφος ἀνθρώπων, conversant with men; τόξων εὖ εἰδώς, well skilled in the bow. After a verb, to express (*a*) direction of physical effort—*e.g.*, after verbs like *begin, rule, try, touch, aim at, desire, guide, reach, fail of*—as: ἔτυχε (τυγχάνω) οἴκτου, He gained pity; ἅψασθαι (ἅπτομαι) χειρός, to cling to someone's hand; οὐ πολέμου ἄρχομεν, We do not begin war. (*b*) direction of mental effort, after verbs like *hear, know of, speak of, remember, remind, forget, perceive*—as: φωνῆς ἀκούω, I hear a voice; ἀλκῆς μνήσασθαι, to remember one's strength.

4. Quality or Description—as: ὄμμα τόλμης πικρᾶς, an eye of cruel daring; τινὲς τῆς αὐτῆς γνώμης, some men of the same opinion. With this we may class the "Genitive of Price"—as: πέντε μνῶν τιμᾶται, He is valued at five minae; ἄξιός ἐστι θανάτου, He is worthy of death; ποσοῦ διδάσκει; For what price does he teach? Also the "Genitive of Definition"—as: ἕρκος ὀδόντων, a fence formed by the teeth.

5. Material—as: εὐνὴ ἐσθῆτος μαλακῆς, a bed of soft clothes; αἱ δὲ βόες χρυσοῖο (Homeric genitive form) τετεύχατο κασσιτέρου τε, The cows were wrought in gold and tin.

6. Partitive Genitive—*i.e.*, the genitive of a noun which in the nominative denotes a divisible whole—as: δέπας οἴνου, a measure of wine; θεῶν Διί, to Zeus among the gods; πολὺ τῆς γῆς, much of the land. It is often used after an adverb—as: ἄλλοθι γαίης, in another land (*lit.* elsewhere of land). But the most important use is after a verb: (*a*) Predicatively after "to be"—as: ἤθελε τῶν μενόντων εἶναι, He wished to be one of those who remained. (*b*) The genitive denoting that of which part, not the whole, is given or taken—as: τῆς ἑαυτοῦ γῆς ἔδωκε, He gave some of his own land. Similarly after verbs like *fill, lack, enjoy, taste, smell, spare, share*, etc.—as: κρομμύων ὀσφραίνομαι, I smell onions; μέλιτος γεύεσθαι, to taste honey; μετέχω τῆς λείας, I share the spoil. Sometimes after a negative adjective—as: ἀδωρότατος χρημάτων, taking (of) no bribes. (*c*) A genitive of *place* or *time* may be used in loose dependence on a verb to denote the limits within which the action is confined, as the accusative is used to denote the extent of the action. *Place:* ἔρχονται πεδίοιο, They go through the plain; ποῦ γῆς; Where on earth? In prose this use is found in a genitive neuter of an adjective used adverbially with a verb of "wanting"—as: δέω πολλοῦ, I fail by much; ἐλαχίστου ἐδέησε διαφθεῖραι, It came within an inch of destroying (*lit.* it lacked very little to destroy). It may even be used as a plain adverb, as μικροῦ, nearly. *Time:* νυκτός, by night; δραχμὴν τῆς ἡμέρας, a drachma a day.

B. **The Ablative Genitive.** This denotes the "terminus a quo"—*i.e*, motion or separation from a person, thing, or place. It is used (*a*) after a verb, to denote motion from—as: Ὀλύμποιο (Homeric genitive) κατήλθομεν, We came down from Olympus; or to denote "hearing from" a person, after ἀκούω, κλύω, κ.τ.λ. It may also denote separation in general—as: Τρῶας ἄμυνε νεῶν, He kept the Trojans off from the ships. (*b*) After a comparative—as: μείζων ἐκείνου, greater than he; the idea being "the greater, starting from him, or as viewed from him." This genitive is used after verbs, adjectives, or adverbs implying comparison—as: ἡσσᾶσθαί τινος, to be weaker than someone, to be beaten by him; ἕτεροι τούτων, others than these; ὕστεροι τῆς μάχης, too late for the battle; κάλλιστον τῶν προτέρων, fairest of those before (*i.e.*, fairer than all predecessors); μεγίστην τῶν πρὸ αὐτῆς, greater than any before it.

C. **The Genitive Absolute.** A noun and a participle, not connected with the main construction of the sentence, may stand by themselves in the genitive. This is called the genitive absolute (corresponding to the ablative absolute in Latin)—*e.g.*, δύοντος τοῦ ἡλίου ἀφίκετο, As the sun was setting, he arrived; ἐμοῦ καθεύδοντος ταῦτα ἐγένετο, This happened while I was asleep; τούτων οὐκ ἀφικομένων ἀπήλθομεν, As they had not come, we departed; ταῦτα ἐπράχθη Κόνωνος στρατηγοῦντος, This was done when Conon was general; μηδενὸς ἐπαρκοῦντος ἀπόλωλα, If no one aids, I am ruined. The participle sometimes stands alone, the noun being understood—as: οὕτω δ' ἐχόντων, εἰκός ἐστιν, κ.τ.λ., And this being so (understand πραγμάτων, *lit.* things being so) it is likely, etc. This is the regular construction, the accusative absolute being confined to certain impersonal verbs.

Key to Translation ("The First Glimpse of the Sea").

Thence they marched through the Chalybes and came to a great city which was called Gymnias. From this city the ruler of the country sends a guide for the Greeks, and he coming said that he would bring them to a spot whence they could see the sea. So he led them, and on the fifth day they reach the mountain. When the vanguard were on (the summit of) the mountain and caught sight of the sea, there arose a great shout. Xenophon and the rearguard, hearing it, thought that an enemy was attacking those in front. But when the shouting became more, and those who kept coming up ran at full speed to those who kept on shouting, it seemed to Xenophon to be something more serious (*lit.* greater); so mounting his horse and taking the cavalry, he went to the rescue. Soon, however, they hear the soldiers shouting, "The sea! The sea!" and encouraging one another. Then they all ran; and when they got to the top, there they embraced one another, generals and captains alike, weeping. Immediately the soldiers carry stones and make a great heap. After this the Greeks dismiss the guide, giving him gifts: a horse, a silver vessel, a Persian dress, and money; and he, having shown them a village where they ought to encamp, and the way which they should go, went away in the night.

A CARPET OF FLOWERS

TALL PLANTS & GLASSHOUSES

The Tall-growing Flowers. The Management of Glasshouses. Greenhouse and Hothouse Plants and Ferns for Home and Market. Orchids

By H. H. HAVART

WHEN first laying out a garden, or altering the appearance of an existing one, the proper use of the taller plants is a matter which requires very careful consideration. In a small garden the employment of many tall plants is a mistake, for not only do they overshadow the humbler plants growing at their feet, but their general effect is to make the garden appear smaller than it really is. In fact, the only positions in which tall-growing flowers can be employed with advantage in small gardens is in the borders against a wall or fence. Even then, if there are many of them, they give the place a somewhat military appearance, with their spiky heads standing in rows like bayonets.

In large gardens the tall flowers can be used in profusion almost everywhere, to break up the monotony which would otherwise be produced by the dead level of height of about 2 ft., which is attained by so many of our fairest garden flowers. They may be used in clumps in borders, or in the centres of large beds, or they look particularly charming in beds by themselves set in the middle of an expanse of turf, so that they can be admired at a little distance.

Hollyhock and Larkspur. The hollyhock is one of the most useful of the tall-growing flowers, and, although it is sometimes called old-fashioned, it is without a rival for effectiveness in poor soils. It is no uncommon thing to find these plants self-sown in gardens, but such varieties are best relegated to the wild garden. The choicer sorts, however, deserve to be cultivated everywhere. There are two ways of growing hollyhocks. One is to sow seed in autumn in a cold frame, protecting it during the winter, and putting the little plants out in spring; and the other is to sow in February in heat, and plant out in spring or early summer with the bedding stuff. The former method usually gives sturdier plants. The average height of the hollyhock is about 6 ft. or 7 ft., though there are many instances on record where they have attained an altitude of nearly 20 ft. Nurserymen keep a good many sorts, varying in colour from white to a very dark crimson, which is almost black, and including yellow. There are also double-flowered sorts, all of which are worth growing where there is sufficient space.

The tall-growing larkspur (Delphinium) must not be confounded with the ordinary larkspur of the garden. Though both belong to the same family, the tall larkspur is a perennial [29], while the ordinary larkspur is an annual, and must be sown afresh every season. The perennial larkspurs can be raised from seed, either by sowing in heat in the early spring, and planting out the seedlings where they are to flower, or by sowing in the open ground in the summer, in which event good strong plants will be obtained to bloom the following year. Though the larkspurs do best in loam, they may be made to thrive in a light sandy soil provided it is well manured and freely watered. The many new hybrids embrace all sorts of colours from pale yellow to purple and red, but the rich blue sorts are, perhaps, of the greatest value for general garden purposes. Their average height is about 5 ft., though some of the newer hybrids are much taller. As these larkspurs increase rapidly, they should be dug up and the roots divided every four or five years. When once they have started flowering, they can be made to continue to do so for several months by cutting off a flower spike as soon as it has done blooming, when another one will immediately begin to make its appearance from the root of the plant.

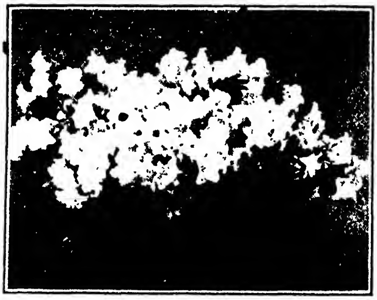
The Garden Foxglove. To the novice who knows the foxglove only as a tall, pale purple plant of our lanes and hedgerows, and is apt to regard it as almost a weed, the idea of growing it in a garden may seem peculiar. As is the case with many other flowers, however, it has been taken in hand by nurserymen, who have raised many new and valuable sorts. Foxgloves require a good deal of space, however, and for that reason must be introduced into a small garden with care, as they soon develop a habit of sowing themselves. Hence, under such circumstances, they are best used as specimen plants in large beds. The method of culture is similar to that already given for the delphinium, and the white variety is the most imposing, often attaining a height of 6 ft. Canariensis, with flowers of a brown colour, and Grandiflora, having yellow blooms, are two interesting sorts if variety is desired, while there are several sorts with spotted flowers known as gloxinia-flowered foxgloves, which are interesting.

As with the larkspur, it is the perennial lupin which is the tall-growing variety of lupins. The culture of lupins is simplicity itself, as the seed simply needs to be sown in any garden soil in spring, and the plants thinned out when they are a few inches in height. The thinning should be drastic, for the lupin is of bushy habit as growth proceeds. Though, strictly speaking, perennials, lupins frequently fail after three or four years, but they are so easily grown from seed that this is not a matter of great importance. The best sort, especially in a poor soil or a rocky corner, is the tree lupin (*Lupinus arboreus*), a stout, bushy plant, with stiff spikes of yellow flowers, reaching to a height of 4 ft. or more. *Lupinus polyphyllus* is an even taller sort, with purple-blue flowers, and of this species there is a white variety—Albus. All the tree lupins are excellent plants to employ in large places where the formal garden melts away into the woodland, and the soil is probably not so rich, or constantly worked, as it is nearer to the house.

Flame Flower or Torch Lily. This is a valuable plant of many names. It boasts two Latin names—*Kniphofia* and also *Tritoma*; while it is also known in different parts of the country as the torch lily, and sometimes as the red-hot-poker plant. It is a hardy perennial, cultivated in the same way as the delphinium, and at its best in a deep rich soil, though it will thrive in practically every garden. When it is desired to increase the plants, they should be taken up and the roots divided, either in spring or autumn. The most popular variety of the flame flower is *Kniphofia aloides*—attaining a height of 6 ft. or more, and

having long flowering spikes of particularly brilliant scarlet flowers, shading to orange. It is the peculiar brilliance of the flower's spikes which has earned for it the name of red-hot-poker plant. An excellent plan to adopt with it, though it is rarely put into practice, is to mass it near the edge of a lake, in company with bamboos and pampas grass, where it gives a charming effect in the autumn.

The Despised Sunflower. Although many people pretend to despise the sunflower (Helianthus) [25], to do so practically amounts to a profession of ignorance regarding the plant. Certainly the ordinary annual sunflower, frequently met with in suburban cottage gardens, is not a plant which it is desirable to employ extensively, as it takes a lot of nourishment out of the soil. Several of the varieties of perennial sunflowers, however, are among the most valuable of the taller flowers of the garden, as the brown-centred yellow blossoms give a blaze of colour equalled by few other flowers of this class. The flowers are not particularly large, being in most of the varieties about 3 in. in diameter, but they are borne in great profusion. Their best use is, perhaps, singly, in beds, as they are of bushy habit, and, consequently, take up a good deal of room, though where there is a large shrubbery they may be massed with good effect. They are raised from seed in the same way as delphiniums, and may be sown in the open air early in April, where they are to flower. It is well to dig them up and part them every three years, as they increase very rapidly, and are apt to get out of hand if left undisturbed for a period longer than this. The best sorts are: Gigantous (10 ft.); Orgyalis (8 ft.); Decapetalus (6 ft.).



23. DUTCH PEARL AZALEA
For the greenhouse

Other Tall Flowers. Though most of the hibiscuses are generally considered to be greenhouse flowers, there are several of them suitable for open-air culture in favoured spots, particularly in the gardens in the south and west of England, and where deep and rich soil is available. In such circumstances, the best way to grow them is to treat them as half-hardy annuals, sowing the seed under heat in February, and planting out in the late spring. The variety most likely to succeed is *Hibiscus manihot*, which sometimes reaches a height of 5 ft. or more, and has yellow flowers, with a dark crimson centre. Another hardy hibiscus, which is often classed as a shrub, is Syriacus (the Rose of Sharon), reaching to a height of 8 ft. or 9 ft. under favourable circumstances. It makes a good centrepiece for a bed on a lawn, but should be used sparingly. There are hybrids with flowers of all colours from white to crimson.

24. GREENHOUSE HEATH

Humea elegans is a half-hardy biennial plant—that is to say, seed must be sown one year for it to bloom the next, after which it dies. The seed should be sown after the middle of the summer in pots of rich soil, and given an occasional dose of liquid manure during the winter, as only by feeding them liberally can the best results be obtained. About a year after sowing they will be ready to plant out, and they may be used either at the back of the border, as a specimen on the lawn, or as centrepieces to a bed. They range from 5 ft. to 8 ft. in height, according to the soil and position in which they are grown, and have long feathery-like spikes of red-brown flowers.

In addition to the foregoing, many beautiful flowering shrubs may, with advantage, be introduced into bed and borders, instead of confining them to the shrubbery. It is necessary to make such introductions with care, as if overdone the tenderer plants will soon be starved to death. Shrubs which are suitable for such a purpose include the hydrangea, pæony, *Daphne mezereum*, some of the choicer rhododendrons, magnolias, flowering currants, spireas, and the mock orange.

How to Manage a Glasshouse. Glasshouses are roughly divided into three sections—the cool house, the intermediate house, and the hot house. In the cool house, no artificial heat of any sort is employed. The intermediate house, which may, perhaps, be more readily recognised by its popular name of "heated greenhouse," is one in which the winter temperature is always kept at least 15° above freezing point, and the hothouse, or stove, where most of the exotics are grown, should always be held up to a minimum of 10° above this. All houses require the same sort of treatment in their general management.

Hot water is the universal system by which houses are heated, and soft water, if it can be procured, is the best to employ, hard water quickly fouling the pipes. With the ordinary upright boilers, coke is practically as good as coal for stoking purposes, and has, at the same time, the merit of being more economical. It will burn longer, however, and maintain a regular heat better, if it is first slightly damped and mixed with coal dust. This latter is the best method to employ when making up the fires to last all through the night, as, if once the temperature of the house is allowed to fall below the point at which it ought to be maintained, fatal results may follow. Every greenhouse should be furnished with maximum and minimum thermometer, the tube of which contains tiny glass indexes, one of which indicates in the morning the lowest point to which the temperature has fallen during the night, while the other shows the highest point touched.

Although the purpose of greenhouses is avowedly to grow tender plants, it must not be forgotten that the more a greenhouse is ventilated, the healthier will be the condition of its occupants, provided the atmospheric conditions are right. On dull, wet, or foggy days, but little air can be given, but when the

weather is bright and warm, the ventilators can be opened all day long, provided an eye is kept on the thermometer. Cleanliness is an essential feature in the management of a greenhouse. Before any potting is done, the pots should be scrubbed perfectly clean, and this cleanliness should be maintained after they are filled by washing them over outside at intervals of a week or two. The shelves of the greenhouse should be washed down at least once every three weeks, and the glass itself, as well. This operation also affords facility for looking over the plants. Such a house cleaning, if it may be so termed, not only benefits the plants themselves, and improves the appearance of the house, but it also helps to keep away insect pests.

Never use cold water in a hothouse when watering plants. It should always be a few degrees higher in temperature than the atmosphere in the house. The best time of the day to water is about the middle of the day in winter and the evening in the summer-time. In the spring and autumn, watering may be done early in the morning. Greenhouses in very sunny positions will require to be shaded in the summer-time from the glare of the sun in the middle of the day. This shading usually takes the form of a blind which can be pulled down over the roof and let up again when necessary. Five or six hours in the middle of the day is generally long enough for this shading to remain down, provided the sun does not go in, in which case it should be pulled up immediately. In the place of these blinds, or shades, a mixture of whitening and water is sometimes thrown over the sunny side of a house, but this rough and ready method of shading has two drawbacks—it whitens everything with which it comes in contact, and cannot, moreover, be removed instantaneously during a cloudy time.

The Flowers of the Greenhouse. The proper arrangement of the greenhouse is one of the gardener's most difficult duties, especially if the space under glass at his disposal be limited.

Where there are two greenhouses only, it is certainly better to devote the larger one entirely to show, and keep the smaller one for rearing seeds and cuttings—that is, assuming that one is a warm and the other a cool greenhouse. The ideal way is, of course, to have houses of three different temperatures in duplicate, one for show and the other for use, looking at it from the gardener's point of view. So much depends, however, upon the likes and dislikes of an employer that no definite rules upon the subject can be laid down.

For the purposes of this article, the word "greenhouse" is intended to mean the general purpose, or intermediate house, the temperature of which is not allowed to drop below 40 deg. in the winter. Practically all the summer and autumn bedding plants mentioned on page 6492 may be flowered in the greenhouse, and bloom had several weeks earlier than if they are planted out in the open ground. Daffodils, tulips, lilies of the valley, and all the other spring-flowering bulbs may readily be forced on in boxes for cutting or table decoration.

The Most Important Greenhouse Plants. The abutilons are a family of fairly large sized shrubs requiring a good deal of room, and therefore out of place in a small greenhouse. They are raised from seed sown in early spring, or from cuttings of old plants taken at the same time. As soon as the plants are big enough to handle they must be repotted into larger pots, and the process repeated at intervals until the plants are full grown; in this state they often attain a height of 6 ft. The best sorts, especially for commercial purposes, are Boule de Neige (white), Royal Scarlet (red), and Golden Fleece (yellow).

The acacia is better known by its popular name of mimosa, and is best raised from seed sown in spring in the ordinary way, as attempts to propagate it from cuttings are rarely successful. There are several sorts, all very much alike, but the best for general purposes is *Acacia dealbata* where space is of no object. It is this variety which is sold in such huge quantities in the streets of towns and cities. A lot of it comes to London from the South of France, but English grown mimosa usually realises an average price of 4s. per "pad." All the acacias flower in spring time, except Platyptera, which is an autumn-flowering variety.

25. DWARF SUNFLOWER
(Helianthus multiflorus)

Azalea. The azalea in the greenhouse is now usually grown in the form of the small pot plant, so familiar in the florists' windows. Although a hard wooded plant, its culture is very similar to that of the camellia, except that it should be grown in pots instead of tubs. It flowers during the early spring, and should be stood out about June, giving plenty of water so that the wood can ripen properly. In the south and west of England some sorts grow into bushes in the open. *Azalea mollis*, Indica, Fielder's White, and Dutch Pearl [23] are the most useful sorts. Good market plants fetch from 24s. to 30s. per dozen.

Begonias are among the most valuable winter-flowering plants of the greenhouse, while there are in addition some sorts equally desirable on account of their brilliantly marked foliage. They are not at present seen to a great extent in private greenhouses, but they are largely grown for the market. They are best propagated by cuttings taken in the spring, and potted up in tiny "thumb" pots, in loamy soil, with a good layer of silver sand on the top of it. If allowed to have a warm corner in the greenhouse for the first month or two they will make rapid growth, and when the pot is full of roots the plant should be shifted into a 5-in. pot, where it will flower the following winter. The best sorts are Gloire de Lorraine, President Carnot, Winter Cheer, Metallica, and Semperflorens, while of the fine foliage sorts the varieties of Begonia Rex are mostly sought after. Average market price, 10s. per dozen in pots.

Calceolaria and Camellia. The shrubby section of calceolaria used for bedding out has already been dealt with, but the herbaceous varieties are equally important, as they include many choice new hybrids for specimen and exhibition purposes. They must be sown one summer to bloom the next, in very finely powdered loam and sand, moistening the soil first and sprinkling the seed very finely over the surface. The box, or pan, in which the seed is sown must then be covered with a sheet of glass, and put in a moist corner of the house. As soon as the plants are large enough to be handled they must be transferred to "thumb" pots, and afterwards to those of larger size, in which they are to bloom. As herbaceous calceolarias like moist and shade care should be taken to shield them from the direct rays of the sun. Practically every nurseryman of any note has his own choice list of hybrid calceolarias, of all sorts of colours and markings.

By far the best way to grow the camellia is in a tub. Although essentially a greenhouse plant, it can be moved out of doors the summer after it has done flowering, and its home in the greenhouse occupied for a few months by something else. The best time of the year to start camellia culture is in August, when the plants should be repotted, in a mixture of loam with a little peat. In the case of the camellia, repotting does not necessarily mean putting into a larger pot, for it is one of those things which seem to do best without too much root room. The plants should be brought indoors in October, and given an occasional weak dose of liquid manure, and they will flower from the end of November onwards. The well-known white camellia is called Alba Pleno, and is the easiest of all to grow. The best pinks are Lady Hume's Blush and Beauty of Waltham; of the reds, C. M. Hovey and Donckelaari. Although there is a huge demand for market camellias it is not a very paying branch of horticulture, as the prices run low. From 1s. to 1s. 6d. per box of two dozen blooms is the average price.

26. STEPHANOTIS
The sweetest-scented flower of the greenhouse

Cinerarias are pretty decorative plants of many hues and colours, and are best raised fresh from seed every year. This seed may be started in a cool frame in light, sandy soil in the month of May, and the seedlings transferred to "thumb" pots as soon as they are large enough to handle, repotting them once more as required. As soon as the first sign of frost makes its appearance they must be transferred to the greenhouse, but not the hottest part, as they are satisfied with quite a moderate temperature. They will bloom from Christmas until quite late in the spring. There is generally a good demand for them at Covent Garden during the winter months, their chief use apparently being to stand on the dining-tables of hotels, a purpose for which they are well adapted, as they last in bloom a long time.

Hardy Greenhouse Flowers. In the south and west of England, the hydrangea is hardy, but it is generally grown as a greenhouse plant. In its popular form, and the one in which it is always seen on the market, it is a one-stem plant with a big head of bloom. These plants are obtained by taking the stout shoots of old plants and treating them as cuttings, in any ordinary potting soil, when they strike readily and make rapid growth. The natural colour of the flowers is pink, but they may be induced to show blue blossoms by soaking the soil with alum water, or growing them in soil in which there is naturally a good deal of iron. Limited market demand at 10s. to 15s. per dozen.

The heaths [24] are best grown in a mixture of peat and silver sand. They are useful for table decoration in winter, and are not difficult of culture if kept liberally watered and well drained. The most popular sorts for greenhouse culture are Gracilis, Hyemalis, and Ventricosa. There is a constant market demand for them, as, in the hands of an amateur, they usually bloom to die, and, in the winter plants in 5-in. pots may realise anything from 9s. to 20s. per dozen. There are over 500 sorts, mostly differing but slightly.

Primulas, Carnations and Chrysanthemums. The seed of the hybrid Chinese primulas should be sown in June in well sifted soil composed of loam and leaf mould, and treated in the manner described for calceolaria, taknig care to keep them in the dark until the seed germinates. Their final potting should be into a 5-in. pot, and they will bloom from November until spring. The flowers are all shades of white, red, blue, magenta, and pink. A branch of the family much grown is *Primula obconica*, but it should never be handled except in gloves, as it is prone to set up an irritating skin disease.

Hardy flowers cultivated in the greenhouse include the carnation and chrysanthemum Their culture is practically the same as that recommended for out of doors. The variety of carnation for greenhouse culture is known as the tree carnation. It may be had in flower in either autumn, winter, or spring, according to the time the cuttings are taken, hence it is easy to arrange for a succession of bloom. Cut flowers of winter carnations fetch anything from 1s. to 2s. 6d. per dozen. For market purposes, chrysanthemums realise 3s. to 4s. per dozen bunches, of about two dozen blooms each, but the large specimen chrysanthemums are marketed at anything from 2s. to 5s. per dozen blooms.

The Ferns of the Greenhouse. Most of the maidenhair ferns thrive well in greenhouse temperature, especially the popular variety *Adiantum cuneatum*. Large quantities of maidenhair ferns are grown for market purposes, chiefly by division in spring, or from spores, but they need special houses for their culture if they are to be profitable: this particularly applies to the small maidenhair ferns which are frequently to be seen hawked about the streets in "thumb" pots, and for which the market price is about 1s. per dozen.

The peculiarity of the hare's-foot fern (Davallia) is the curious, brown creeping stems which lie on the surface of the soil, and give rise to the popular

name. The ferns are well suited for a small greenhouse rockery, as they are shallow rooting things, and may be well grown in peat and moss. One of the varieties, Mariesi, comes into this country in large quantities from Japan, rolled up in the form of balls, and twisted on wire into the shape of frogs, monkeys, and other curious devices. These are the well-known "Japanese fern balls," and, given gentle heat, and plenty of moisture, soon cover themselves with green shoots. They are useful as novelties, but otherwise are of little horticultural value.

The following ferns are also well adapted for greenhouse culture: *Asplenium bulbiferum, Lastrea patens, Nephrodium molle, Polypodium aureum, Pteris argyraea*, and *P. tremula*. The same methods may be applied to almost every fern that requires the aid of artificial heat to bring it to perfection. A general mixture of loam, leaf mould, and sand should be employed, and the mixture carefully gone over to see that it is not lumpy.

27. LADIES' SLIPPER ORCHID
Cypripedium

Repotting young ferns, or the separation of the roots of old ones, should be done towards the latter end of March, care being taken that at no time are they subjected to the full rays of the sun. Moisture should be given in plenty, but the pots or brackets in which the ferns are grown should be provided with sufficient drainage to allow the water to clear away easily, as stagnant moisture at the roots is fatal to them. The majority of ferns may be propagated from the spores, found on the under side of the leaves. When these cases begin to burst the frond should be cut off and carefully wrapped away in clean paper. In the course of a few days, the remainder of the spore cases will have burst, and a very fine dust will have come out of them. This dust should be carefully spread very thinly on the top of a shallow pan or box, containing plenty of drainage and a mixture of loam, sand, and a little peat. The pan should be gently moistened and covered with a sheet of glass, and, in the course of six weeks or so, if the moistening has been regularly attended to, what appears to be a covering of young green moss will show itself on the surface of the soil. This moss is simply a huge collection of tiny ferns, and may be pricked off as soon as it can be handled into other boxes or small pots to develop.

The Care of the Hothouse. The hothouse, which is also known as the "stove," is used for preserving and growing all the choicest exotics which come to us from the tropics. Though the maintenance of a row of tropical houses is an essential feature of large establishments it is often overdone in gardens of moderate size, for, with the exception of the orchids, the flowers of the "stove" are not of great importance so far as their beauty is concerned.

The remarks on the care of a greenhouse given above apply equally to the hothouse, except so far as temperature is concerned. The hothouse should never be allowed to fall below 60° in the winter, and though much less heat than is usually thought necessary will be required in the summer, the thermometer should never fall below 70° at this period. Most exotics are moisture loving plants, and the use of hot-water pipes has a tendency to dry the atmosphere. Moisture must, therefore, be artificially supplied, either by fitting shallow troughs filled with water over the pipes, or else by liberally syringing the floor and wooden stages with water at frequent intervals.

Popular Inhabitants of the Hothouse. The Amazon lily (Eucharis) is a beautiful white lily like flower, the plants bearing it attaining a height of about 18 in. The flowers are deliciously fragrant, and, as there is always a huge demand for them for bouquets and wreaths, they are well worth growing for market purposes, especially as they can be made to flower practically all the year round. They are grown from bulbs, which should be potted up in a mixture of loam and leaf mould, one bulb to a 5-in. pot. As they will not bear repotting frequently, the nourishment which they would have found in fresh soil must be applied by doses of liquid manure. Under this treatment they will yield two or three crops a year, and the average price of the flowers is about 3s. a dozen.

Though not grown to any large extent in private places, there is an enormous demand for gardenias at blo , both for cheap buttonholes, and also for funeral wreaths. The gardenia is a small bush about 18 in. in height having very deep glossy green leaves, and white flowers with rather a sickly perfume. If potted up in the ordinary mixture of loam and leaf mould with a little red sand, and given plenty of heat and moisture during spring and early summer, they will flower freely through autumn and winter, or they may be had at practically any time by checking the growth. Cuttings stuck into sandy soil in spring root freely, and soon bear flowers, and this is the method generally adopted by market growers. The average price of the cut blooms is 1s. a dozen.

28. CATTLEYA ORCHIDS

Stephanotis [26] is the most widely grown of all the climbing plants in the hothouse. It has white waxy-like flowers of great fragrance, and is best grown in pots plunged into the border, or on a staging, as, if the roots are allowed too much room, the plants run to leaf instead of flower. The ordinary potting mixture suits it admirably, and it is increased from cuttings in the spring.

Ferns in the Hothouse. To avoid repetition, the reader is referred to the ferns of the greenhouse which have been dealt with above for details of culture, these details being equally applicable to the hothouse, the great difference between greenhouse and hothouse ferns being the natural one of temperature. It is more important than ever, however, that in the hothouse the ferns should be well shaded and kept moist—accidental exposure to bright sunshine, especially if the atmosphere happens to be a little dry, will wither them up and kill them

almost immediately. The following ferns are most useful for stove cultivation, and, as they have no English names, it is necessary to set forth their Latin ones in order that the plants may be readily procurable: *Adiantum caudatum*, *A. farleyense*, *Asplenium formosum*, *A. longissimum*, *Blechnum brasiliense*, *Davallia elegans*, *Gymnogramma calomelanos*, *Lomaria boryana*, *Polypodium diversifolium*, *O. pectinatum*, and *Pteris tricolor*.

Orchids. There is no branch of gardening which has been made more bewildering, and more difficult to understand for the young horticulturist, than orchid growing. This is in a great measure due to the fact that new hybrids, the differences in which are indistinguishable even to experts, are being introduced every day. It is appalling to think that at the present time there are over 4,000 varieties of orchids, many boasting Latin names of six words in length, ranging from the Odontoglossum, for which 1,150 guineas was paid in London in March, 1906, down to the *Cœlogyne cristata*, procurable for a shilling or two. A general knowledge of the requirements of the varieties of the great families of orchids is, however, all that the young gardener can reasonably be expected to possess.

When orchids first arrive in this country from abroad they are naturally in a very dry, shrivelled condition, and can have no better treatment than that recommended by Mr. W. H. White, F.R.H.S., in his excellent work, "The Book of Orchids." "The plants should, within a few days after their arrival, be suspended head downwards in an intermediate temperature in a shady part of the house, and be slightly syringed at least once a day. In a very short time the leaves will have assumed their natural colour, and the stems and old root stumps will commence to emit their new succulent roots. Immediately this is observed the plants should be taken down and placed in as small pots as possible, using the crocks for potting, so as to come up almost to the edge of the pot, covering the whole with good living sphagnum moss, and pressing it down moderately firm."

29. PERENNIAL DELPHINIUMS

The Most Important Genera of Orchids. The Calanthes are winter flowering orchids, the different varieties of which will give a succession of bloom for at least three months. They are grown in pots, half filled with drainage, this being covered with a piece of turf, grass downwards, and the pot filled with loam, sphagnum moss, and silver sand. A little water should be given to the bulbs until the foliage begins to make its appearance, but as the plant grows the quantity should be increased until a copious supply is found needful. This quantity should be gradually decreased as the foliage dies down, and the flowers make their appearance. After flowering they should be given rest for a month or two, and the bulbs repotted again in the spring. Some of the Calanthes do not lose their foliage in winter.

Among the largest flowered orchids are Cattleyas [28], purple in one of its many shades being the predominating colour. Many of them will thrive in the coolest part of the hothouse, and they can be grown by planting the pseudo-bulbs in pots, half filled with drainage as recommended for the Calanthe and the remainder a mixture of leaf mould or peat and moss. In their youngest stages they like shade, but as they progress they should be brought into full light and air. After blooming they should be given very little water during the time they are resting. Very closely allied to the Cattleyas are the Lælias, the culture of which is similar in every way, and there are many hybrids between the two families, known as Lælio-Cattleyas. There is a good market demand for Cattleyas. This demand fluctuates a good deal, and the prices change also, but six shillings a dozen blooms is quite an ordinary figure—they sometimes fetch double that price.

One of the easiest grown orchids is Cœlogyne, a variety of which, Cristata, with pure white flowers, is the most useful orchid that can be grown in a small house, or where space is limited, as the flowers are borne so abundantly. The orthodox orchid potting mixture of peat and moss suits the Cœlogynes admirably, and the practice recommended for the Calanthes, of gradually increasing the quantity of water as the plant grows, and decreasing it afterwards, should be carried out.

Cypripediums are more familiarly known as "The Lady's Slipper Orchids" [27], on account of the peculiar pouch which is a prominent feature of the flowers. They are a popular buttonhole flower, and there is hardly a month of the year when one or other of the varieties cannot be had in flower. The mixture of soil already recommended suits them, and they like one of the hottest corners in the house, protection from the direct rays of the sun, and plenty of water all the year round. Care must be taken with the drainage of the pots, however, in order that the water does not remain stagnant about the roots of the orchid, for this is fatal. They usually fetch about 3s. or 4s. per dozen blooms in the market.

Although the Odontoglossum numbers among its varieties the most expensive kinds, there are plenty of others quite within the reach of the very smallest grower of orchids. They may be given the coolest corner of the house; in fact, some of them—notably Crispum—will flower in the greenhouse.

An orchid family most remarkable for its long sprays of flowers, which, in the majority of cases, hang downwards, in graceful showers, is Oncidium. Oncidiums will grow almost as readily in ordinary well-decayed leaf mould as in the orchid mixture.

Members of the following families of orchids are the others most generally met with in large collections, and the broad rules of culture laid down will be found sufficient in most instances: Cymbidium, Epidendrum, Habenaria, Lycaste, Masdevallia, Maxillaria, Miltonia, Phalænopsis, Stanhopea, and Vanda.

CAN THE MIND KNOW ITSELF?

The Eternal Question—What Are We? Relation Between Mind and Body. Does the Mind Influence the Body or the Body the Mind?

Continued from page 6470

By Dr. C. W. SALEEBY

PRAGMATISM amounts to this in practice, that you are to make up your mind as to what you want in the way of a creed, and see that you get it. Whatever you want to believe, whatever suits you to believe, that is truth for you, proving its truth by its suitability. Quite evidently this involves the utter destruction of the idea of truth at all. Absolutely opposed beliefs may suit one man and his neighbour respectively, and each is, therefore, on the pragmatic principle, true or as true as may be. "But they cannot both be true," says the smallest child—thus showing how deep the belief in the consistent One is planted in the constitution of mankind—and the pragmatist in his heart of hearts agrees with the child.

The Essence and Humour of Pragmatism. If only the pragmatic argument could be confined just to those beliefs which we want to have established! But unfortunately it cuts both ways, and the pragmatic argument which you adduce as the final warrant for your belief is precisely applicable to the case of your neighbour who finds that the negation of that belief is what suits him. Thus white is white if you like to think it white, but of course, if you so prefer, black is white—"if you do not see what you want in the window, please step inside," we will find something to suit your measure. Here verily is that royal road to learning the existence of which old Euclid denied. Truth is now a matter of taste. You need not go to seek her, she will always come to you. Nothing is either true or false, but thinking makes it so. That is pragmatism. It is quite the best joke in the history of philosophy. But at least let us attempt to learn one useful lesson from the pragmatist. Is it possible to say what it is that they have confused with truth? The answer to this is possible. That which the pragmatist confuses with truth is *value* It is perhaps the profoundest conviction of the philosopher that, at the last, when all secrets are unveiled, the true and the valuable will be found absolutely to coincide. But let him who thinks that they have always coincided glance but for a moment at human history and see how strangely it contradicts his assumption.

Mind and Brain. Having paid so much attention to the history of criticism in philosophy, let us turn to the main philosophic problem as it presents itself to us to-day. Someone has said that the proper business of philosophy is not to answer our questions, but to teach us how to ask them. That saying may be applied, perhaps, to the case of philosophy as we see it to-day. Perhaps it has answered no question since its dawn, but at least it is teaching us how to ask our questions, and that is a magnificent service to the intellect of Man.

We have agreed, have we not, that the problem of philosophy, with its inevitable belief in Oneness or Monism, is to explain the apparent dualism which existence presents to us—the dualism of mind on the one hand and not-mind on the other hand. We have traced throughout the generations various stages of the attempt to resolve this dualism, and we have hinted, perhaps, that both the materialists and the idealists may have been somewhat too ready to assume that one or other of the terms of the dualism was an ultimate. Let us now return to this question, and pose it in the form that most clearly states the issue. This form is undoubtedly "Mind and Brain."

The Nonsense Caused by Confusing Terms. The brain, of course, is a material thing which may be seen and handled and cut—or, as in the case of the calf, may even be eaten. Very few of us, however, can be accounted guiltless of the monstrous error of speaking of mind and brain as if they were interchangeable terms. This absolutely indefensible confusion of thought leads to such ludicrous results as the following, which is taken from a recent American author: "The modern scientific definition of mind is that part of the sensorium capable of the greatest molecular activity." This unfortunate writer has achieved the triumph of superseding the ordinary materialistic view that the mind is a product of the brain, by the magnificent fatuity that the mind *is* the brain. Thus, if you find that part of the sensory area of the brain which is "capable of the greatest molecular activity," and if you cut it thin and put it under the microscope and draw what you see, you will have the pleasure of cutting and drawing a piece of mind itself; or, if you desire your intelligence to develop, you might eat it, for what could possibly serve your purpose better than a diet of mind itself, unless, of course, mind happens to be tough and indigestible?

This is the sort of nonsense that follows from the use of the words mind and brain, as if they were one and the same thing. It is one more illustration of the manner in which we are deceived by language.

If We Could See the Brain. Here is the place to quote one celebrated argument of which those who think that the mind is the brain are apparently ignorant—an argument which, simple though it be, is seen to be more and more significant the more we think about it. We may quote it from Professor Mitchell, of Adelaide, the most recent writer on the subject.

"Adapting an old illustration, let us suppose that we had the means of so magnifying

the brain—each examining his own brain in a mirror, if you like—that its minute structure, and every movement in it, became visible. We are assuming that the effects of a stimulus upon it would be seen as a continuous series of physical changes in which the total energy is accounted for at every point by the work done (including the potential energy of new structural arrangements) and heat. At some point in the series, where the cerebral cortex is involved, we should see the various actions on which the course of feeling depends. We should not see the feelings; they would be something of which we had no sensation, something over and above the physical process. If the brain we examined were another's, we could only know of his feeling, say of red, from himself; if it were our brain, we should at the same time have the feeling of red, and see its immediate physical correlate, but our feeling of red we should not see."

A Monstrous Doctrine. This is surely clear enough. The only explanation of the fact that any contemporary writer should think that the mind *is* the brain must be an ignorance of the literature of the subject so great as to make this argument unknown to him. The argument shows that even the simplest of psychical facts, a mere uncomplicated colour sensation, cannot possibly be explained away in terms of the physical: it would still remain unreckoned with, even if we could watch every movement of the atomic dance within our heads. If this be so of a mere sensation, what shall we say of such a psychical fact as self-consciousness? How much the more monstrous must not the doctrine be which involves the proposition that my recognition of myself *is* the movement of atoms within my brain!

It is worth while to hold clearly to the distinction between the nervous system, or the brain, and the rest of the body, never losing sight of the fact that the brain is a material thing, as is the rest of the body. The initial recognition of this bodily division is all-important because of its bearing upon the theory of interaction between the psychical and the physical. There are innumerable cases familiar to all of us which seem to illustrate this interaction—as, for instance, when depression causes dyspepsia or dyspepsia causes depression. These are instances of the action of the mind upon the body or the body upon the mind, and unless they are more closely examined, they lead us to the apparently simple, but actually inconceivable, belief in causal interaction between the physical and the psychical. If, however, we insert this conception of the body as divided into brain and not-brain, we can express such instances in reasonable language. We then find that they are all within the realm of the physical.

The Relation between Mind and Brain. Let us take it that our problem may be confined to the brain and the mind. This physical brain may have been in many ways modified by physical causes without it. We fully recognise the action of such physical causes, but we have also to recognise that this demonstration of the action of the physical upon the physical tells us nothing as to whether the physical can act upon the psychical.

Now let us address ourselves with minds undeceived to the question of the relation between mind and brain. And here, fortunately, it is possible to state the various theories in self-explanatory language. What are the conceivable relations of the psychical and the physical? Well, in the first place, there is the relation of interaction, and that is, properly enough, expressed by the phrase *Psycho-physical interaction.* Over and against this phrase we may set another, which is of extreme importance in current philosophy, and is known as the theory of *Psycho-physical parallelism.* Now we must attempt to discuss the arguments expressed by these two phrases. Obviously, we must begin with psycho-physical interaction, one form or other of which has been believed by the vast majority of men ever since men began to think at all. Our previous discussion must already have made it quite clear to us that if there be any interaction it may act in either or both of two ways.

The Three Theories of Mind and Body. On the one hand, there may be interaction from the physical to the psychical—physical causes producing psychical effects. That, of course, is the view of uncritical common-sense, and it is the basis of all forms of materialism. On the other hand, there is that theory of interaction which asserts that psychical effects can produce physical causes, as expressed by our old friend, the phrase about the "influence of the mind upon the body." And, thirdly, of course, we may boldly brush aside the difficulties involved in each of these conceptions, and declare that interaction in both directions is possible. The mind can produce physical or brain changes, and changes in the brain can produce mental or psychical changes.

This is all very well so far, perhaps, but philosophy, profoundly distrustful of the unexamined opinions of common-sense, begins to ask inconvenient questions, and these are based upon that fundamental idea which we call the idea of causation. Can we really conceive at all, asks philosophy, that a sequence of material events should cause another sequence of events which belong to the psychical? That is what materialism asserts, and yet we find that the most thoughtful of the so-called materialists avow the absolute impossibility of accepting such an idea. Our conception of causation fails us. In a sense we can understand how a billiard ball may push another billiard ball, or an atom another atom, but the passage over from the collision of atoms within the brain to the psychical we cannot bridge.

Professor Tyndall's Incomprehensibles. There is a classical passage from Professor Tyndall which expresses this difficulty in the clearest and most authoritative manner. In allusion to the *conscious automaton* theory of Huxley, which we briefly stated in the course on PSYCHOLOGY, Tyndall wrote:

"Do states of consciousness enter as links into the chain of antecedence and sequence, which gives rise to bodily actions, and to other states of

consciousness; or are they merely *by-products*, which are not essential to the physical processes going on in the brain? Speaking for myself, it is certain that I have no power of imagining states of consciousness, interposed between the molecules of the brain, and influencing the transference of motion among the molecules. The thought 'eludes all mental presentation,' and hence the logic seems of iron strength which claims for the brain an automatic action, uninfluenced by states of consciousness. But it is, I believe, admitted by those who hold the automaton theory that states of consciousness are *produced* by the marshalling of the molecules of the brain, and this production of consciousness by molecular motion is to me quite as inconceivable on mechanical principles as the production of molecular motion by consciousness. If, therefore, I reject one result, I must reject both. I, however, reject neither, and thus stand in the presence of two Incomprehensibles instead of one Incomprehensible. . . . I bow my head in the dust before that mystery of mind which has hitherto defied its own penetrative power, and which may ultimately resolve itself into a demonstrable impossibility of self-penetration."

Materialism Refuted by Physics. This passage may well be submitted by the serious student to the callow writers who can swallow whole the ordinary materialistic belief without beginning to recognise how monstrous it is. Tyndall had every kind of motive to induce him to accept the materialistic hypothesis. It is not merely that he had freed himself from bias against it, but that all his bias was for it. He was, of course, one of the greatest physicists of the most wonderful century in the history of physics. When he declares that the production of consciousness by molecular motion is to him "inconceivable on mechanical principles," the assertion is that of one who really understands mechanical principles.

Nor must it be for a moment thought that this declaration was some personal eccentricity of Professor Tyndall's. On the contrary, it is the inevitable conclusion to which physical science is forced. These questions are often discussed by people such as Vogt, who depend for their scientific information entirely upon hearsay. Such an imbecile assertion as that the brain secretes thought as the liver secretes bile could only be made by one from whom the principles of the physical sciences were utterly hidden.

Materialism Inconceivable on Mechanical Principles. Mind, whatever it is, is demonstrably no form of physical energy—as we have seen. If it were produced in the course of physico-chemical changes in the brain and as the effect of those changes, then all the physicists' conceptions of energy and its conservation would be invalidated. The physics and chemistry of the brain constitute a complete system in which the laws of the conservation and transformation of energy are observed just as they are in a test tube. That may not yet be a fully demonstrated fact, but every materialist is bound by his own hypothesis to believe it. But this belief as such involves and necessitates a denial of the assertion that anything more than physico-chemical effects are produced; else something is being made out of nothing and we are talking babble. The materialistic theory of mind, which asserts that, though the physical series is complete and closed within itself, yet mind is produced by it, is "inconceivable on mechanical principles."

Mind and Body Interaction Inconceivable. Equally inconceivable is the production of molecular motion by consciousness, as suggested by the common phrase "the influence of the mind upon the body." This suggests the incursion of something from without into the physical series of transformations of energy. Either this something from without does nothing at all or else it must disobey the law of the conservation of energy. It must either create energy or destroy it—which every materialist, like every other student of the physical sciences, is bound to deny.

Thus, every form of the theory of psycho-physical interaction is incompatible with the law of the conservation of energy. That and that alone is a fatal argument against any such theory.

The second argument, which has already been referred to, is really more fundamental still. It depends upon that analysis of our ideas which shows that we cannot really conceive of such interaction. True, we may think that we can imagine it, but that is only because of the carelessness of our minds. The time has not yet come when men will cease to be contented with what Herbert Spencer called "pseudo-ideas." This of psycho-physical interaction in any of its forms is a pseudo-idea. The words expressing it can be put together in a grammatical form, so as to make a sentence which can be parsed and analysed and which may sound as if it meant something intelligible.

False Ideas. Yet if we come to look at it more closely, such a sentence contains nothing any more conceivable by us than the pseudo-idea of a "moral fluid" or a "square thought." Just as we really cannot conceive of the movement of billiard balls or atoms producing consciousness, so we cannot conceive the generation of motion in a billiard ball by an idea. We are mistaking mere combinations of words for rational concepts. "How can anything impalpable, non-material, utterly distinct from anything palpable or material, be the cause of changes in a material thing? 'Which of you by taking thought can add a cubit to his stature?'" Even if the law of the conservation of energy were not there, defying us to assert that mind can create or annihilate energy, the very laws of thought forbid us to entertain, except as a mere verbal proposition, the notion of psycho-physical interaction.

A curious comment upon the fallibility of our minds is constituted by the fact that there are many people who think they can entertain the notion of psycho-physical interaction from the

physical to the psychical—that is to say, from brain to mind—but who quite agree that the notion of any interaction in the other direction—that is to say, from mind to brain, is unthinkable. "They think they have no difficulty in conceiving how the redistribution of a number of atoms in the brain can cause the production of ideas. But a moment's consideration will show that if the one notion is untenable so is the other. If an atomic collision can cause an idea, then an idea can cause an atomic collision; but, as we now see, idea and collision are in different worlds."

Equally curious is the existence of other people whose opinion is precisely the reverse. They hold that "the action of mind on matter is the only kind of action or causation that we are capable of understanding."

The Extreme Theories. Finally, it is evident that if we reject as inconceivable (and as, even if conceivable, contradicted by mechanical principles) interaction in either direction, we reject still more summarily the easygoing views of those who hold that interaction between mind and brain in both directions is an obvious and commonplace fact. But before we pass on to the more modern theory of psycho-physical parallelism, we may briefly observe how the theories of interaction may develop at their two extremes. At the one extreme is the solution of idealism, which is not merely content to assert an action of mind upon matter, but declares that matter is actually nothing more than a convenient fiction of the mind: "into the man's head the whole world goes, including the head itself." At the other extreme is the notion of Huxley, already referred to, which goes one better than the assertion that matter can act upon mind, and declares that the psychical manifestations which accompany brain activity are mere accidents. They "are somehow thrown off from the brain, like sheets from a printing-press, and they are barely formed when they pass into nothingness, being too ephemeral to remain anything at all or make a difference to anything else. They are likened to words from our mouth, to the shadow and to the whistle of a passing train and to whatever is incidental and easily disappears." (Mitchell, "Structure and Growth of the Mind." Macmillan, 1907.)

The Physical and Psychical are Parallel. If, then, we are to reject any form of the belief in interaction between the physical and the psychical—that is, between mind and brain—and if we are not to ignore the indisputable fact that there is some kind of relation between them, there remains only one possible escape from our difficulty—if it is really an escape—and that must consist in the assertion that the relation between psychical and brain states is one not of dependence nor interdependence but parallelism. Two other modes of expressing this theory may be quoted: "The two kinds of events or processes in consciousness form two series that run parallel to one another, but never meet or interact." Or better still, since it hints at a philosophic conclusion: "The physical and the psychical are two modes in which one series of real events appears to us, and therefore the two series of appearances run parallel to one another."

The advantages of this mode of statement are that it by no means questions, but on the contrary emphasises, the indisputable fact that mind and brain *are* related; whilst, on the other hand, it avoids the difficulty of pledging us to any of those kinds of psycho-physical interaction which, as we have seen, do not admit of rational conception at all.

The Philosophic Inference. And now it is our business to observe the philosophic inference from this which seems to be the most warrantable conclusion of psychological science. It is the conclusion which has already been hinted at. We are not warranted either in regarding matter—for instance, the brain—as an ultimate, nor yet in regarding mind as an ultimate. On the contrary, mind and brain—that is to say, mind and that particular part of not-mind with which it is most commonly associated—are to be regarded as the correlative and proximate expressions for us of a One Something that lies behind them. Our analysis and recognition of this proximate dualism involves a monism beyond it. Mind and matter are related. We deny that there is any interaction between them, though we assert an absolute parallelism between them. Palpably this leads us to the inevitable conclusion that, as has been said before, they are the "subjective and objective faces of the same fact." That same fact, need we say, must be the ultimate reality of which philosophy is the quest.

Indeed, there can be no more important argument for the theory of psycho-physical parallelism, than the fact that it leads us directly to monism. Materialism and idealism led us to monism by denying respectively what seems impossible to deny—mind in one case, and matter in the other.

Our Knowledge of the Eternal. Short of these solutions there seemed to be no choice but to reject our ideal of monism altogether, and to rest discontent, with a "disastrous dualism." The whole story of existence must then be conceived in terms of a constant battering and interaction between these two irreconcilables. But when further criticism leads us to see that this interaction is as inconceivable as a constant relation is undeniable—then we are forced to the conclusion that our dualism is only proximate, and that mind and matter—or "mind and brain," or "mind and not-mind"—are like the concavity and the convexity of a curve, different aspects of one fact.

And if that one cannot be known and seen face to face by us—by us who are so bound that our belief in the existence of another's consciousness is only an inference from the material facts of his behaviour—what may fairly be inferred from our knowledge of its manifestations? We need not here concern ourselves with the names under which this one has been described by various thinkers. The Absolute of Hegel, the Substance of Spinoza, the Ineffable of many a poet, the Unspeakable of St. Paul, the Unknowable of

Spencer, the Unconditioned of Hamilton, the Nature of the pantheists—all of these correspond with an endeavour to express some aspect or other under which this inaccessible yet omnipresent eternal presents itself to us. Let us here contemplate what is in modern thought the noblest and most celebrated expression, in a poetic form, of the existence of this ultimate. It is taken from the lines "Composed above Tintern Abbey," by William Wordsworth, then aged 28:

"And I have felt
A presence that disturbs me with the joy
Of elevated thoughts; a sense sublime
Of something far more deeply interfused,
Whose dwelling is the light of setting suns,
And the round ocean and the living air,
And the blue sky, and in the mind of man;
A motion and a spirit, that impels
All thinking things, all objects of all thought,
And rolls through all things."

Knowledge Lives—Shall That which Knows Die? But apart from the more or less poetic names given by the philosophers, and from the poetic expression of Wordsworth, how much are we entitled to set forth as our warrantable and rational knowledge of something beyond? At least we are entitled to make what inferences we may from our knowledge of its phenomena. We have agreed already that it is one and consistent. There are not many realities but one reality—in the last resort not many incomprehensibles but one incomprehensible.

Again, all our physical sciences, in their close study of phenomena—that is to say, of one aspect under which reality expresses itself to us—warrant the conclusion that reality is "eternal and uncreated." Ceaseless change there may be and is—change the best sign of vitality—but there is neither creation nor annihilation. Hence there spring to our minds the words from the Athanasian Creed: "eternal and uncreated," reminding us of the words of the psalmist, "from everlasting to everlasting thou art God."

Furthermore, this conception of indestructibleness has its immediate bearing upon the question of the Hereafter, as to which science knows only that she can neither affirm nor deny; but she is bound to listen to the famous question asked by Shelley as he mourned the untimely death of his friend Keats:

"Nought, we know, dies. Shall that alone which knows
Be as a sword consumed before the sheath
By sightless lightning?"

A Mighty Conception. One, eternal, uncreated—but not intelligent; such has been the amazing conclusion of some. The reality which can manifest itself as intelligence is itself non-intelligent! Can any more ludicrous belief be conceived? If mind exists at all, that in which it lives and moves and has its being must be at least no less than mind. Rather must we incline to the belief that the "infinite and eternal energy from which all things proceed" "wells up in ourselves in the form of consciousness"; palpably it is monstrous to regard reality as lower and less than one of its own manifestations. Yet there remains the highest conception of all, the mightiest thought of an all but peerless mind. "Is it not possible," says Herbert Spencer, "that there is a mode of being as much transcending Intelligence and Will as these transcend mechanical motion?"

Here, perhaps, we have reached the highest of the uses of philosophy. Let us summarise the forms in which it has worth for us, directing our summary against certain recognised criticisms. These are, in the first place, that philosophy reaches no conclusion. Then, in the second place, there is the criticism that philosophy has taken away men's activities from this world in which we live—which still has need of every fine mind and energetic spirit. Lastly, there is the criticism that even if the answer of philosophy were obtainable or obtained, it is not necessary. As Goethe hinted, man was born to live his life and not to solve the problems of existence.

What, then, is our reply to these criticisms? In the first place, we may make small points as that the study of philosophy helps to train the mind, and then we may go on to something more substantial. We may point out that, even if philosophy returns no final and complete answer to the world riddle, at least it refutes the shallow conclusions of those who think that they have found the answer. Now that is a very great service indeed, and if the study of philosophy had done nothing more, this would have been sufficient to justify it.

The Service of Philosophy to Religion. Without philosophy there would be the gravest risk that the common run of scientific students should forget the limitations under which they work—should imagine that their atoms and forces and cells and metabolisms were ultimates, and that their conclusions were final and complete instead of being merely proximate, tentative, and symbolic. So long as men go on thinking, the services of philosophy will be necessary in order to remind them that upon merely phenomenal knowledge no warrant can be grounded for denying the reality of truths that lie beyond the grasp of any phenomena. And plainly, these services of philosophy, as the necessary critic of science, constitute on the other hand, and more positively, a service to religion itself.

Philosophy also has its constructive side, and it is this which comprises its service to religion. Have we not seen that there is philosophic warrant for certain, at least, of those ideas which, apart from philosophy, can be reached by faith only? Plainly, if rational support can be found, for instance, for such an expression of the poet as "from Everlasting to Everlasting thou art God"—plainly that is a very real service of philosophy. No less is the service if, when science, so critical, has succeeded in destroying certain of our religious conceptions, and thereafter would persuade us that beyond the visible and the transient there is nothing—if, then, philosophy should teach us and compel us to believe that beyond the visible and the transient, behind the mind itself, there is and remains an Eternal Power which "rolls through all things."

PHILOSOPHY *concluded; followed by* RELIGION

8. SOME DISEASE-PRODUCING MICROBES AS SEEN UNDER THE MICROSCOPE

IMMUNITY FROM DISEASE

Bacterial Sewage Disposal. How Microbes Cause Disease and their Products End it. Microbe-digestion. Natural and Acquired Immunity

By Dr. GERALD LEIGHTON

WE have already seen that the natural processes which break up organic material are of a microbic nature, and during recent years the opinion has been growing that advantage should be taken of this fact in order to dispose of the organic material in sewage. The idea is to imitate Nature in this matter as closely as possible. We know that some bacteria exist naturally in sewage, where they break up organic compounds, converting the nitrogen into nitrates and nitrites. It would therefore appear that the most reasonable way of disposing of sewage would be to encourage the growth of such bacteria as are naturally present.

The Bacterial Treatment of Sewage.

The method adopted, speaking generally, is given in the following paragraphs. [See also CIVIL ENGINEERING, pages 4742 and 4821.]

"It is usually effected by running the sewage on to beds of coke, allowing it to stand for some hours, slowly running the effluent out through the bottom of the bed, and leaving the bed to rest for some hours before recharging. The final result is better if the effluent be afterwards run over another similar coke-bed. According to some authorities, the sewage, as it runs into the first bed, takes up from the air considerable free oxygen, which, however, soon disappears during the stationary period, so that on leaving the first bed the sewage contains little oxygen. In the latter part of its stay it has thus been submitted to anærobic—that is, without oxygen—conditions. Further, while by the passage of the effluent out of the first bed oxygen is sucked in, it rapidly disappears, and during the greater part of the resting stage the interstices of the bed are filled with carbonic acid gas, with nitrogen, partly derived from the air, partly from putrefactive processes, and thus in the filter anærobic conditions prevail, under which the bacteria can act on the deposit left on the coke. . . . Probably the best results in sewage treatment are obtained when it is practicable to introduce a step where there can be no doubt that the conditions are anærobic. This involves, as a preliminary stage, the treatment of the sewage in what is called a septic tank, and the method has been adopted at Exeter, Sutton, and Yeovil, in this country. . . .

"In the explanation given of the rationale of this process, sewage is looked upon as existing in three stages. First of all, *fresh sewage*—the newly mixed and very varied material as it enters the main sewers. Secondly, *stale sewage*—the ordinary contents of the main sewers. Here there is abundant oxygen, and as the sewage flows along there occurs, by bacterial action, a certain formation of carbon dioxide and ammonia, which combine to form ammonium carbonate. This is the sewage as it reaches the purification works. Here a preliminary screening may be adopted, after which it is run into an air-tight tank—the septic tank. Thirdly, it remains there from 24 hours to 36 hours, and becomes a foul-smelling fluid—the *septic sewage*. The chemical changes which take place in the septic tank are of a most complex nature. The sewage entering it contains little free oxygen, and therefore the bacteria in the tank are probably largely anærobic, and the changes which they originate consist of the formation of comparatively simple compounds of hydrogen with carbon, sulphur, and phosphorus. As a result, there is a reduction in the amount of organic nitrogen, of albuminoid ammonia, and of carbonaceous matter. The latter fact is important, as the clogging of ordinary filter beds is largely due to the accumulation of such material, and of matters generally consisting of cellulose. One further important effect is that the size of the deposited matter is decreased, and therefore it is more easily broken up in the next stage of the process. This consists of running the effluent from the septic tank on to the filter beds, preferably of coke, where a further purification process takes place. By this method there is, first, an anærobic treatment, succeeded by an ærobic one; in the latter, the process of nitrification occurs by means of the special bacteria concerned. The results are of a most satisfactory nature.

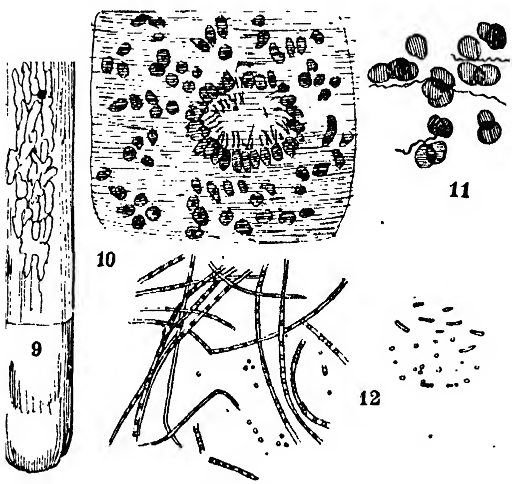
"Sometimes the effluent of a sewage purification system contains as many bacteria as the sewage entering, but, especially by means of the septic tank method, there is often a marked diminution. It is said by some that pathogenic bacteria do not live in sewage, but in an effluent Bacillus coli, B. enteritidis, and streptococci have been constantly found, so that the observation is of little value, and it is only by great dilution and prolonged exposure to the conditions present in running water that such an effluent can be again a part of a potable water." (Muir.)

The Relation of Bacteria to Disease.

We must now turn our attention to the special point to be dealt with here—the relation of microbes to the existence of disease, perhaps the most fascinating study in connection with medicine and pathology. Our illustrations [**8** to **16**] show some of the more common and important disease-producing germs, as well as their methods of culture. The cholera bacillus [**13**] is shown in two stages of growth in nutrient gelatin, which it is liquefying as it grows [**16**]. It is also shown *in situ* in the intestine, where it is producing its effects [**14**]. The deadly germ of anthrax and wool-sorter's disease is seen as it appears when sporing [**12**]. The germ of tuberculosis (the tubercle bacillus) is shown growing in blood serum [**9**], and also as it is sometimes found in a "giant cell" in the tissues, a large cell produced in tubercular areas [**10**]. Another organism, of the spirillum shape, is that of the disease called relapsing fever [**11**]. These, together with the various forms of cocci found in suppuration, illustrate the most important kinds of germs associated with the common diseases.

We have already realised the omnipresence of microbes around us—that some are innocent or useful, and others pathogenic. It now remains to see how the disease-producers do their deadly work; how they gain access to the individual; how he resists their attacks, and how he may become immune to their ravages.

How Microbes Enter the Body. In order that a microbe can adversely affect a person, it must first of all get *on to* or *into* his body tissues and act upon them. No germ arises *de novo*; every microbe springs from a pre-existing one. The popular idea that a defective drain will cause microbes to come into existence is a pure myth: all it does is to provide a suitable nidus for germs, already present, to grow and multiply there. A microbe may get on to the surface of an individual, on to his skin, by actual transference from the skin of another person, by contact or contagion. Once on the skin, the microbe must gain further entrance through some scratch or abrasion, in most cases, before it can do any harm. (We are not now referring to small animal parasites, such as that of itch, which burrow in the skin, or those which attack hair.) The healthy unbroken skin is an effective barrier to germs, else we should never be safe from their presence. But once the microbe has passed this barrier, many ways are open, all of which involve serious results. The germ may settle down at the point of entrance, there multiply and produce its poison or toxin, which is absorbed into the system, and kill the patient without further invasion. This occurs in tetanus or lock-jaw. Or, having passed through the skin, the germ may pass into the blood circulation or the lymphatic vessels [see PHYSIOLOGY], and be carried with great rapidity to every part of the body, multiplying as it goes and carrying the possibility of disease and death along its path. The organisms of suppuration spread thus, and produce abscesses wherever they settle in organs such as the liver and kidney, as well as at the point where they gained their first entrance.



TUBERCLE AND OTHER BACILLI

9. Tubercle bacillus in blood serum. 10. Tubercle giant cell with bacilli. 11. Relapsing fever bacillus. 12. Anthrax bacilli, showing spore formation

Other Paths of Invasion. Two other portals are open to the invasion of the army of bacteria — the digestive system through the mouth, and the respiratory system through the nostrils and mouth. Large numbers of germs are taken into the alimentary tract along with food and water, many of which do no harm at all; but many pathogenic ones also enter thus, and act either on the stomach or bowels, or gain entrance through the mucous membranes of these organs into the general circulation. Their results will be found mainly in the organs named, or the liver, and later on in the general poisoning of the whole system from their products. The typhoid bacillus is a case in point; it selects a special portion of the bowel for its chief site of operations, there producing the ulcers which constitute the great danger of that condition. In this case, contaminated food or water is the usual carrier of the germ.

The third great path of invasion is through the breathing passages into the lungs. Many microbes or their spores float about in the atmosphere, and are inhaled during the act of breathing, and some of these air-borne germs are active agents in the production of disease—for example, the bacillus of consumption and that of wool-sorters' disease. The germ of consumption is coughed up by tubercular patients and expectorated upon the pavements, where, after the moisture of the sputum is evaporated, it is left dried, carried about by the air, and inhaled. It is for this reason that spitting in public places should be and is prohibited by law.

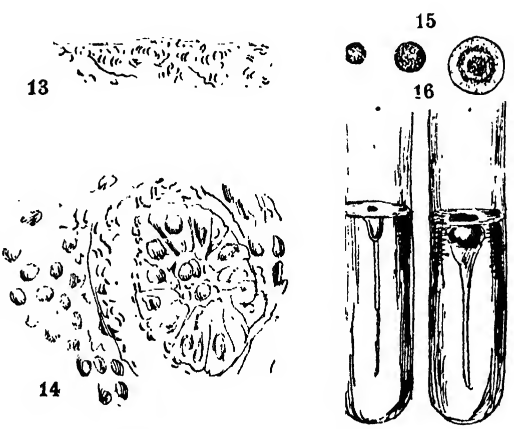
The question which at once suggests itself from these facts is, "How does anyone escape infection, since pathogenic germs are apt to attack individuals from all these sources?"

How we Escape the Attacks of Microbes. It is quite obvious that were there not some means of repelling the attacks of the microbes all around us no one would escape infection. In other words there must exist in human beings some degree of natural resistance to these attacks, a resistance which is born with the individual, without which he could not live. And this is actually the case. This resistance is termed *natural immunity* or innate immunity, because it is inborn. The phrase introduces us to one of the most important words in the whole of natural science, the word *immunity*. This word must be clearly understood if we would understand life itself in any way. Immunity is the key which unlocks almost all the important problems which a man has to settle for himself in every sphere, be it physical, mental, moral, or religious. It is, or should be, his aim in life to become immune to all agencies of whatever nature which threaten his existence or his perfect development in any of these spheres. There is nothing of so great importance. The most perfect character ever known in the history of the world was so in virtue of His immunity to sin. The healthiest man that lives is so in virtue of his immunity to disease. We must, therefore, carefully define the term, and thoroughly grasp its meaning.

What is Immunity? It will conduce to simplicity if we consider immunity first of all simply from the point of view of disease, carefully remembering that this is but one phase of a general principle. From this aspect we may define it thus: Immunity is that condition of an individual, an organ, or a tissue, in virtue of which infection can be partially or absolutely resisted. Let that definition be read several times and let the reader ponder it carefully, grasping its full significance before proceeding with the consideration of this vital matter. Immunity is that condition of ourselves which enables us to keep free from infection, either entirely free or comparatively so. In

other words it enables us to resist attack. Without it all would become infected and none could resist when attacked. Life would be impossible, for life itself is the sum total of our immunities. In the sphere of disease, total immunity means complete insusceptibility to a given disease, whether under natural conditions or from artificial inoculation. Immunity from disease is therefore the great aim of modern scientific medicine. If not possessed naturally, the next best thing is to acquire it artificially in some way, which we shall consider in a moment. For the present we are concerned with natural resistance.

Examples of Natural Immunity. Many examples of natural resistance to disease occur in man and the lower animals. Thus, human beings are immune from a disease which attacks pigs—namely, swine fever. They are naturally so immune simply because they are human beings. On the other hand the lower animals are absolutely immune from some diseases to which man is susceptible, such as typhoid fever and Asiatic cholera, neither of which attack animals under natural conditions. This does not mean that when the organisms of these respective diseases are introduced into the body artificially, no ill effects follow. It means that the characteristic symptoms and changes associated with the diseases in question do not appear.



CHOLERA BACILLI

13. Cholera bacilli. **14.** Growing in intestine. **15.** Colonies of bacilli on a plate culture. **16.** Cholera bacilli in gelatin

Natural immunity, therefore, varies with the species of animal under consideration; some species are immune from one infection, some from another. It also varies with different races of the same species. Thus, the various races of human beings, white and black, exhibit varying degrees of immunity from and susceptibility to the same diseases. So in the lower animals, such as sheep, the different breeds of which show varying degrees of resistance.

This natural, innate, or inborn immunity depends upon the power of certain cells and tissues and secretions in the body to overcome and destroy microbes which may gain entrance to the body.

As a matter of fact the tissues in the body have great power of destroying microbes during life. Natural immunity is therefore chiefly the power of resisting infection.

Natural Destruction of Bacteria. Two factors are mainly responsible for the natural destruction of living germs within the living body. The first is the action of certain body cells which attack germs; the second is the power of the blood serum to destroy them likewise. The cells which operate in this manner are called *phagocytes* (cell-eaters). Most of our knowledge concerning these is due to the splendid work of the famous pathologist Metchnikoff. He noticed that it was a very common property of animal cells that they could take up small particles into their interior and destroy them by digestion. On this fact he based his theory of *phagocytosis*, which implies that certain body cells thus take up and digest the germs of disease. The cells in the human body which do this are the leucocytes in the blood [see PHYSIOLOGY], and certain cells such as endothelium and those of connective tissue. The more active these phagocytes the greater the degree of immunity possessed by the individual, and vice versa. When germs enter the body they seem to attract the leucocytes towards them, and the greater this attraction the better for the animal, because the greater the destruction of the bacteria.

Secondly, it has also been shown that ordinary blood serum possesses the power of destroying various germs, and upon this fact is based the recent serum treatment of disease, in which the serum is made to acquire this power artificially against special diseases.

Acquired Immunity. In addition to this inborn or natural immunity which we have considered there is a second kind or type, which the individual acquires during his lifetime. Physicians have long known that certain diseases confer upon the individual who recovers from their attacks an absolute immunity from further attack for a longer or shorter period, in some cases for years, sometimes practically for a lifetime. Now, this immunity is something which the patient did not possess before. It is something new, acquired, and hence is termed *acquired immunity*. We see examples of this acquirement every day. It is observed in those who have suffered from smallpox, scarlet fever, and measles. It is extremely rare that anyone has these diseases more than once in their lives. This acquired immunity is not to be looked upon as the result of the disease as such; it probably depends in some way upon the products of the germs which are introduced into the system during the attack. In fact, by suitable administration of the products of bacteria, a very high degree of this kind of immunity may be conferred upon a person without his undergoing the disease and without the occurrence of any symptoms at all.

This acquired immunity may be obtained in various ways. When a person is vaccinated he is really inoculated with a modified small-pox germ product from the cow. The effects of this operation of vaccination are trifling if the vaccine be pure and the patient healthy, so trifling as to be of no account when compared with the terrible results of actual small-pox. Nevertheless, we find that the result of vaccination is to cause the patient to acquire a complete immunity from small-pox for a number of years. It is less lasting than recovery from the disease itself because the virus introduced is less potent.

It is too risky to inoculate from a small-pox pustule; the patient is immune if he recover, but he may very easily die. So the vaccine or lymph

is weakened or attenuated by passing it through another animal.

Acquired Immunity Ending Disease. "Recovery from an acute infective disease shows that in natural conditions the virus may be exhausted after a time, the period of time varying in different diseases. How this is accomplished we do not yet fully know, but it has been found in the case of diphtheria, typhoid, cholera, pneumonia, etc., that in the course of the disease certain substances appear in the blood which are antagonistic either to the toxin or to the vital activity of the organism. In such cases a process of immunisation would appear to be going on during the progress of the disease, and when this immunisation has reached a certain height, the disease naturally comes to an end. It cannot, however, be said as yet that such antagonistic substances are developed in all cases; and it is by no means the case that the degree of immunity is always proportional to the amount of these substances in the blood." (Muir.)

How Bacteria Cause Disease. It is convenient at this point to note that bacteria produce their effects by two distinct modes of action. First of all their action may depend upon their rapid multiplication in the body after gaining entrance, thus causing a rapid distribution of themselves throughout the tissues and a general infection. When this rapid multiplication occurs in the blood, the condition known as *septicæmia* is produced. Secondly, their chief effects may be due to their own chemical products, not to rapid multiplication of individual germs. These poisonous or harmful products are called *toxins*. These diffuse out from the bacterial cells into the blood or tissues, and produce effects upon the various parts of the body which are susceptible to the action of the special toxin developed. Thus, some toxins produce a high temperature or fever; others depress the action of the heart, causing cardiac failure; others, acting on special parts of nerves, cause spasms of muscles, while others act upon the tissues in their immediate locality, causing their death or necrosis. The results are, therefore, local (on the spot), or general (throughout the body).

What an Anti-toxin is. Bearing in mind these two methods of bacterial action, we may now return to the question of immunity. We see now what it is against which a patient must become immune in order to recover from an attack of an infective microbic disease. In order to resist infection he must be able to destroy, kill, or digest the actual germs which gain entrance to the body, and prevent their rapid multiplication in the tissues. In other words, he must have within him certain anti-bacterial or bactericidal (germ-killing) substances. These, we have seen, are leucocytes, other cells, and serum. But should these fail in their efforts to destroy the invading microbes; should these latter effect an entrance and begin to flourish in the body, producing as they do so their powerful toxins, then, in order to recover and become immune to further attack from the same source, something more is necessary. Not merely do the bacteria require to be killed, but their toxins must be neutralised in some way. Indeed, this is more important than killing the germs themselves. The physical effect of the presence of the microbe is trifling in comparison with the result of the action of the potent chemical toxin which it may produce. If this latter can be antagonised, the former in many cases is of little moment. Any substance which is capable of nullifying or antagonising the evil effects of a toxin is termed an *anti-toxin.* If this anti-toxin be contained in a serum from an animal the whole is termed *anti-toxic serum,* such as that which is used in the treatment of diphtheria and other microbic diseases whose worst action is that of their toxins.

In acquiring immunity from a disease as the result of recovery from that disease, as in small-pox or scarlet fever, the patient obviously manufactures for himself during his illness his own anti-toxin or anti-bacterial substance. Having manufactured it, it is available for future use, and protects him against further infection from a similar scourge. During the process of manufacture, he is more or less dangerously ill. It is for this reason that we must trust to artificial production of immunity in place of that conferred by recovery from disease; the latter is too risky, for the patient may die. Immunity is not so powerful when artificially conferred, but it is free from risk, and can be renewed when necessary. Hence it is made illegal to give people small-pox by inoculation, on the chance that they may recover and become immune, though this was done formerly. We use the artificial method of vaccination, which, though not quite so powerful, is harmless, and confers protection for some years.

Treatment by Anti-toxic Serum. All that is necessary is to find an animal which is susceptible to the action of the germs against which it is required to produce or acquire immunity. By various methods, the technical nature of which need not be discussed here, the animal is rendered immune artificially. That is to say, by carefully increasing the doses of germs the animal is gradually brought to such a stage that it can withstand the inoculation of a dose which previously would have proved fatal. The horse (in the case of diphtheria) has acquired immunity from the diphtheria germ and its toxin. Not only so, but it is found that the serum of such an animal contains the anti-substances ready made, and in such a form that they can be transferred from an immunised animal to another. The serum is anti-toxic, and it has merely to be drawn off and preserved in a sterile condition to be ready for use as an anti-toxic serum. Such a substance is a great advance upon such a method as vaccination, from one point of view—that it can be used as a *curative* agent immediately. Vaccine cannot be so used; it is a *preventive* agent. From its use the patient is enabled to make his own anti-toxin, but he must be free from the disease when he does this. Having done it, he is immune for years. With the anti-toxic serum, however, the doctor can attack a case of diphtheria actually in progress, because he has a weapon which contains the substances ready made which will neutralise the diphtheria toxins from which the patient dies. On the other hand, though he saves the patient's life, the injection of the serum does not confer immunity for long; it becomes eliminated from the body. The one may prevent death after the disease is in actual progress, the other prevents infection if used before exposure to infection. The future of curative and preventive medicine is wrapped up in the further elaboration of anti-toxic and anti-bacterial remedies, and considering what bacteriology has accomplished in this direction in a very few years, he would be a rash man who would venture to set a limit upon its future possibilities. Thus it will be realised that in the sphere of disease, as in all others, the great aim of man is to become immune from deleterious and destructive agencies.

Continued

A SHORT DICTIONARY OF BACTERIOLOGICAL TERMS

ACID-FAST—A term applied to those organisms which retain stains even though treated by decolourising acid solutions.

Actinomycosis — A disease most common in cattle, especially in the jaws, caused by the actinomyces or ray fungus.

Ærobic—A term applied to micro-organisms which require oxygen to enable them to grow.

Agar-agar—A substance prepared from the roots of seaweeds, used to solidify the medium in which organisms are grown.

Agglutination—The phenomenon observed when organisms are placed in a serum prepared from an animal immunised against similar organisms. The organisms thus treated are observed to lose their motility, and become aggregated or "agglutinated" into clumps.

Agglutinins—Definite substances in a serum, which causes the phenomenon of agglutination.

Alexins—Substances present in normal blood serum, which help to confer natural resistance to infection.

Anærobic—A term applied to organisms which will not grow in the presence of air.

Anthrax—An infective disease caused by the anthrax bacillus; communicable to man, in whom it causes woolsorters' disease of the lungs; malignant pustule in the skin.

Anti-bacterial Serum—A preparation of blood serum from an animal, which is destructive to certain microbes.

Antitoxic—Having the power of antagonising toxin.

Antitoxic Serum—A preparation of the blood serum from an animal, which antagonises the poison or "toxin" of certain microbes (*e.g.*, anti-diphtheritic serum).

Antitoxin—A substance which antagonises a toxin.

Attenuation—The process by which the virulence of a microbe can be reduced.

BACILLUS—Literally a small rod; a term applied to many organisms, which are of that shape.

Bacteria—Literally rods; but used to refer to micro-organisms in general.

Bactericidal—Having the power of destroying bacteria.

Beggiatoa—A group of organisms composed of indistinctly articulated threads, containing sulphur granules.

Blood Serum—A nutrient medium in which organisms are grown.

CHEMIOTAXIS—The name applied to the attraction or repulsion exercised upon bacteria by chemical agents (positive and negative chemiotaxis respectively).

Chromogenic—A term applied to organisms which produce pigment.

Cilia—Minute protoplasmic threads attached to the sides or ends of organisms, by means of which they move.

Cladothrix—A group of organisms in which there is an appearance of branching, really due to two terminal cells lying side by side.

Clubs—Elongated, pear-shaped bodies seen at the periphery of a colony of the actinomycosis parasite.

Coccus—A round organism occurring either singly, in pairs, in fours, in chains, or in bunches.

Colony—The term applied to a number of organisms growing together.

Complement—A substance developed during the process of immunisation.

Culture—The name applied to the growth of one single species of microbe when artificially cultivated.

Cytolytic Sera—Sera which are destructive to cells.

DIPLOCOCCUS—A coccus occurring in pairs.

Disinfectant—Any substance which has the power of destroying the life of microbes.

Drying—One method employed to weaken the virulence of organisms.

EHRLICH'S SIDE-CHAIN THEORY—The term applied to the recent theory advanced by Ehrlich to account for the formation of antitoxins in the body.

Enhæmospores—Spores found in the blood (as in malaria).

Exhaltation—The increase of virulence of microbes; the converse of "attenuation."

Exotospores—Spores occurring in the body of the mosquito; a stage in the life cycle of the malaria parasite.

FACULTATIVE—A term applied to organisms which can live either with or without oxygen.

Farcy—A form of glanders, affecting the lymphatic vessels and glands.

Fever—An abnormal rise of body temperature, frequently caused by microbes or their toxins.

Fission—A process of multiplication in microbes.

Flagella—Delicate protoplasmic threads [see *cilia*].

GELATIN—A substance used to solidify nutrient media.

Gentian-Violet—A stain much used to demonstrate microbes.

Gram's Method—A process of staining which differentiates certain organisms from others.

HÆMAMŒBA MALARIÆ—The parasite of quartan fever in man.

Hæmamœba Vivax—The parasite of tertian fever in man.

Hæmolytic Serum—The blood serum of one animal which has the power to a certain extent of dissolving the red blood corpuscles of another animal of different species.

Hæmomenas Præcox—The parasite of malignant or aestivo-autumnal fever of man.

Hydrophobia—An infectious disease occurring chiefly among carnivora, especially in the dog and wolf; transmitted by bite.

IMMUNE BODIES—Substances developed during the process of immunisation.

Immunisation—The process of rendering an animal immune.

Immunity—That condition of an individual, an organ, or a tissue, in virtue of which it is enabled to resist infection either absolutely or partially. Immunity may be natural or inborn, or it may be artificial or acquired. According to the means used for the production of immunity, it is active or passive. Active immunity is obtained by injections of organisms either attenuated or in sub-lethal doses; or, secondly, by injection of their products or toxins. Passive immunity is the injection of the serum of one animal, highly immunised by active immunity, into another animal, the latter being thus rendered immune.

Incubator—An apparatus used to cultivate organisms which require constant warmth.

Inoculation—The injection into an animal of microbes or toxin by means of a hypodermic syringe. Also, a means of separating one organism from a mixture of organisms.

LEUCOCYTES—White blood corpuscles, which act as phagocytes *i.e.*, they have the power of taking up microbes into their protoplasm.

Leucocytosis—An increase in the number of leucocytes.

Lysogenic Action—The destructive action of an anti-serum upon organisms. It is due to two substances the immune body and the complement, or alexin [see above].

MACROPHAGES—Any cells larger than the small leucocytes which have the power of ingesting bacteria.

Mallein—A substance used to diagnose glanders, prepared from cultures of the glanders bacillus.

Micrococcus—A general term applied to any small round microbe.

Microphages—The smaller leucocytes which ingest bacteria.

Myelocytes—Cells in bone marrow from which leucocytes develop.

NITRIFYING BACTERIA—Bacteria in the soil which make nitrogen more available for plant nutrition by conversion of ammonia into nitrites and nitrates. Others take up free nitrogen from air, and combine it into compounds.

OPSONIC INDEX—A means of stating the power of opsonins. The opsonic index is the ratio of the bacilli ingested by leucocytes incubated in the patient's serum to those ingested by an equal number of leucocytes incubated under similar conditions in healthy serum. Thus for tubercle bacilli the opsonic indices of healthy persons may vary from 0·8 to 1·2; in tubercular patients it may be as low as 0·3 or as high as 1·8.

Opsonins—Substances contained in blood serum which act upon bacteria rendering them more easily eaten by leucocytes. (From Greek words meaning "prepared for being eaten.")

PASSAGE—The process of passing a microbe through the body of an animal for purposes of attenuation or isolation.

Pathogenic—Productive of disease.

Pfeiffer's Phenomenon—A destruction of organisms by lysogenic action [see above] due to a specific substance in the serum.

Protective Inoculation—The conferring of immunity by active methods.

Ptomaines—Substances containing nitrogen isolated from putrefying matter or from cultures of microbes.

RECEPTORS—The name given by Ehrlich to groups of atoms with affinity for certain foodstuffs.

Ricin—A vegetable poison (allied to bacterial toxin).

SARCINÆ—Coccus-like organisms which divide in three axes at right angles to one another, usually seen in cubes of eight.

Septicæmia—A condition in which microbes multiply within the blood stream, and give rise to symptoms of general poisoning without the production of abscesses.

Spirilla—Organisms which are in the shape of cylindrical, wavy, or spiral cells.

Staphylococcus—A coccus which occurs in clusters.

Sterilisation—The process of rendering any substance free from microbes.

Streptothrix—An organism consisting of a mass of filaments in which true branching occurs.

TETRAD—The occurrence of an organism in fours (Tetracoccus.)

Toxin—A bacterial product of poisonous action.

Tuberculin—A curative or diagnostic agent for tubercular affections, prepared from cultures of the tubercle bacillus.

UNIT OF IMMUNITY—The amount of antitoxic serum which will neutralise 100 times the minimum lethal dose of toxin, serum and toxin being mixed, diluted, and injected subcutaneously. A normal antitoxic serum is one of which 1 c.c. contains an immunity unit

Following TELEPHONES from page 6[illegible]

MAKING ELECTRIC CABLES

Varieties of Electric Cables. Conductors and Insulation. Making, Covering, and Testing Cables

FOR the distribution of electricity in large quantities, cables are in general use. The electrical cable is an insulated or separated artificial path or track along which electricity will flow readily. The path is a metal core, known as the *conductor*, and the material which separates it from the surrounding objects is known as the *insulation*. Copper has been found to conduct better than most other substances, hence we find the conductor in nearly all cables made of a copper-wire rope or strand. The insulation is a coating of a material which will not allow electricity to pass through, or along it, except under very great pressure; therefore, when this material is placed round the core, the current flowing through the conductor is entirely separated from objects around it, and is consequently under control.

Insulation. Insulations fall naturally into two classes: (1) *hygroscopic*, or moisture absorbing; and (2) *non-hygroscopic*, or moisture resisting. The more common of the first class are jute and paper, and of the second, vulcanised indiarubber, gutta-percha, and bitumen.

The first successful experiment in which a continuously insulated cable was used was in 1812, when Baron Schilling exploded a mine by electricity conveyed by a wire insulated with indiarubber, and laid across the River Neva. In 1815, or 1816, Ronalds carried out some experiments in telegraphy, and, in addition to an overhead wire, which was suspended by silk threads hanging from wooden frames, he laid one, a little less than a furlong in length, underground. This was drawn through glass tubes, the separate lengths of which were joined together by small glass sleeves placed over the joints and fastened in position with wax. The glass tubes containing the wire were then placed in a wooden trough and covered over with pitch. This method of insulation was not very successful, as the glass was very liable to break and leave the wire uninsulated. The stranding of wires was introduced when large sectional area and flexibility were required. In 1837, a line was laid in London in which the wires were covered with cotton steeped in resinous compound, and then laid in grooves cut in baulks of wood. The insulation of these wires soon gave way, because the cotton decomposed and left the wires practically bare. The dampness which caused the decomposition also acted as a conductor, and allowed the electricity to escape.

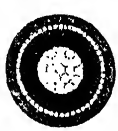
In the following year a line was laid from Paddington to Slough. In this instance the wood was replaced by iron pipes; but the line had the same fate as its predecessor, and an overhead system was substituted. In 1845, a proposal made by Wheatstone and Cook to enclose the cotton-covered wires in lead tubes, was a step in the right direction, and a patent was taken out in the same year for lead-covered wires. Cables covered with lead gave much better results than previous ones, and about this time a new insulation was discovered in gutta-percha, Faraday being one of the men who found that it was a good insulator. The first wires insulated with gutta-percha were laid in London in cast-iron pipes in the year 1849.

Conductors. The chief conductor nowadays is the copper-wire strand or rope. The separate strands which form this rope are usually tinned in order to keep their surfaces clean, because tarnished copper is not so good a conductor as clean copper. The most commonly used moisture-resisting insulators now in use are indiarubber, bitumen, and gutta-percha, and the principal moisture-absorbing, jute and paper. The indiarubber insulation is laid on in two kinds. The first kind, which touches the copper strand, is pure and free from sulphur, because sulphur tarnishes metals. The second kind is a compounded rubber containing sulphur. This will vulcanise and become firm and resilient. The bitumen is first thoroughly refined and then mixed with sulphur and other chemicals, and vulcanised like the second layer of rubber. Before the bitumen is applied, a layer of thin rubber-coated cotton tape or paper is wound round the strand to prevent the sulphur in the bitumen tarnishing the copper. Gutta-percha is used in a flexible state chiefly for low-pressure work, such as telegraphic insulations.

The paper used for insulating purposes is strong manilla paper soaked in resinous compound. The jute is usually applied in the form of a braid impregnated with oily compound.

So far, mention has been made only of the two essentials in a cable—namely, the conductor and the insulation; but it is not often that one meets with a cable in use made only of these two. Nearly every cable has some extra coverings, either to make the insulation perfectly waterproof, or to give the cable some mechanical protection. Lead sheathing, steel tapes, galvanised iron wires, and jute braid are extensively used for these purposes, as will be shown in the following descriptions of cable-making.

Varieties of Cables. Of the several kinds of electric lighting and power cables made, the most widely used are the "Single," the "Concentric," the "Twin," the "Triple concentric," and the "Three core." The *single* cable [1] consists of a central copper strand, a layer of insulating material, a covering of braid, and a sheathing of protective armouring.



1. STRAND CABLE

The process of making a "single" indiarubber insulated cable begins with the conductor. The copper wire for this purpose has usually a tin coating, and comes from the makers, when not drawn at the cable works, in hanks. These hanks are sorted into the various sizes of wire, and the desired size for the cable about to be made is chosen, and thoroughly cleaned to remove all traces of tarnish, dirt, and grease. After being cleaned and examined, single lengths of the copper wire are wound on separate small metal drums or bobbins, which fit round the circular frame of the stranding machine. The number of drums used at one time, and the size of wire wound upon them, depend upon the amount of current the finished cable will have to conduct. A large number, of a large size, are required for a large current. When the drums are in position there is passed through the centre of the machine a central wire to which the ends of all the

wires on the small drums are attached. As this central wire is drawn along the machine is set in motion and the frame containing the drums rotates in such a manner that it twists or strands all the other wires round the central one, so as to convert them into a wire rope or strand [see page 5175].

Applying the Insulator. If the conductor is free from grit and grease after this operation, it is ready to receive its covering of insulation. For this purpose, if it is a small-sized cable, it is taken to the longitudinal machine, which consists of a long, raised bed, at each end of which there is a pair of grooved rollers. Rolls of narrow indiarubber strip are placed before each pair of rollers, the first lot being pure, and the second one compound indiarubber. As the end of the conductor is brought up to the first pair of rollers, the ends of two strips of pure rubber are placed about it, one on top and one below; so that when it comes out at the back of the grooves the indiarubber strips are pressed round in the form of a complete covering, with a firmly-pressed longitudinal joint at each side. Although this joint is made only by pressure, yet if the surfaces of the edges of the strips are perfectly clean, it is thoroughly sound. On approaching the second rollers, two strips of compound rubber are applied in a similar manner, so that when the conductor finally passes out of the machine, it is completely covered with two layers of indiarubber.

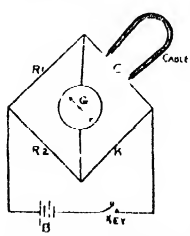
If the cable is of large size, the two kinds of indiarubber are applied by the lapping machine, which covers the conductor by spirally wrapping the indiarubber strips round it instead of pressing them on as at the longitudinal machine. The wrapping of large cables is preferred because the pressure given by the longitudinal machine has not been found satisfactory for the greater thickness of insulation required by them. The separate layers of strips are wrapped in reverse spiral so as to prevent, as far as may be, the possibility of a weak spot in each of two strips, occurring right through the insulation at one place. The thickness of the rubber coating is decided by the considerations of the pressure and disruptive strain that the insulation will have to withstand.

The Indiarubber Covering. When the requisite thickness of indiarubber has been applied, the cable is given a wrapping of indiarubber-covered cotton tape, at the taping machine. This is to add firmness to the covering of indiarubber, which, up to this time, is a plastic substance, of the consistency of stiff dough. In this state it can be easily moulded into any desired shape, and will stick in the shape it is formed. This, of course, is very convenient while the indiarubber is being pressed or wrapped on the conductor, but before the armouring materials are applied over the insulation, it is necessary that it should be firmer and more resilient. With the object of giving these properties to the substance it is taken to the vulcanising house. This is a room containing large, hollow, cylindrical, iron pans to which the necessary pipes, taps, valves, etc., are attached, so that steam may be let in or out as desired. In this room the cable is placed inside one of the pans, after being wound on the drum made especially for the purpose. The pan is closed up by a steam-tight door, and the steam turned on until a certain pressure is reached. This pressure is kept up for a certain time, until the indiarubber is properly vulcanised. The pressure and time of vulcanisation depend upon the quality and thickness of the rubber applied. When the steam in the pan has been let off, and the cable taken out and cooled, it will be found that the outer layer of indiarubber has acquired the desired properties of firmness and resiliency. The acquisition of these properties is chiefly due to the indiarubber containing as one of its ingredients sulphur, which is a vulcanising agent, and which, under the action of steam pressure, chemically combines with the other ingredients and gives the springiness so characteristic of all indiarubber goods. The full chemical action which takes place is not thoroughly understood even in indiarubber manufactures. During the whole process of applying and vulcanising the rubber great care is taken that the surface is quite clean and free from grease of any kind, as the successful manufacture of vulcanised indiarubber cables greatly depends upon the careful handling of the indiarubber.

The cable is now completed as far as its essentials are concerned—it has its conductor and its finished insulation; therefore, before any further coverings are added, either for protection against dampness or mechanical injury, it is taken to the test-house to be tested. Here the cable undergoes a rough test under water, to see that its insulation is sound. A second and more careful test is given when the cable is complete, details of which process will be given later.

Braiding the Cable. If, after the rough test, the insulation is found satisfactory, the cable is allowed to dry, and is then taken to the braiding machine to be covered with a stout jute braid. This braid is moisture-absorbing, and in order to prevent it from rotting, it must be protected from damp. For this purpose the cable covered with braid is passed through the serving tanks, which contain a hot compound, composed chiefly of paraffin wax, and similar substances. The coating of compound on the braid as it comes out of the tanks, besides being damp resisting, is also an insulator, and therefore adds a little to the better insulation of the finished cable. Since indiarubber is a waterproof material, it is not necessary to cover the cable with a lead sheathing, although one is sometimes put on for mechanical protection. The more common method of protecting indiarubber insulated cables against mechanical injury is by encasing them with galvanised iron wires or steel tapes. The wires are stranded over the jute braid by the stranding machine, and the steel tapes are wrapped on by the steel taping machine. Although the iron wires are galvanised as a protection against rust, yet a jute braiding is often applied on the outside of them as a further safeguard.

Testing the Cable. The cable is now ready for its final test, and for this purpose it is taken to the test-house, placed in tanks of water, and allowed to remain there for about twenty-four hours. The testing operation is very important, and takes a day or two to complete. The chief tests made by the makers are those of the conductor, the insulation resistance, and the capacity of the cable.



2. DIAGRAM SHOWING CABLE TESTING

The test of the conductor is usually made by comparing its resistance with that of a known resistance. The comparison may be rapidly made by an instrument known as the Wheatstone bridge [see also page 791]. A simplified diagram of the connections for the comparison is shown in 2.

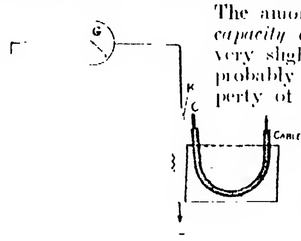
The proportion of the resistance through R1 and R2 is the same as that through C and K when the current passing round the arms causes no deflection in the galvanometer G. R1 and R2 may be read off the bridge scale, and K is a known resistance: therefore the resistance of the conductor under test is easily found from the formula

$$\frac{R1}{R2} = \frac{C}{K} \text{ or } \frac{R1}{R2} K = C.$$

Suppose the proportion of R1 and R2 is 2 1, and the known resistance equals 5 units; then from the second formula the cable will have a resistance of 2×5, or 10 units. Another method of testing the conductor is by the metre bridge, the principle of which is somewhat similar.

The Water Test. The test for the insulation is made after the cable has been in water, at a constant temperature, for twenty-four hours. With the cable still in water, the insulation resistance is tested by a method of comparison. The leakage current through the insulation is compared, by means of a galvanometer, with the flow of current through a known high resistance, when the same battery power is applied. The galvanometer is an *instrument* in which there is a sensitive needle, placed over a graduated circular scale, and surrounded by a coil of wire. This is its simplest form.

As the current passes through the galvanometer, the needle is deflected through a certain angle. The comparison, in its simplest form, is made thus Suppose a circuit is made up of a battery, a galvanometer, and a length of wire. After the current has passed round the circuit for a short time the galvanometer needle will remain stationary at certain deflection from its original position. If the wire is now taken out, and another one of equal length, but of different substance, put in its place, the galvanometer needle, when the current is next sent round the circuit, will come to rest at a deflection different from the one in the first instance. In both these circuits the battery, the galvanometer, and the length of the wire are the same; the only difference is the substance of the wires, therefore any change in the current can be due only to this alteration. Now the current in a circuit is approximately equal to the electromotive force sent out by the battery, divided by the resistance offered to this force by the wires or other substances in the circuit. If the electromotive force is represented by E, the resistance by R, and the current by C, then $C = \frac{E}{R}$. Applying this formula to both instances above, we see that E is the same in both, but C, as shown by the deflection of the needle, is different; therefore the resistance must have altered in inverse proportion to the current. A numerical example will make this clear. Suppose the battery sends out a force of 6 units and gives a deflection, in the first instance, of, say, 30°, and in the second of 20°. Then since the current is proportional to the deflection, we may take it that the first current equals 3 units, and the second 2, and from the formula $C = \frac{E}{R}$ we get, first, $3 = \frac{6}{R}$, and second, $2 = \frac{6}{R}$. Therefore the first resistance equals 2 units, and the second 3 units. Thus the second wire has a resistance of one and a half times the first one.



3. CONNECTIONS FOR INSULATION TESTING

Insulation Resistance Test. In the actual testing of cables the resistance which the insulation should offer when sound is first calculated, and the circuit is made up of a powerful battery, a galvanometer, and a known high resistance, which is approximately equal to what the calculation gives. Figure **3** shows a diagram of connections for insulation resistance testing. A deflection is obtained with the known resistance in circuit by pressing the key K into contact with R. The known resistance is disconnected, and one pole of the battery is connected through the galvanometer to one end of the cable by pressing the key to the right to make contact with C. The other end of the cable is left entirely free, not even allowed to touch the sides of the tank in which the body of the cable lies. The other pole of the battery is connected to earth at E. To complete the circuit, the electricity will have to flow from the battery through the galvanometer into the cable, through the insulation into the water, down the sides of the tank to earth, and along the earth to the wire earthed at E. Thus it will be noticed that the electricity will have to go *through* the insulation as it had to go *through* the known high resistance, and since these are, approximately, equal, the deflection obtained when the cable is in circuit should be nearly the same as that when the known resistance was in. This will be the case when the cable's insulation is sound, and when the ends, which are never allowed to touch the water, are painted with paraffin wax to prevent surface leakage.

A point may be mentioned with regard to reading the galvanometer deflection when the cable is in circuit. When the electricity enters the instrument, a deflection will be shown, but as the electricity continues to flow the deflection will gradually decrease for a few minutes, and then remain stationary. This slow decrease is due to the electrification of the cable; that is, the absorption by the cable of a certain quantity of electricity into itself. The amount of absorption is known as the *capacity* of the cable. If the decrease is very slight, or proceeds unsteadily, there is probably a defect in the cable. This property of electrification may be used as a further test for the soundness of the cable in this way. If after electrification the cable is connected to earth through the galvanometer after the battery has been removed, the deflection of the galvanometer will show that a steadily decreasing current is flowing from the cable. If the deflection decreases at the same rate as when the battery was first put on, the cable is sound.

Testing Capacity. The capacity of the cable may be tested by comparing it with a condenser of known capacity. The condenser is first charged by a battery, and then the accumulated charge is sent through a galvanometer. The cable is first connected to earth to remove all residual charge, and then electricity is sent through it until it has absorbed to its full capacity. This point is reached when the galvanometer needle remains steady. The battery is removed, and the cable connected to earth through the galvanometer, and the deflection compared with that obtained from the condenser. The capacities are roughly in proportion to the deflections.

INDIA AND AUSTRALIA

Clive and the Battle of Plassey. The Famous Trial of Warren Hastings. The Indian Mutiny and the Tragedy of Cawnpore. Australia To-day

By JUSTIN McCARTHY

THE formation of the East India Company, in 1591, was of great importance in England's relations with Hindustan. The beginning of this enterprise consisted of only three ships, of which but one reached India. The captain of that ship had much trouble with his crew, but he brought back such good news of the prospects in India that a private mercantile company was started, and obtained its first charter in 1600. Its stock valued £72,000, and its fleet consisted of four ships. This was called the London Company, and its charter was renewed by successive enactments. There was a magnificent opening in India for commercial enterprise, because of its vast wealth and varied resources. In September, 1698, a rival company was started called the English Company, and the two companies were afterwards united, and became that East India Company which exercised so important an influence in the condition of India and the financial affairs of England.

India Divided into States. The Portuguese had in the beginning of the sixteenth century made a settlement in India for trading purposes, and the Dutch were also early in establishing an East India Company. They came a little later than the English, while the French East India Company was not established for more than a century after. Soon the whole world of adventure began to send out its fleets to India. India was divided into several empires and states, between which were frequent internecine wars. Dynasties established far back in history were now and then overthrown by a new movement among its own people, or by invasion by some outlying race, and the condition of the country offered continual opportunities to European speculators and adventurers, who sometimes took possession of whole territories. Bombay had been annexed to Portugal, and when Catherine of Braganza became the wife of Charles II., Bombay was ceded to England as part of her dowry. Madras was colonised by the English in 1640, and was afterwards made a presidency under an English governor. Calcutta, which had been a subordinate part of Madras, was created a separate presidency in 1701. There were many disturbances between the natives and the European settlers, and between the European occupants of different territories; wars between the English and the French, and continual rivalry between the Dutch, Portuguese and Spanish, and the later European settlers. New native dynasties were founded on the ruins of native sovereignties, and the different faiths of the people led to many internal revolutions.

Throughout a great part of India a system prevailed which allowed each village to manage, to a certain extent, its local affairs, under the control of the Imperial power, and if the state of which it was a part passed under the rule of a new sovereign or of an invader, the village accepted the new rule, and still managed its local affairs. Owing to this system the settlements of foreign invaders passed in many cases harmlessly over the heads of many of these village populations, and the invader was not likely to encounter much resistance from them.

Dupleix and India. At the opening of the eighteenth century the French were the great rivals of the English in the struggle for the possession of territory and supremacy throughout India. One of the most celebrated men of this time was Joseph François Dupleix, a Frenchman who had early in life been made a member of the French East India Council, and was, in 1741, appointed Governor-General of the French possessions in India. Dupleix showed such marvellous skill in his dealings with the native princes of that region that they entered into cordial terms with the French, and seemed likely to become willing instruments in the promotion of his policy, which was to found a French empire in India. This brought about a struggle between the French and English, and many battles took place by land and sea.

But among the representatives of England was one man who was too much even for Dupleix. This was Robert Clive, the maker of England's Indian Empire. Clive began his career as a clerk in the East India Company. When he had settled in India he was seized with the ambition to become a soldier, and in due course he distinguished himself in many engagements.

The Black Hole of Calcutta. In 1753 he came back to England, where his military fame had preceded him, and on returning to India two years later he recaptured Calcutta, which had been taken from the English, where some 150 English prisoners had been crammed into the infamous "Black Hole," a prison 18 ft. square, from which only twenty-three came out the next morning alive. Clive also captured some of the French settlements, and on June 23rd won the famous victory of Plassey, in Bengal, over the Hindoos under Surajah Dowlah, in which 68,000 of the enemy were completely conquered by about 1,000 English and some 2,000 sepoys, thus securing the establishment of British power in India.

Clive returned to England a rich man, and entered Parliament as member for Shrewsbury, was raised to an Irish Peerage as Lord Clive, and was created Knight of the Bath; but he had to return to India in 1765, where his presence was indispensable. The affairs of the East India Company had been mismanaged, and were

threatened with collapse. Clive went to Calcutta and devoted all his energies to the reformation of the civil and military services, and soon accomplished a complete reform in both departments, proving himself as great a civil administrator as he had been a military commander. Indeed, the practical working of British administration in India dates from Clive's last visit. In 1767 Clive returned to England, and the rest of his story is all sadness. His reforms during his later years in India had made him many enemies; he was attacked by Parliament, and his government of India was made the subject of inquiry by a Select Parliamentary Committee, which ended in something like a vote of censure on Clive, qualified by a few words of praise. Clive felt the reproach thus put upon him most deeply. Some of his actions might have been justly censured, but it is certain that he had made enemies, who put the worst construction on everything he did. He tried to relieve his mental depression by opium, which only increased his melancholy, and on November 22nd, 1774, the great soldier and statesman committed suicide. It is strange that Dupleix, his rival for the mastery of India, also fell upon evil days. He had been recalled from power by the French Government, and he died, neglected and poor, in 1763.

Warren Hastings. The next famous Englishman who took part in the rule of India was Warren Hastings, who was born in 1732 of an old Oxfordshire family. Like Clive, he was compelled by family circumstances to make a living for himself, and in his eighteenth year obtained a place as a writer in the service of the East India Company, and before long became a member of the Council of Calcutta. In 1772 he was made Governor of Bengal and President of the Council, and soon after Governor-General of the British Dominions in India. As Governor-General he had a council of four members, three of whom were sent out from Great Britain. Hastings occupied himself in endeavouring to restore the finances of the Indian Administration, which had been reduced by neglect, bad management, and in some cases by selfish rapacity. He was severe and sweeping in his reforms. Nuncomar, a Brahmin official, being unsuccessful in his intrigues, accused Warren Hasting of peculation. Hastings, in return, had him tried for forgery, of which he was found guilty and sentenced to death. Hastings was accused of unfairness in pressing this charge, and of not having proceeded against Nuncomar in the same manner as against the other officials accused by him. The majority of the Council were opposed to Hastings, and that majority was led by Sir Philip Francis, who is still believed to have been the author of the famous "Letters of Junius," which began to appear in the "Public Advertiser" in January, 1769. In one of the letters, which were a series of attacks on Ministers of the Crown and other public officials, "Junius" said: "I am the depository of my own secret, and it shall perish with me." The enmity between Hastings and Francis had gone so far that they fought a duel, in which Francis was wounded. He retired from office in 1780. Hastings reorganised the revenues, revised the assessments, and greatly improved the administration of justice, and at the same time carried on an almost continual war with the Mahratta tribes, and spread the power of the East India Company more widely. Many of his acts as a ruler were harsh and unjust, and he had little scruple as to the means by which he attained the results at which he aimed. In 1784 he resigned, and returned to England.

A Famous Trial. Not long after this his conduct in office was made the subject of one of the most celebrated Parliamentary inquiries ever held in England. William Pitt was then Prime Minister, and the charges were made by Edmund Burke, Charles James Fox, Richard Brinsley Sheridan, and other members of the Opposition. Hastings was impeached at the Bar of the House of Lords, and his formal trial began in Westminster Hall on February 13th, 1788. The trial lasted more than seven years, for the sittings of the House of Lords were not continuous, like those of a court of justice. On April 23rd, 1795, Warren Hastings was acquitted by a majority of some of the charges, and acquitted unanimously of all the accusations that affected his personal honour and character. But the public in general were certainly not unanimous in his acquittal, and the subject is still a matter of controversy. He was probably too severely judged by the leaders of one party, and too readily exonerated by the other. The principle that a British ruler in India, having many special difficulties to contend against, was justified in adopting any course which helped him to maintain English rule was that against which Edmund Burke declaimed in some of his most eloquent speeches. Sheridan's famous "Begum speech," "relative to the Begum Princesses of Oude," was delivered during the impeachment.

Warren Hastings spent the rest of his days in England, living the life of a country gentleman. Most of his large fortune had been spent on his defence in his trial, but the East India Company made a liberal provision for his closing years. He had numberless admirers throughout the country. He was made Privy Councillor by the Prince Regent in 1814, and four years later his long and eventful life ended.

The Indian Mutiny. In 1784 Pitt had passed a measure establishing a Board of Control to assist, and, when necessary, to overrule the Executive Government of India and the East India Company. The president was to be a leading Minister of the Crown, and a member of the Cabinet. This lasted until 1858, when the Government of India was transferred to the Crown. The history of India, in the meantime, was a series of wars and conquests, wars against native princes, risings against British power, many checks and disasters to the British forces, but complete success ultimately for British arms, until at last the whole of the great peninsula was under the rule of England.

The most memorable event of this period was the Indian Mutiny, the mutiny in the

Bengal native army, which began in 1857. One of the greatest difficulties at this time was caused by the large number of natives whom the rulers of India had to employ, as it was impossible to provide a large enough army of Englishmen. A number of sepoys who seemed willing to enter the service were therefore employed. Some of these troops were found to be in sympathy with the Indian princes in their struggles against English dominion, but the mutinies which, in consequence, occasionally arose were easily suppressed. But the Mutiny of 1857, which began with incendiary fires at Barrackpur in January, and a mutiny of sepoys in February, was more extensive, and had a more definite object. The 11th and 20th Native Infantry and 3rd Cavalry in the garrison at Meerut, near Delhi, mutinied on May 10th, killed their officers, and marched to Delhi, and were there joined by the native troops, and received with enthusiasm by the native population, who killed the Europeans. The rising was not merely a sepoy revolt or military mutiny, but a sudden combination of mutiny, race hatred, and fanaticism against the dominion of England. The uprising of the native soldiers may have been the signal for the outbreak of that religious and political storm which had long been gathering.

The Cause of the Outbreak. The native princes and soldiers acted together, while the Mohammedans and the Hindoos suppressed for the time their own religious differences and united against the Christians. It was at first believed in England that the revolt was caused by the distribution of the Enfield rifles, the cartridges being wrapped in paper greased with cow's fat or hog's lard. This would have been to the Hindoos a profanation of the cow, which they venerated, and to the Mohammedan it was pollution to touch any product of the pig, which he regards as an unclean animal. The Government made every effort to assure the native soldiers that the cartridges were not so greased, and that nothing had been done to offend their religious feelings or caste sentiments. But if the alarm about the greased cartridges had not set the mutiny alight, some other cause would undoubtedly have done so. The mutineers in Delhi claimed the protection of the descendant of the great Timur, the King of Delhi, as he was still called. He was a man of over eighty, who had long been a pensioner of the East India Company, and it had been arranged that the title of King should die with him. The mutineers proclaimed him Emperor of India and leader of their revolt. Thus the mutiny became an uprising.

Lord Canning and the Mutiny. There had been a prophecy well known throughout India that the hundredth anniversary of the Battle of Plassey would see the end of England's dominion, and at the time that it was being celebrated in England the mutiny was in full movement. Lord Canning, the third son of the famous George Canning, was then Governor-General of India. He had succeeded to the title on the death of his mother, on whom it had been conferred after her husband's death. He held office for some years in England, and in 1856 he succeeded Lord Dalhousie in India. Though he had been there such a short time before the mutiny broke out, he proved equal to the occasion, and in that period of commotion he remained resolute and calm.

The Tragedy at Cawnpore. Lord Canning considered that the first thing to be done was to recapture Delhi, which had become the centre of the rebellion. A large body of English troops on their way to China were summoned to India by him to help in putting down the mutiny, which had broken out at Lucknow, at Cawnpore, and at other places. The tragedy of Cawnpore is one of the most terrible events of the war. It was caused chiefly by the treachery of Nana Sahib, the adopted son of an Indian prince, who professed to be an ally of the English, and was trusted by them, but he had long been plotting against the English Government because he felt aggrieved by Lord Dalhousie's rejection of his petition for the Peishaw's pension. He went over to the mutineers as soon as the mutiny began, became one of its chief instigators, and it was under his leadership the mutiny at Cawnpore broke out on June 5th.

He surrounded the Residency, where the English inhabitants had taken refuge. They were sheltered by entrenchments of a worthless character, but the garrison, diminishing daily in numbers, held out with splendid courage, and prolonged the defence until June 24th, when the ammunition and food were exhausted. The condition of the women and children was terrible, having neither food nor water nor adequate protection from the fire of the mutineers. But the sepoys showed themselves unwilling to approach too close to the fire of the indomitable British soldiers. Nana Sahib saw that he could not take the Residency by assault, and he could not wait until the garrison had died of hunger as he feared some large body of soldiers might come to their relief. He therefore offered to transfer all those who would surrender in safety to Allahabad, and to supply them with food in the meantime. The English, seeing no other chance of safety, accepted his terms.

The Treachery of Nana Sahib. The evacuation of the garrison took place on June 27th. The women and children were helped into the boats, and the officers and men were about to follow, when the sound of a bugle was heard—a signal from Nana Sahib—and the native rowers set fire to the straw roofs of the boats, from which they themselves escaped. At the same moment shots were fired from both banks of the river at the blazing boats. This deadly fire lasted until the greater number of the passengers had been shot, and the survivors were brought back to Cawnpore. Nearly all the men captured by the natives were immediately shot, but 112 women and children were imprisoned in a small house near Cawnpore. Some of the women were compelled to grind corn for their gaolers, but it seems that no other indignity was offered them.

After the English victory on July 15th, it was decided that all who remained should be killed, and on the following day they were murdered, some by shot and some by sword, and their bodies thrown into a dry well. There seems to be no

doubt that some were still alive at the time. Sir Henry Havelock fought his way into Cawnpore, but only in time to see the horrible evidences of the massacre. The well was filled up after the bodies had been buried, and a memorial chapel raised on the spot. Nana Sahib made his last stand against the English near Cawnpore, and was completely defeated. He managed to escape, however, and nothing was known of him after. Leaving Neill at Cawnpore, Havelock marched on Lucknow. He was afterwards reinforced by Sir James Outram. On September 10th Brigadier Greathed surprised and routed the mutinous troops from Rajpootana and Agra. Sir Colin Campbell, afterwards Lord Clyde, effected the final relief of Lucknow in November 1857. The capture of Delhi was accomplished in September of the same year.

A young English officer, William Steven Hobson, who formed the body of cavalry known as "Hobson's Horse," offered to capture the King of Delhi and his family, and was permitted to do so by General Wilson, on the condition that he spared the life of the king. He found the Royal Family surrounded by armed men, but his manner convinced them that he had a large force within call, and they surrendered. Hobson spared the life of the king, according to his promise, but regarded the three princes as rebels, and, taking a carbine from one of his troopers, he shot them dead.

The End of the Mutiny. By the end of 1857 the revolt in Bengal had been nearly suppressed, and in many other parts of India order had been restored. At the beginning of the following year the last of the Moguls was transported to Burmah. During January and February Sir Colin Campbell succeeded in clearing Oude and Rohilkhund, and in March went to Lucknow, and at last wrested the city from the enemy. Meanwhile, Sir Hugh Rose, commanding the Bombay division, advanced to the relief of Saugor, and defeated the rebels at Muddunpore. In April he defeated Tantia Topee, and took the fort of Jhansi, and in May the fort of Kalpy. In June he again defeated the rebels outside Gualior, and captured the city. Napier defeated the rebels at Alipore, and this ended the campaign.

It was found that the cost of suppressing the mutiny was not less than £40,000,000. When order was restored, the proportion of native troops was much reduced, the artillery being mainly composed of English gunners. On September 1st, 1858, the Government of the East India Company came to an end, and on November 1st Queen Victoria was proclaimed Sovereign throughout India, with Lord Canning as her first Viceroy.

AUSTRALIA

One of the most important parts of England's Empire is that made up of the Australian Colonies. It was not until 1686 that Englishmen landed on the great island. William Dampier landed there in 1686, and Captain Cook, the famous navigator, in 1770; and with him really begins England's ownership of Australia. England sent before long a stream of emigration to the new soil. The whole of the Australian continent became a recognised part of England's dominions. The name Australia was only given to the island when English influence began to prevail, for it had been named New Holland, while the Dutch claimed to have been its earliest discoverers.

For a long time—indeed, down to recent days—some of the Australasian Colonies were used by England as places to which convicts from these islands could be transported and held in penal servitude. Nor was this sentence inflicted only on criminals convicted of gross crimes, but upon men of the highest character and honour who had taken part in Ireland's rebellions—men like Smith O'Brien and John Mitchel. The Colonies might have made less complaint if such men as these were the only convicts sent into Australia by British law; but it became intolerable to the Australians, after a while, that their soil should be used as a place of imprisonment for men whose presence England would not endure even within her prisons. The system was gradually relaxed, and came to an end in 1857.

Discovery of Gold. In 1851 gold was discovered in New South Wales, and soon after in Victoria and other parts of Australia, and there was a sudden rush of immigration from Europe and many other parts of the world into the gold-producing regions. The population of Australia has been steadily growing during recent years, and prospering with its growth.

The Government in England acted with a wise liberality towards the Australian colonists in allowing them as far as possible the management of their own affairs, and no such crisis has been provoked as that which once brought the people of Canada into actual rebellion.

The different Colonies of Australia have been for the most part on friendly terms with each other, and the principle of local self-government has been proving itself more and more effectually as time went on. The Australian Colonies on more than one occasion showed their loyalty to the British Crown by giving their assistance to England in some of her foreign wars. At length a scheme of colonial federation was formed, by virtue of which the Australian Colonies became associated in one federal system with the sovereign of England at its head, each Colony managing its own local affairs for itself, and the interests of the whole continent being under the care of what may be described as the federal government. Each Colony has a Legislative Council or Senate, and a Legislative Assembly corresponding in its arrangements to our House of Commons. The Legislative Assembly is elected by manhood suffrage, or by voters whose qualification, so far as property is concerned, it is not difficult to obtain; and all votes are taken by ballot. The Bill for the founding of the Australian Federation was finally passed by the Imperial Parliament in 1900, and came into force on January 1st, 1901.

TEA, COFFEE, AND COCOA

Cultivating Indian and China Teas. Black and Green Teas. Tannin. Coffee Growing and Manufacture. Chicory. Cocoa and Chocolate. Soluble Cocoas

By CLAYTON BEADLE and HENRY P. STEVENS

TEA is an infusion of the prepared leaves of the tea plant, the species usually employed being the *Thea chinensis* and *Thea assamica*. It was first met with in China, where it is said to have been used four centuries B.C. It was, however, a very common article in the eighth century A.D. Its introduction to Europe dates from the beginning of the seventeenth century, and the import into this country had grown into considerable magnitude by the middle of the eighteenth century, when it became quite a general beverage.

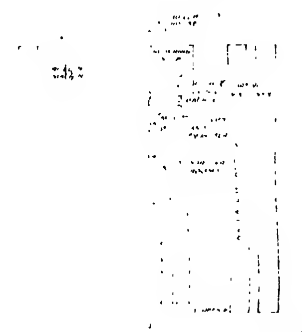
The tea plant is a native of China, and was introduced into India in 1850, but as now grown in India it is generally a hybrid with Chinese varieties.

Tea, as it is put on the market, may be divided into two classes, the green and black teas. This distinction is based solely on the method of manufacture, and is not due, as originally supposed, to a difference in the tree from which the leaves are derived. Both green and black teas are produced in China, Japan, Assam, and Ceylon, although it is usually admitted that the best green teas are made in China [see also pages 1960 and 1961].

Cultivating the Tea Shrub. The cultivated plant is a bushy shrub, not exceeding 6 ft. in height, and somewhat resembling a Portugal laurel. The leaves should not be plucked when the trees are too young, otherwise, when they come to maturity, the yield is much impaired. The plan usually adopted is to pluck the leaves when the plant is three years old: the yield will then be about 80 lb. of tea per acre. The best yields will be obtained from trees which are six or seven years old, when the yield will amount to 320 lb. per acre, although maximum yields, amounting to 800 lb., have been obtained in India. After the eighth year it is preferable to replant. The seeds are usually gathered in October, about a year after the flower has faded, and are then kept in sand and earth until the following March. By this time the will have germinated, and are ready for planting out. Old trees are removed every year and replaced by seedlings. In selecting the ground, attention should be given to thorough drainage and irrigation, for which purpose a good supply of water is necessary. In general, hilly districts are best adapted for the purpose, and the soil should be a rich loam.

Gathering the Crops. Whether for green or black tea, the leaves are plucked three or four times a year, those first plucked producing the best tea. The crops are classed according to the age of the leaf, and designated according to their source. Some of the more important are Hyson, Pekoe, Souchong and Congou. Hyson is a term applied in China to the leaf-buds and the first leaves picked in April and made into green tea. Other green varieties are known as "gunpowder," Tankay, and Imperial. Of the black varieties, Pekoe represents the youngest leaf and leaf buds gathered in April. Sometimes it is flavoured by the addition of orange and other flowers, when it goes by the name of "Orange Pekoe." The same term is applied in Assam as in China. The term "Flowery Pekoe" is also applied to this class. Souchong is plucked next, and is followed by Congou.

Chinese Methods. The manufacture of green tea differs from that of black tea in that it is prepared as quickly as possible from the freshly-plucked leaves, without allowing any fermenting processes to set in. On the other hand, with black tea a certain amount of fermentation is encouraged. The processes employed vary somewhat in different countries, but in the case of green tea they do not differ so much. The leaves gathered in the morning are treated the same day. The first process consists in steaming, with subsequent drying, although in India the steaming process is usually omitted. When dry, the leaves are roasted—that is to say, they are heated in pans over the fire, stirring continuously. The temperature should not rise above 160° F., and the process lasts about five to seven minutes. The leaves, now in a soft, pulpy state, are rolled to break the cells and liberate the aroma; the rolling operation is followed by drying in the sun; and these processes are repeated three times in succession, and then followed by another roasting, after which they are sifted and sorted, and finally roasted again, although the order of the last two operations may be reversed.



1. PLAN OF INDIAN TEA-HOUSE

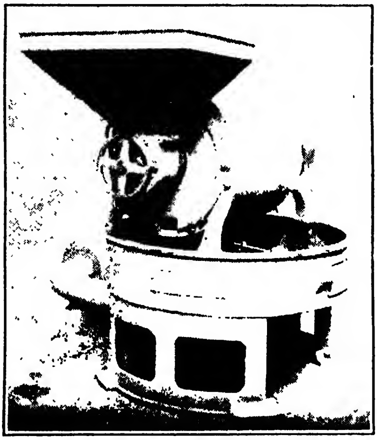
In the case of black tea, after drying in the sun and rolling, which may be accomplished either by hand or in the rolling machine, the leaves, in the form of balls, are left to ferment. This process must be put an end to at the right moment in order to obtain the best result, and it is effected by breaking up the balls and spreading the leaves in the sun to dry. This is followed by firing, the leaves being spread on trays with gauze bottoms, heated from underneath by fire. After hot firing, the leaves are ready for the market.

Tea Cultivation in India and Ceylon. As by far the greater proportion of tea imported into this country comes from India and Ceylon, we shall describe the methods there employed for cultivation and manufacture.

In March the young shoot, with fresh leaves, or the first "flush," is ready for gathering. This consists of a shoot or new growth bearing the bud and five or six leaves. The pluckers gather the bud with one, two, or three leaves, according to the quantity desired. The buds yield the finest tea, known as "golden or silver tip." The top leaf

produces Orange Pekoe, or, when large, " Pekoe." The second or lower leaf also yields Pekoe, but, when large, Pekoe Souchong (Christison).

The pluckers go round the gardens at intervals of about a week. It is very important that they should avoid gathering leaves which are too coarse, or unripe shoots. The baskets with the leaves are returned as quickly as possible to the tea-house.



2. COCOA-ROASTING MACHINE

Manufacturing Operations. These are as follows [see illustration 1, showing plan of an Indian tea-house]: (1) Withering or limping; (2) rolling or curling; (3) drying or firing; (4) separating or sorting and cutting or equalising; (5) final firing; (6) packing for export. These operations take together some 22 hours to 26 hours. The withering is carried out in houses built open at the sides, fitted with layers of trays or racks. The object of withering is to remove 20 per cent. to 50 per cent. of the water, so that when subjected to the next operation, the rolling, the leaf is sufficiently tenacious to stand this somewhat rough treatment. The leaves are now taken to the rolling machines. These are of special construction, and give to the leaves the necessary twist, at the same time rolling them into balls. The balls are then broken down.

The next process consists in spreading out the withered leaves on the concrete floor of a large chamber. The chamber is kept dark, and the leaves are covered with cloth or muslin saturated with cold water. In the course of from two to eight hours the so-called fermentation process is complete.

They then pass to cooling and oxidising machines, in which they are spread out on wire-gauze covered tables, through which a current of air is drawn.

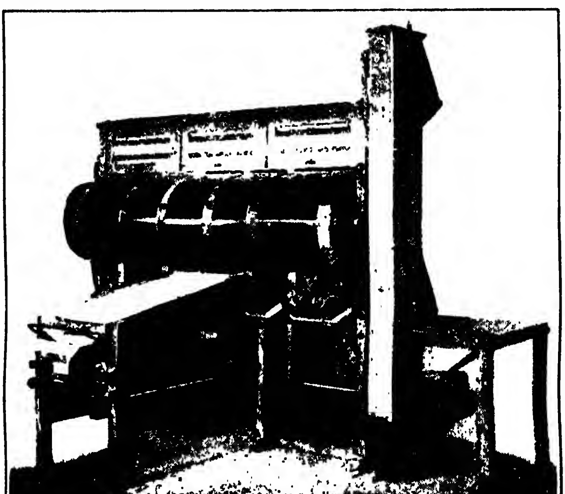
Methods of Firing. They are now taken to the tea drying and firing machines. In large factories this is best accomplished in three stages. In the first stage the leaf is passed quickly through an automatic machine which immediately checks the fermentation by exposing the leaves to a temperature of 300° F. The effect of this is to turn them darker in colour, and they leave the machine half dried. The second is a similar automatic drying machine, the temperature of which is 200° F., and on leaving this machine the leaves are almost dry. The third stage is accomplished in a machine under control, so that the operation may be carefully watched. The object of the process is to drive off the moisture as completely as possible without losing the essential oils.

The roasted leaves are next picked over by hand and then passed through a mechanical sorting machine to remove foreign matter, stones, dust, etc. The leaves then pass to circular or revolving sieves fitted with wire of different mesh, so as to separate the leaves into two or three qualities. The general principle of the machine is similar to one which has been already described [see MILLING, page 3079]. The different products are now subjected to a final firing to remove any residue of moisture, after which they are ready for packing.

Chemistry of Tea. The aroma of tea is due to small quantities of volatile oil not exceeding ½ per cent. of the weight of the tea. The peculiar physiological action is due to a substance formerly termed "theine," but now generally known as "caffeine," as it has been found to be identical with the alkaloid obtained from coffee. Teas also contain a considerable quantity of tannin, averaging from 10 per cent. to 20 per cent. The public analyst is not often called upon to examine teas, as all that is imported into this country is examined by the Customs authorities, and rejected if found to be adulterated.

CONSTITUENTS OF TEA-LEAVES

Constituents.	Original leaves dried.	Same made into green.	Same made into black.
Crude proteins ..	37·33	37·43	38·30
Crude fibre ..	10·44	10·06	10·07
Theine (caffeine) ..	3·304	3·200	3·300
Tannin	12·91	10 64	4·89
Hot-water extract	50·97	53·74	47·23
Ash	4·97	4·92	4·93



3. COCOA-NIBBING, HUSKING, WINNOWING AND GERM-EXTRACTING MACHINE

The proportions of essential oil, caffeine, and tannin vary considerably, and there is also a distinction between the quantities in green and black teas.

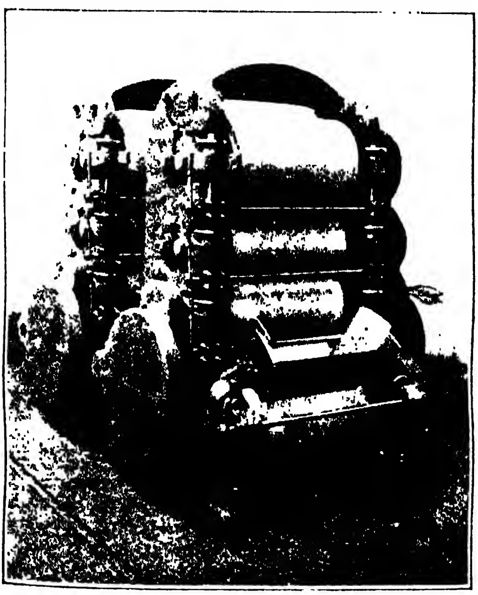
A great number of analyses have been made on tea by different authorities. The table given above, obtained by a Japanese chemist, will give some idea of the effect of constituents on the original leaves when converted into green and black tea.

In the above figures it will be seen that the constituent most affected by the process of manufacture

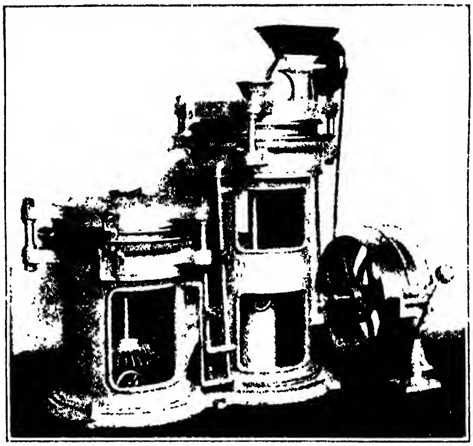
is tannin, of which the green tea contains more than twice as much as the black, from the same leaves [see also page 3378].

Coffee. Coffee consists of the roasted seed contained in the fruit of the coffee tree (*Caffea arabica*). A number of species and varieties have been discovered, three of which are now cultivated: (1) The Arabian or Mocha coffee, which differs from the others in that it usually contains only one seed in each berry; (2) Jamaica coffee, which has usually two seeds in the berry: and (3) East India or Bengal coffee, characterised by its small berries. The cultivated plant is usually about 6 ft. high, and would grow much higher, but its height is kept down by pruning. It is grown in various parts of the world, generally at some height above the sea-level. It is cultivated in the West Indies, Mexico and Central America, Brazil and various parts of Africa, Arabia, India, Ceylon, and parts of the East Indies, but it is chiefly grown in Brazil. The fruit has been likened to a small black cherry and consists of sweet pulpy matter surrounding one or two seeds, which seeds are themselves enclosed in a thin tough membrane termed the parchment.

Manufacturing Operations.. The fruit is allowed to ferment to help the removal of the outer pulp, and the parchment is got rid of by passing the seeds between rollers and winnowing out the husk. The bean is yellowish in colour, and has to undergo a process of roasting to fit it for consumption. The roasting effects two objects - it brings about important chemical changes which develop the flavour; and at the same time the raw bean which is tough, is rendered brittle, so that it can be more easily ground. The process of roasting requires care: under-roasted beans yield an infusion with a raw flavour, whereas if too strongly heated they are burnt. Usually some sort of rotary apparatus is adopted by which the beans are kept in motion and uniformly heated [see also Roasting Cocoa]. The temperature should not rise above 450 °F., and the beans should lose about 18 per cent. of their weight when roasted to a chestnut brown colour.



5. CHOCOLATE-REFINING MACHINE



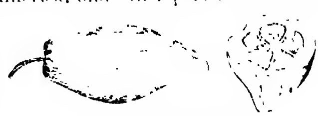
4. COCOA-GRINDING MILL

It is stated that a loss of 20 per cent. means injury to the beans.

Composition and Constituents. The most important constituents of coffee are the volatile oil, to which its fragrance is due, and the alkaloid caffeine which has already been described under Tea. The oil was isolated by Bernheimer from the distillate obtained by heating coffee beans. It is an oil boiling at 195 to 197 C., and has been termed "caffeol."

Coffee is frequently adulterated, and while the substitute generally used is chicory, many other substances have also been employed, including according to Penman and Moor dandelion root, mangel-wurzel, turnips, beans, peas, flour, and condemned sea biscuit more or less caramelised by baking, and burnt sugar. In addition to this, a patent has been taken out for the manufacture of artificial beans from chicory and other adulterants. Anyone familiar with the bean would have no difficulty in detecting the imitation article, although they are not met with much in this country, it being more profitable to adulterate the ready ground coffee. On chemical analysis coffee contains about 1½ per cent. of caffeine, 12 per cent. to 20 per cent. of fat, 30 per cent. to 37 per cent. of cellulose, and about 4 per cent. of ash.

Cocoa. - Cocoa, sometimes spelt "cacao," is made from the seeds of the *Theobroma cacao*, a tree of some size which grows in the West Indies, Brazil, Central America, and other parts. The fruit is elongated in shape and consists of five compartments containing a sweet pulp in which the seeds or beans are embedded [6]. The fruit is split in two and the beans separated from the surrounding pulp and spread out to dry on bamboo floors exposed to the sun. To rid them of a certain amount of adhering pulp, and also to improve the flavour, they are submitted to fermentation. For this purpose they are placed in wooden barrels, covered over with leaves, and left a day or two. The process is complete when the colour has changed from red to chocolate. The beans are then taken and washed to remove the adhering portion of pulp, and after drying are ready for export. The cocoa seeds or



6. CACAO FRUIT

beans are the raw material for the manufacture of chocolate, cocoa, and various sweetmeats.

Manufacturing Chocolate. The manufacture of chocolate comprises the following operations (Zipperer): (1) Storing, cleansing, and sorting; (2) roasting; (3) crushing, shelling, and removing radicles; (4) mixing the different kinds of beans; (5) grinding the beans until they yield a homogeneous pasty mass when warmed; (6) the incorporation of sugar and spices with the liquefied cocoa mass; (7) trituration by rollers; (8) extraction of air and division and moulding; (9) cooling the finished chocolate.

In general chocolate may be defined as a mixture of pure cocoa (free from shell or germ) and sugar, with the addition of cocoa butter, spices, vanilla, or other flavouring as required.

The beans are first cleaned or roughly sifted, so that the dirt and flat beans are separated out. A cocoa-bean cleaning machine may be used, and the clean beans are delivered on to a travelling web, and any stones or foreign substances which have passed the machine, being about the same size or larger than the beans, are picked out by hand.

Roasting Cocoa-beans. The picked beans are next roasted for the purpose of developing the aroma, gelatinising the starch granules, and rendering the husk or shell brittle so that it is more readily removed; at the same time the astringency is largely got rid of. The plant usually employed consists of a roasting drum similar to that used for coffee, but the temperature required is lower, and should not exceed 130° C. to 140° C.

The illustration [2] represents a gas cocoa-roaster. The revolving drum is heated externally, and the gas is mixed with heated air to render the combustion more complete. The beans are fed through the hopper at the end, and the inside of the drum is fitted with helical blades to ensure the beans being turned over and fed constantly to the centre. The heated gases and steam from the beans escape through the hollow shaft of the trunnion of the bearing.

Separation of Husk and Germ. After roasting, the beans are delivered into a cooler below, the bottom of which is provided with a perforated plate so that air can be drawn through the beans by means of a fan. When sufficiently cooled, the beans are treated to separate the husk or shell and germ from the particles of kernel. For this purpose they are crushed, keeping the pieces of shell as large as possible as this facilitates subsequent separation. The cocoa nibbing, husking, winnowing, and germ-extracting machine is shown in 3. At the bottom of the hopper is a "nibber," with two pairs of rollers (seen on the right-hand side of the figure) to crack the beans, which are then taken up by the elevator and delivered into a revolving drum made up of six different sections of perforated metal, each of which is somewhat coarser than the last. Each section is provided with a fan which blows away the particles of shell, leaving the clean cocoa-nibs to fall upon inclined sheets fitted to each section. As a small amount of nib may be carried over with the shell, an intermediate chamber is provided, into which it falls, most of the lighter husk being carried beyond. This chamber is fitted with a worm so that the mixture of nib and shell is returned to the hopper for treatment over again. About the centre of the drum the perforations are of such a size that medium-sized nibs and germ pass through together. They are conducted to inclined sieves and a perforated drum, by means of which the germ is removed much in the same way as cockle is taken out of wheat [see MILLING, page 3080]. Here it is the particles of kernel lodge in the hollows of the walls of the cylinder, while the germ passes off as tailings.

Grinding and Refining Machines. For whatever purpose the cocoa is required it is essential that it should be finely ground. For this purpose the French form of mill, consisting of two stones, a bed-stone and a runner on a vertical axis, is usually employed. The action of this form of mill has been described in PAINTS AND POLISHES [page 5142]. Figure 4 shows a double stone cocoa-grinding mill.

The cocoa, which is fed into the middle, leaves the stones in a semi-liquid condition. The ground cocoa is not heated until it is liquid, when it is transferred to a melangeur or to a mixing and kneading machine, where the necessary sugar and spices are added.

The stiff paste is then passed through chocolate refiners. These are built either with inclined rolls or are upright machines with rolls superimposed. Two upright refiners are shown [5] coupled together to form a battery. The refining process reduces the chocolate to a smooth condition; it is then usually stored in blocks for some time in a dry room. Illustrations 2 to 5 are from photographs of machines constructed by Messrs. Joseph Baker & Sons, Ltd.

For conversion into tablets it is mixed or kneaded as required and passed through a weighing machine, which also compresses it and extracts any air, and thence to moulds. For certain kinds of chocolate, especially if larger quantities of sugar are added, an addition of cocoa butter is made; but for some cheap ordinary chocolate this is replaced by a cheaper vegetable butter such as coco-nut fat, and the outer shell or husk of the bean, representing 20 per cent. by weight of the whole, is also ground up and utilised. Milk chocolate contains a large proportion of con centrated milk, and a smaller proportion of cocoa.

Cocoa Powder. For use as the beverage commonly known as cocoa or "soluble" cocoa, the preliminary processes are carried out as we have already described: but at some stage the material is treated with weak alkalies, such as carbonate of soda, potash, or ammonia, and heated, the effect of which is to modify the cellular matter or saponify part of the cocoa butter in such a manner that, on mixing with hot water, the cocoa remains suspended instead of settling at once (so-called Dutch process).

Some English manufacturers, however, do not use alkali and yet are able to obtain a cocoa quite as soluble as with the Dutch process, but perhaps somewhat lighter in colour, the effect of the alkali being to darken the cocoa when in the cup. French makers are not allowed to use alkali. It is also necessary to remove a large proportion of the oily or fatty matter contained in cocoa—namely, the cocoa butter. This is carried out after roasting by hydraulic presses. Altogether the cocoa butter forms about half the weight of the seed. It is a white solid fat which melts at the low temperature of 30° C., a little below the normal temperature of the body.

Cocoa contains an alkaloid, theobromine, which is a characteristic and important constituent. It is chemically closely allied to caffeine, but its physiological action is stronger.

The amount of theobromine is usually about $1\frac{1}{2}$ per cent.

FOOD SUPPLY *concluded*

INDUSTRIAL USES OF PAPER

The Manufacture of Envelopes, and of Paper Bags and Boxes. Cellulose and Artificial Silk

PAPER-MAKING continued from page 6401

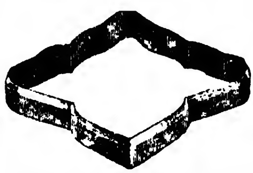
By CLAYTON BEADLE & HENRY P. STEVENS

ENVELOPE MANUFACTURE

Envelopes first came into general use with the introduction of the penny prepaid postage system in or about the year 1840. Prior to this period the written documents were folded and sealed, but with the introduction of the aforementioned prepaid postage system this method was found unsuitable and inadequate, and the envelope was invented and brought into general use. At this time envelopes were made by hand throughout, but as the demand increased, machinery was brought into use, and very few envelopes now are made by hand, only the very best envelopes, and those of an unusual size, being made in this way. Envelope manufacture by machinery may be classified under three headings—namely, cutting or punching, gumming of the sealing flap, and folding.

Punching or Cutting. For this a cutter or die [45] is used of the shape or outline of the envelope when it is in the "blank"—that is before it is folded. This cutter is made of the best steel, and is usually 1¾ in. to 2¼ in. deep. The paper out of which the envelopes are cut is placed in a pile of suitable height on the bed or lower platen of a specially constructed machine known as a punching or envelope cutting machine [46]. The cutter is then placed upon the paper, and the top platen is clamped down on to the cutter; this sets the driving gear into motion, and the cut takes place, the top platen is released, automatically opened, and the machine stopped, ready for placing the cutter in position for the next cut, the entire operation occupying but three seconds.

Gumming of Sealing Flaps. The blanks are then taken to the gumming machine [47] for gumming the top or "sealing" flap of the envelopes. A pile of blanks (about 4 in. high for thin paper, and 6 in. high for thick qualities) is placed on the feeding table of the machine. The blanks are then carried round a drum, being held in position by means of tape under the gummer, thence over the drying plates, under which gas jets are burning, and are delivered on the collecting table at the other end of the machine. The pressure of the gas can be adjusted according to the thickness and quality of paper used. This machine will automatically gum, dry, and deliver envelopes at the rate of 20,000 per hour at an inclusive cost of less than a farthing per thousand. One of these machines is sufficient to keep six folding machines employed.



45. ENVELOPE CUTTER OR DIE

Folding. The blanks are then taken to the folding machine [48]. The machine as illustrated is the well-known "Reay" machine, as used by the Stationery Department of the General Post Office. With this machine the feeding, creasing, folding, delivering, and collecting of the envelopes are performed with the aid of but one attendant, who has ample time to band the envelopes so produced. The attendant sits down in front of the machine and places in the proper receptacle a number of blanks, the number being regulated by the substance of the paper. The blanks are conveyed singly by pickers (the pickers also gumming the bottom flap of the envelope) to the creasing box. After having been creased, the envelopes are, by a double action of the plungers, securely and correctly fastened at the bottom flap, and folded. After leaving the plungers, they are mechanically collected and delivered to the attendant for banding. From the time the blanks are delivered to the machine till the perfect envelope is turned out, the attendant has nothing to do with them, thus having ample time to band them up. This machine turns out high-class envelopes at the rate of from 2,000 to 3,000 per hour.

"Leader" Envelope Folding and Gumming Machine. This machine [49] completely folds and gums envelopes or bags ranging in size from the well-known small coloured packet which contains garden seeds to the very large official end and side opening envelopes, used for specifications, documents, and the like, at a speed of from 60 to 105 per minute. In a factory where this machine is installed it is imperative that a platen cutting machine is also at work supplying the folding machine with the blanks cut to size out of the flat reams of paper, a steel knife or cutter of the proper shape of the envelope or bag required being used. The blanks, when cut, are passed to the folding machine and placed on the work table in front in a pile about 6 in. high and automatically lifted off, a sheet at a time, as the formed gummer takes them off the pile, and leaves them on the carrying rails to pass underneath the top plunger, which in turn creases them through a convenient sized box with the four side flaps turned up ready for the folders, turning them over and closing same into shape. A hinged platform instantly falls down, which is carried on the main table of machine, and allows the folded envelope to fall through side guides into the drying chain, which, at the proper time, has a pair of its links in an open position to receive the envelope and carry it one space along out of the way of the next one following.

While the machine is at work, and the finished product gathering in front of the attendant, he or she is engaged gathering the bundles of envelopes, —which are counted into 25's by a counter on the machine—and placing the band round, the packets being then laid in a box ready for the packing-room.

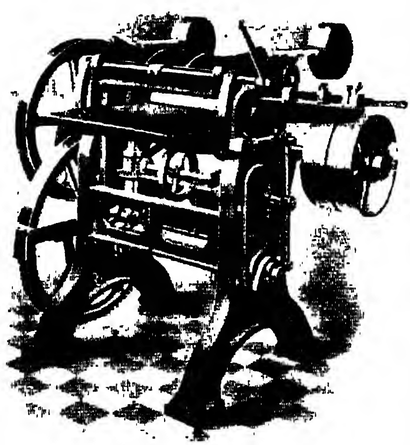
PAPER BAGS

The manufacture of paper bags has during the past fifty years developed into a considerable industry. Hand-made bags still survive, but in lessening proportion to the ever-increasing bulk of the machine-made bag. Paper bags, whether hand or machine-made, divide as to form into three main classes: (*a*) The "plain" or "flat" bag, made like a wheat sack without attempt to prepare the bottom for squaring or flattening; (*b*) the "square,"

otherwise "block-bottom" bag, with its bottom folded so that on filling it with little or no assistance forms itself into a square or oblong square package with a flat bottom (the satchel bag is also in this class); and (c) the "conical bag," that makes no pretensions to standing on end, but is of shape that affords ready access to the fingers.

As regards structural formation, one thickness of paper only is the rule, but all are occasionally made of two thicknesses (lined bags), the outer for strength or display, the inner often of impervious material to retain the aroma of the goods or prevent contents exuding, or to protect the contents from exterior damp. Further, to separate the goods contained from contact with a coarse or highly-printed or coloured wrapper, a clean and tasteful lining is often advantageous.

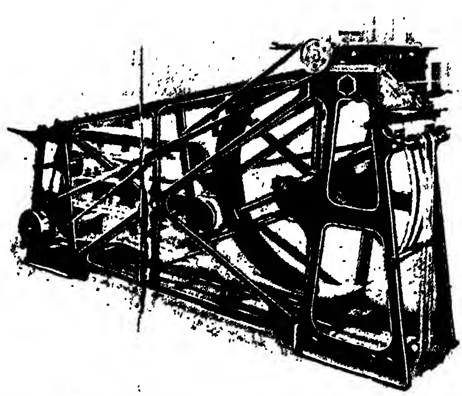
Special Requirements. Hand-made bags are now practically confined to special requirements, such as bags of unusual size, elaborately printed bags, most kinds of lined bags, and bags which must not show certain peculiarities inherent to machine-made bags, or where the quantity ordered is small. To these must be added the output of firms who, by cheap hand labour, struggle to compete with machinery.



46. ENVELOPE CUTTING MACHINE (Joseph Richmond & Co., Ltd.)

Flat "formers" of tin or zinc are used by the hand-workers to fold the sheets of which the bags are made, and in the case of block-bottom bags a hinged flap is sometimes added to assist in making the "diamond" fold of the bottom. In the hand-making of self-opening satchel bags a collapsing "former" is used. In some cases the bags are made partially by machine and partially by hand, the paper being folded and pasted by machine into long, flat tubes, and by it cut into lengths, the bottom being formed on these lengths by hand.

Except when they can be used without packing together for transport, bags, whether machine or hand-made, are always made "on the flat" — that is, the tubular body and the bottom are folded in the same state in which they are subsequently packed and transported in bulk. All kinds of adhesives are used in hand and machine work, wheaten paste predominating, dextrins and gums following next.



47. GUMMING MACHINE (Joseph Richmond & Co., Ltd.)

Continuous & Intermittent Machines. *Paper-bag machines* may be divided into three main types. Class I. comprises *high-speed, continuous action machines*, producing flat, often called plain bags [50], satchel bags (simple style), satchel bags (compound style) in all thickness papers, and oblong block-bottom bags in medium and thick papers; also conical bags (all thicknesses). The speeds of these machines on medium-sized bags range from 120 to 200 per minute, small bags still faster, conical bags one-third slower. These machines always draw their supply of paper from a web of paper of suitable width wound into a roll. The usual maximum size for ordinary bags in this country is about 12 in. wide by 19 in. long, flat make, or its equivalent capacity in other shapes; but in the United States and Canada bags of double this size are met with. Conical bags are seldom used to contain more than ½ lb. of goods. Millinery bags are made up to 22 in. wide and of proportionate length.

Class II. comprises *intermittent action machines*, of the square block-bottom [52], oblong block-bottom [51], and one kind of triangular bag [see 50], drawing, as in Class I., their supply from the web, but stopping the bag blank one or more times during the process of manufacture, while the bag blank is cut off from the web, the "bottom" folded, etc.

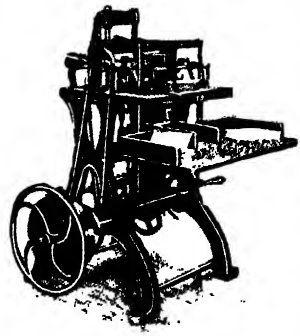
The speed on medium-sized bags varies from 35 to 60 per minute. The usual maximum size is the same as in Class I. The formation of these bags is almost exactly similar to hand work, an expert being required to point out the differences, which appeal more to fancy than utility.

Class III. are *machines which make from the sheet.* A few hand-fed machines for making large flat millinery bags are used, with indifferent commercial success; 20 to 25 per minute is their usual speed. These machines much resemble an ordinary folding machine, with pasting arrangements added. A more numerous class make the huge quantities of block-bottom bags required by the firms packing powder and grain goods. These machines automatically pick the sheet from the pile by suction or by an adhesive arrangement, fold it into a bag on a block, and deliver it, distended, fit for removal to the packing-room. They are necessarily operated by the firms themselves in the same factory in which the bags are used, because it would be impossible to transport the distended bags any distance. The

machines are slow (25 to 35 per minute), but the advantage of being able to use printed blanks, and the bags being distended ready for filling, compensate for their complexity and slowness.

A few machines are in operation automatically "working from the sheet," which make both "plain" and "block-bottom" bags "in the flat," but they are confined to large quantities of the same size of bag—nothing sufficiently universal and useful to the ordinary bag-maker seems as yet possible in this kind of machine.

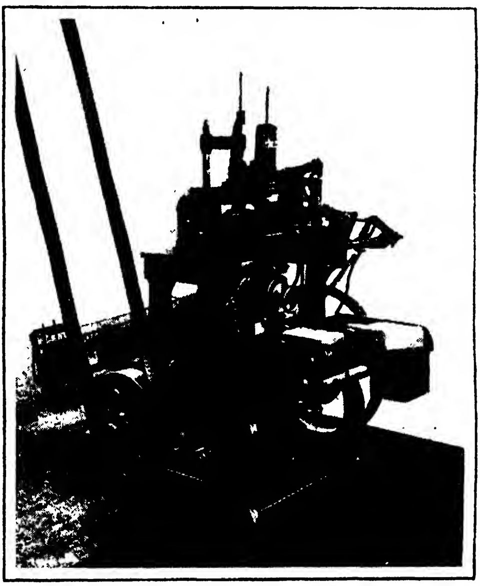
The folding of the bottom of a block-bottom bag is begun by means of what is called the diamond fold—that is, the flat tube of the bag is pulled into a diamond, usually lengthwise, of the bag. The two V ends are then folded inwards to complete the bottom. The V in oblong bags has a flat point. As in continuous action machines, the block bottom is always oblong, one of the V's has frequently a projection cut from the preceding bag in order to make the final seal of the pasting of the bottom. Many peculiar kinds of bag bottoms and bag shapes are occasionally met with, rendering bag-making an interesting study.



48. THE "REAY" ENVELOPE FOLDING MACHINE
(Joseph Richmond & Co., Ltd.)

Pasting Machine-made Bags. The pasting of all machine-made bags varies slightly from handwork pasting. All high-speed continuous action machines "work from the web," which is first pasted on one edge, hollowed into a U-shape, then closed over, and the edges lapped and stuck to form a flat tube. This tube is subsequently cut by differing devices into "bag lengths," and the bottom formed on one end of them. A few machines for very large plain bags work with two webs of paper instead of folding the tube from a single web, the edges of one of the webs being hemmed over, and pasted to receive and join to the covering web, the other operations being as usual.

Another machine hems and pastes the edges of a single web, cuts off a length double that of the bag, and then "dips" or doubles that length at its centre, the two hemmed edges coming together and forming a complete bag with the fold of the bottom.



49. "LEADER" ENVELOPE MACHINE
(David Carlaw & Sons)

Drying. Bags from high-speed machines are discharged from the machine to a drying device, usually a steam or gas-heated wheel or cylinder, where any paste which has exuded to the surface is dried, and the bags are thus prevented from sticking together when piled. The hot cylinders also press the bags, give them a neat finish, and greatly facilitate the thorough final drying. If a printing device is used, the regular delivery from the bag-forming apparatus is used for feeding the bags correctly to it.

The best *conical bags* made on continuous action high-speed machines are of kite shape when flat [see **50**]. This shape is a very convenient one to the shopkeeper. These bags can be printed immediately after discharge from the bag-forming portion of the machine, no drying cylinder being required.

Intermittent action web machines also draw from the roll, and in some instances tube it while being drawn to the cutting and bottom folding device. Others simply cut a sheet off the end of the web, and fold it over sideways before forming the bottom.

Printing Bags. The best class of printed bags, especially those printed on both sides, are usually printed "in the sheet," and then hand-folded, unless made into the distended bags before alluded to, in which case it is possible to fold them by machine. When hand-making is adopted, bags that are printed are always treated "in the sheet."

Plain bags and *simple satchel* bags can be readily and cheaply printed on one side at formation by an automatic printing device attachable to the bag machine, the other side being printed subsequently by ordinary process.

Block-bottom bags cannot be satisfactorily printed after formation, as the fold of the bottom covers much of the lower part of the face of the bag, and limits the space available for imprint: even when the trouble is taken to throw the bottom back too much space is lost. The delivery also from the machine making them is not so regular as with the plain and satchel machine.

Preventing the "Set-off." Many attempts have been made to print the web from which the bag is formed either in the bag machine itself or in the roll previously, but with indifferent success. The bag and the imprint may be made to "register," but there is great difficulty in preventing the "set-off" from the imprint depositing itself on the rollers of the bag machine, which in turn re-deposit the ink they rob from the imprint of the bag on to parts of the bag which ought to be free from ink. By disposing the imprint so as to miss the draw and holding rollers of the bag machine, this may be obviated, but such limit of imprint is unsatisfactory. The imprint on a bag requires to be full and heavy, so as to give good "display." This, of course,

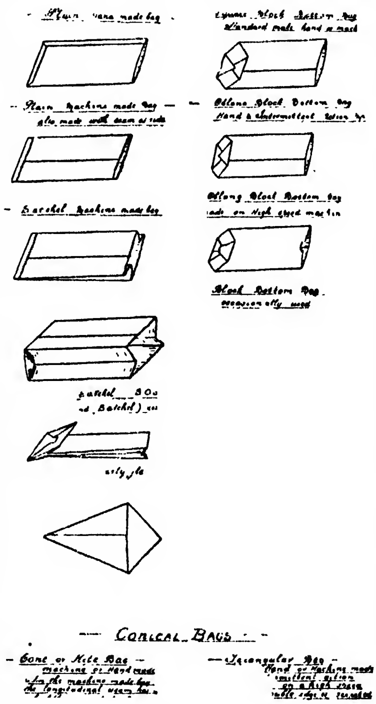
"sets off' easily—not as in newspaper printing, where the ink used is comparatively a mere trace. Even if the roll of paper from which the bags are made is printed months before the bags are made, the ink does not harden sufficiently not to give much trouble. This "set off" trouble prevents the immediately consecutive printing of the bags ("perfecting," as it is called) immediately at their discharge from the bag-forming portion of the machine.

PAPER BOX-MAKING

In making cardboard boxes, several different kinds of boards are used. The cheapest and that most generally used is strawboard. Another board largely used is wood pulp, made from wood in Scandinavia, Canada, and Finland. Leather board is used in wire-stitched and metal-cornered boxes when great strength is required. This board is made in Finland and Scandinavia.

The first process with a Johns, Son, & Watts plant is cutting the boards into pieces of the size required. This is done by passing them between two rollers, the upper roller being fitted with circular knives. Some of these are adjusted so that the board is only partly cut through, or, as it is called, "scored." The boards then pass through a second time at a right angle to the first, and are similarly cut and scored, the double process leaving the board in pieces, as at A in 55, the dotted lines representing scored marks. These pieces are put in numbers before taking out the corners. B and C show the appearance after the corners are removed. In 55, D shows the appearance of the board when bent along the scored lines.

This process takes place only with shallow boxes, the deeper boxes being made in three pieces to save material. The body of the box in one piece [D] and the ends separate [E]. The ends are then attached to the box by means of the strong paper or calico [F].



50. TYPES OF BAGS

On completion of process B, the box is in the flat, ready to be bent up along the score marks, and joined at the corners with calico or paper, according to the strength required. The covering is next put on after having been cut by a guillotine into pieces the size required.

An endless band revolves down the centre of the work-table. At one end a girl glues the papers on a roller, places them on the band, to be taken off by the worker who requires them, as they pass, and put them on the boxes.

The larger quantities of boxes, however, are joined up and covered by machinery. The box is bent up into position, and each corner in turn held on an anvil, the joining-up material being affixed by means of a plunger, which cuts the material off the required length in the fixing. The box is now placed on another machine on a block, which can be adjusted to the size of box required.

On this machine a roll of paper cut to the width desired is passed over a glued roller and the end stuck to the box. The block revolves, gluing the paper to the box as it does so, and at the completion of the revolution the paper is cut automatically.

Fancy boxes are made entirely by hand, and are covered with artistically designed papers, or some material, such as silk, satin, or plush, and hand-painted, and decorated with metal to give a very pleasing effect.

These are used for the sale of higher class confectionery, handkerchiefs, gloves, etc., and for presentation caskets at City dinners and such occasions. To improve the appearance of the strawboard, a white or coloured enamelled paper is affixed, thus ensuring a clean and smooth surface.

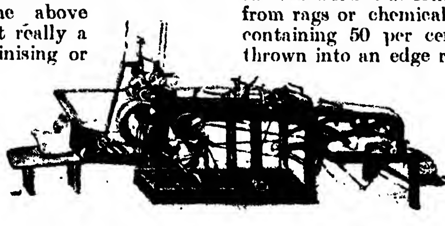
Large numbers of folding boxes or packets are made; these are more convenient for many purposes than the ordinary box, being cheaper and taking up less room for storage. A stronger board has sometimes to be used, and if strawboard is required, a strong paper lining is put on the board to prevent cracking. A strong manilla board is commonly used. This type of box has a large consumption among chemists, soap-makers, tobacco manufacturers, etc. The wire-stitched and metal-cornered boxes are used by milliners, drapers, tailors, and for postal purposes. The metal corners have serrations or teeth that grip into the board, and a box made in this way will sustain very great pressure.

Cardboard rolls for postal and other purposes are made of common strawboard, by coating one surface with glue and rolling on a mandrel in contact with a revolving cylinder, which exerts great pressure, making a very firm and solid roll. Fluted and corrugated packing paper is prepared from strawboard by passing one portion between fluted rollers, whence it emerges in corrugated form. It then comes into contact with and is glued on to a thin strawboard.

SOLVENTS FOR FIBRES

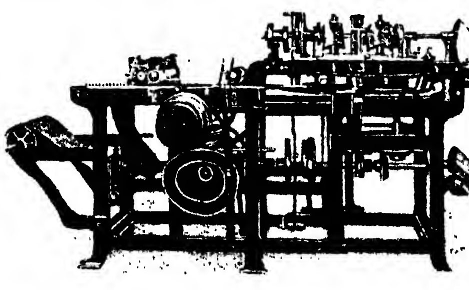
An important industrial application of a solvent for cellulose, or a profound change as the result of chemical treatment upon cotton and other vegetable fibres may be said to date from the discovery of parchment paper. This the student can produce for himself in the laboratory by taking filter paper and plunging it under sulphuric acid previously diluted with from 20 per cent. to 25 per cent. of its volume of water and cooled. The paper becomes transparent and swells up, and the fibres become gelatinised and would, if left in the acid, go into solution. At an early stage, however, the paper is removed, thoroughly washed free from acid and dried. The resulting product is a hard parchment-like material which retains its strength on wetting. This product is produced on a large scale by

passing a continuous web of water leaf paper through a bath which can be lead-lined, but is preferably of glass or porcelain. This bath contains the acid. The web then passes through a succession of baths containing water, which removes the acid. The first washings are recovered by concentration, the later ones are run to waste. The last bath may contain a little ammonia to neutralise the last traces of acid. The above parchmentising effect is not really a solvent action but a gelatinising or hydrating effect, the gelatinised fibres gluing themselves together with their own substances on drying.



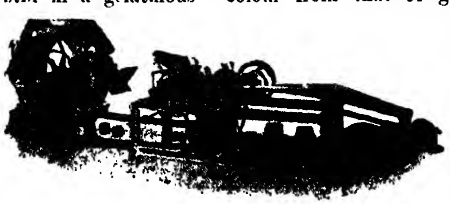
51. OBLONG BLOCK-BOTTOM BAG MACHINE

Cupramonium as Paper Solvent. This is prepared according to the patent of D. C. R. Alder Wright (737, 1883). Towers about 12 ft. high are arranged so that a current of air can be successively blown through them. They are filled with fragments of copper turnings or crumpled up sheet and ammonia solution. The air passing through oxidises the copper, which is dissolved in the ammonia, producing a blue solution. A good commercial result is got from 100 lb. to 150 lb. of ammonia, and 20 lb. to 25 lb. of copper are contained in 100 gallons of the solvent. The student can prepare some of this solvent in the laboratory by pouring ammonia repeatedly through a funnel containing copper filings. If, at the same time, some cotton-wool is present, he obtains a cupramonium solution of cellulose.



52. SQUARE BLOCK-BOTTOM BAG MACHINE

Willesden Paper. This is prepared single ply by passing a continuous web through a bath of the above solvent and drying off the ammonia, or a welded material of several ply is obtained by amalgamating several thicknesses. Thus, if two or more sheets of paper are dipped into the bath and pressed together while the surface is still in a gelatinous state, they produce one compact mass. In order to recover the ammonia the paper or fabric is dried in closed chambers, the ammonia vapour from which is recovered. The paper is strong, durable, rot-proof, and less inflammable than ordinary paper. It has a pale greenish or bluish colour due to the presence of copper, which, however, can be rendered colourless or nearly so by substituting zinc for copper.



53. MACHINE FOR MAKING OBLONG-BLOCK PAPER BAGS (Strachan & Henshaw, Ltd.)

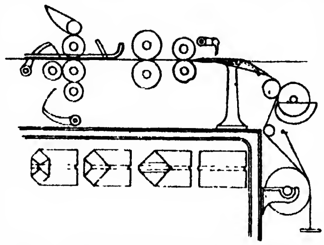
Viscose. Cross, Bevan, and Beadle discovered that vegetable fibres could be rendered soluble by treating successively with strong alkalies and carbon bisulphite. This was patented in 1892, which patent has formed the nucleus of some very important commercial developments. Various classes of raw material can be used, such as rag, beaten to pulp and pressed into cakes, waste fibres from paper-mills, chemical wood pulp, but in the laboratory one can use either cotton-wool or, better still, pure filter paper.

The Mercerising Process. The first process is known as "mercerisation," and in some cases is worked as follows: Well beaten paper pulp from rags or chemical wood is pressed to cakes containing 50 per cent. of moisture. These are thrown into an edge runner, ground up, and to the mass is added a strong caustic soda solution. This causes the fibres to swell up like so many snowflakes, due to the action of the strong soda upon the cellulose, resulting in the formation of a chemical compound known as alkali cellulose. The discovery of mercerisation is an old one, due to Mercer, and has recently been made use of in connection with the textile industry; but its application in this manner as a stage in the production of a solution of cellulose was unknown up to the time of the discovery of viscose.

Making Fibres Soluble in Water. The mercerised product, called often *alkali cellulose*, is put into convenient receptacles, where it is stored at a certain temperature away from the air. When of the right degree of "ripening" it is transferred to revolving tubs or jars to which is added carbon bisulphite, and at a given temperature the alkali cellulose and bisulphite interact, giving rise to a product known as *cellulose thiocarbonate*. The original mass from being fibrous and spongy changes gradually to sticky, buttery fragments of a bright yellow colour. This mass, if incorporated with water, produces a solution of cellulose thiocarbonate of about the consistency of molasses, but varying in colour from that of golden syrup to molasses, according to the manner in which it has been prepared, and the purpose for which it is intended. The above description may sound simple enough, but the various stages are far more complex in commercial practice. Thus, the exact kind of raw material used, its mechanical treatment, the exact proportions of the ingredients, the temperature and the time allowed between each stage are all factors which have to be studied and controlled to suit the purpose for which the soluble mass is to be applied; and it is of absolute importance that such details should be minutely studied. Books have already been written dealing with this one product, and an examination of the Patent Office records shows the number of patents from time to

time taken out covering its various applications and modes of preparation.

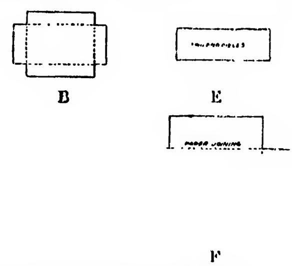
To this solution the name of "viscose" is given on account of its extremely viscous qualities, which can be varied almost indefinitely according to details of manufacture. Viscose, if stored, undergoes changes; in fact, the solution is undergoing a cycle of molecular changes from the moment of its formation. It ultimately coagulates to a gelatinous or rubbery mass. On immersing in water, and by occasionally changing the water, the rubbery mass is deprived of its chemical by-products, leaving a cellulose jelly (hydrate of cellulose). This, on drying down by exposure to the air (dehydration), becomes a hard, horny mass (regenerated cellulose), to which the name *viscoid* is given.



54. DESCRIPTIVE DIAGRAM OF OBLONG BLOCK BAG MACHINE

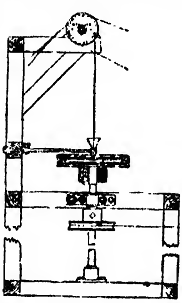
Coagulation. The coagulation is accelerated by heat. Thus, if a thin varnish of the viscose on glass be placed in an oven, in a few minutes it will be dry and coagulate. On plunging this under cold water, a film is procured, which, on drying and pressing, is not unlike a collodion film in appearance, but it softens more in water.

The viscose solution can be used for impregnating cloth, paper, webbing and various articles. On drying down, these products are stiffened or sized and in some cases found to possess waterproof qualities. One great fascination about this product is its protean qualities, which are controllable by a variation of the conditions under which it is manufactured. This makes the product an interesting, although a difficult, study.



55. DIAGRAMS ILLUSTRATING BOXMAKING

Dissolved cotton as viscose can be thrown down from its solution by diluting, warming and agitating. The flocculent mass of cellulose so produced is washed, chemically purified and dried as to a powder. Viscose has been worked in a plastic as well as a liquid condition by suitable machinery, when it is capable of incorporation with various plastic and mineral products, as by the method of incorporation patented by Beadle. The resulting mass when finished is capable of conversion into articles resembling in appearance those made from ebonite, celluloid, vulcanite, ebony, etc.



56. SPINNING BOX

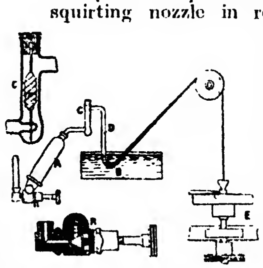
Viscose Artificial Silk, or Lustra Cellulose. In 1894 Stearn projected a solution of viscose through a small orifice into a precipitating or setting solution, which converted the liquid into a solid filament. Viscose has the peculiar property of being solidified by such substances as brine, sulphate of ammonia, etc., so that if a thin thread of liquid be projected into a bath of such solution, it becomes a solid thread. Products of this nature when finished to resemble silk, are called *lustra cellulose.*

Improvements were made by Topham for filtering the solution by passing it through various filtering media to deprive it of every particle of dirt or fibre, the plant being so arranged that every particle of air is eliminated [57]. This is absolutely necessary, or the nozzles would otherwise get blocked and the threads broken. The manner of manipulation now is that a number of threads, perhaps 12 at a time, are drawn through a perforated plate, immersed in the setting solution [B 57], then over a pulley, and then are twisted together by an ingenious spinning contrivance [E 57 and 53], where centrifugal force is taken advantage of in giving the filaments a pull and a twist; the thread is laid as an annular mass which is periodically removed from the box.

In the production of artificial silk absolute control in every respect was found to be essential. Thus, the rate of flow had to be automatically regulated. This is done by a glass valve fitting a tube [C 57], and floating in the solution and covered on its surface with veins or spiral grooves, through which the solution finds its way, causes the valve to rotate, and by the position of the float, the supply is automatically controlled, and delivered in a regular stream from the pump to the squirting nozzles. This valve can be set to alter its delivery according to requirements.

Important improvements rapidly followed in all stages, including the preparation of the viscose, dissolving, agitating, stirring, spinning, precipitating, and in the subsequent treatment of steaming, washing, purifying, bleaching, drying, etc.

Care Required in Spinning. It will readily be realised that the diameter of filament is dependent upon the pull or "draft" from the squirting nozzle in relation to the amount of solution passing through the fine orifices, and that this has more to do with the fineness of the thread than the actual diameter of the holes through which it passes. The lustre, feel, elasticity, and physical qualities generally, are affected and controlled by such considerations. But apart from these, and the chemical and physical qualities of the liquid viscose, the processes that follow the first formation of the thread produce profound modifications, such as stretching while steaming and drying under tension are important in their influences. The appearance of viscose filaments under the microscope affords useful data, and throws light upon the more exact manner of its formation. The tendency is to the formation of



57. VISCOSE SPINNING PLANT

tubes, with a fine capillary hole through the centre. The viscous filament, immediately on its first contact with the precipitating or setting agent, naturally sets on the outside. When dehydration takes place, the plastic interior accommodates itself to the rigid exterior, hence a hollow thread is produced, unless the same is microscopically fine. A pull exerted upon the thread while it is in a semi-plastic condition—that is, before it is rendered insoluble by steaming—will greatly lengthen it, at the expense of its diameter. This is the more readily understood with a hollow tube, hence the diameter may be much diminished by increasing the pull while the supply to the squirting nozzles is kept stationary.

Viscose Filaments. The filaments are not necessarily circular; in fact, magnified sections show them to be angular, due, no doubt, to their contact one with another while still in a mouldable condition. Exactly the same influences are at work in a state of Nature, as with flax and esparto fibres. When a bundle of fibres are pressed evenly together, either by reason of their internal growth and expansion or pressure upon them exerted laterally, the tendency is to the formation of tubes, hexagon in section. Stearn confined his attention to the problem of rendering viscose a homogeneous product, discovering a suitable precipitant that would enable the spinning to be done at a high speed, and investigating the physical changes that occurred during the ripening, and to devising mechanical appliances for producing a uniform product.

In the course of development it became manifest that careful preparation of the solution was of paramount importance. This had to be attended to at every stage, and there is as much science and skill needed to accomplish this as is necessary in the brewing industry, perhaps even more so.

Ageing. We have already stated that the viscose solution is undergoing molecular changes from its very inception to the time of its coagulation. For spinning, the solution has to undergo a process of "ageing," and further chemical treatment, and at the right stage it is spun so that the filament becomes coagulated or solidified *while still in a soluble condition*, and is subsequently rendered insoluble. This important advance we owe to Stearn. Viscose silk [58] is now prepared in large quantities. It possesses the most beautiful lustre and excellent qualities for spinning and weaving. It takes colours either by adding these to the original solution or by dyeing the hanks or skeins in suitable dye-baths. Its silky sheen or gloss results largely from the manner in which it is dried. Its physical qualities in comparison with those of real silk and other artificial silks, have from time to time been referred to in technical and scientific journals.

Very much coarser filaments can be produced from viscose containing hair and fine gut.

The actual production of factories for artificial silk was estimated (1904) at about 1,500,000 kilos, equal to 6 per cent. in comparison with the natural article. The production at first was slow, but there are now a number of factories producing the artificial product, and artificial silk, by one or other of the well-known processes, is likely to become one of the most important industries of the future. A minute examination of the history of these several processes is perhaps one of the most valuable object lessons to the young aspiring chemist.

A monograph on "Cellulose" by Cross Bevan and Beadle (Longmans, 12s.), and later publications might with advantage be consulted by students who desire a closer acquaintance of the chemistry of the subject.

58. SKEIN OF VISCOSE SILK

COLLODION SILK

Such is the name given to artificial silk made in accordance with Chardonnet's patent, and others who have had to do with the development of this industry. It is prepared by dissolving nitro cellulose in a mixture of ether and alcohol, and forcing it through glass capillary tubes, with fine orifices, into the air. The solvent evaporates with sufficient rapidity to allow the filaments to be wound up continuously, leaving the thread insoluble. This is the gist of the process, but in detail it is full of complexities, like that of the viscose product.

Dr. Lehner, of Zurich, after investigating the various problems involved, found that, whereas ordinary collodion containing such a proportion of the pyroxylin (10 per cent. to 12 per cent.) in solution is unworkable under the prescribed conditions, the adding of dilute sulphuric acid causes a molecular change, and gives the solution the requisite fluidity. With such a solution, the conversion into thread is effected as follows. The solution, if carefully filtered, and free from all bubbles, is caused to flow by way of glass tubes to a lower level, where it is delivered through a much narrowed opening with a steady constant flow. The shorter limb ending in this fine orifice is contained in a glass cell, filled with water. On emerging therefrom the solution is at once coagulated to a transparent jelly of considerable toughness. On applying a slight pull to the jelly, grasped with the fingers or forceps, a thread is produced, and on fixing the end to a light wheel revolving at a definite rate, the thread is drawn off continuously of uniform diameter. Several threads being twisted together in the usual way of "silk throwing," the artificial textile thread is produced. After being deprived of water of hydration, the threads acquire the high, white lustre of "boiled-off" silk.

The "artificial silk" has been found to have tensile strength equal to 70 per cent. of that of the natural product of the same degree of fineness. Its elasticity is inferior in about the same proportion; but it has a higher lustre, and is produced at much less cost. Its individual use is, therefore, likely to be considerably extended in the near future.

PAPER-MAKING *concluded; followed by* PHOTOGRAPHY

THE MOON AND THE PLANETS

The Moon's Orbit and Eclipses. The Braking Effect of the Tides. The Superior Planets. Life on Mars. "Mountains Broken Loose." The Perplexing Comets

Continued fro page 6405

By W. E. GARRETT FISHER

The Moon and Her Orbit. The earth, like most of the planets, has a satellite, known as the moon, which moves round it in an elliptical orbit, just as the planets move round the sun. Its globe is rather more than one-quarter that of the earth in diameter, measuring 2,163 miles. It revolves round the earth in an orbit, which, like that of the earth, is an ellipse; but it is not so nearly circular as that of the earth, its eccentricity being about $\frac{1}{18}$. Thus, the actual distance of the moon from the earth varies from about 250,000 miles to 220,000 miles, while the mean distance is 238,840 miles, which is about 60 times the earth's radius. The moon takes about 27⅓ days to complete her revolution round the earth; in other words, she makes a complete circuit of the heavens, from a given star back to the same star again, in that time. Her revolution with regard to the sun, however, on which her phases depend, is not completed in this period, because it is complicated by the earth's motion round the sun. This *synodic* period, of which we usually speak as a month, averages about 29½ days, which is the mean period between successive new moons. The *phases* of the moon depend upon the place which she occupies with regard to the sun as seen from the earth, as has already been explained in the case of the planets Mercury and Venus [27]. When the moon lies between the earth and the sun, the dark side is turned to us and the moon is new. When the earth lies between the sun and the moon, we see our satellite fully illuminated, and speak of her as full. Her degrees of illumination vary steadily between these two extremes in the course of every fortnight. Every night the moon bears a different appearance, waxing through one-half of the month and waning through the other.

26. LINES OF TOTAL SOLAR ECLIPSES

Eclipses of the Moon. If the orbit of the moon lay in the same plane as that of the earth—the plane of the ecliptic—it is obvious that she would pass directly between us and the sun once in every month at the time of new moon, and would then obscure the sun for the length of time which she took to complete her transit. This does occasionally happen, and the consequent blotting out of the sun for a few minutes is known as a *solar eclipse*. Similarly, when the moon was full, the earth would lie in a straight line between her and the sun, and the earth's shadow would blot the moon out of sight by depriving her of the illumination by which alone she becomes visible. This also happens occasionally, and the result is a *lunar eclipse* [30]. But, as a matter of fact, the moon's orbit does not lie in the same plane with that of the earth, but is inclined to it at an angle of about 5°. Consequently, the moon, when lying in the same direction as the sun, is usually a little above or below our luminary, and there is no eclipse.

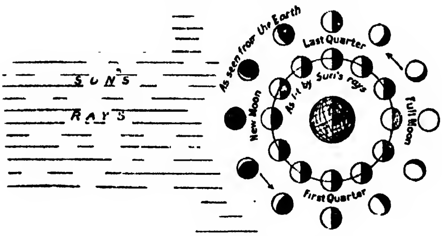
A solar eclipse can only take place, in fact, when the moon lies in the direction of the sun, or is new, near the moment at which she passes the *node*, or point at which her orbit intersects the plane of the ecliptic, which hence derives its name. The same is true of the lunar eclipse, which only occurs when the moon is close to one of her nodes at the time of being full, and, consequently, passes into the shadow of the earth. It follows from geometrical considerations that there cannot be less than two or more than seven eclipses in a year, of which at least two must be solar. From the computed motions of the earth and moon we find that the conditions which determine eclipses repeat themselves with great exactness after a period of about 18 years and 11 days. This recurrence of eclipses was discovered from observations by the Chaldeans, who named this period the *Saros*, and were enabled to predict coming eclipses by its use.

Eclipses of the Sun. There is a notable distinction between solar and lunar eclipses, which also depends upon the relative movements of the earth and the moon. A lunar eclipse is visible from all parts of the earth where the moon is above the horizon; and a moment's thought will show us that this must be so, because an eclipse of the moon is due to the moon entering into the shadow of the earth, and is exactly comparable to the switching off of an electric light. Wherever the moon can be seen at all—even from Mars—it will be eclipsed. But this is not at all the case with a solar eclipse, which only exists for observers who occupy a narrow belt of the earth's surface. A solar eclipse simply means that the moon passes between us and the sun, and that the earth itself lies for a few minutes in the shadow of its satellite. Now, everybody knows that the breadth of a shadow depends upon the relative size and distance of the object which casts it. The sun is incomparably larger than either the earth or the moon, and, consequently, the shadows which they cast are both conical, like the point of a pencil tapering off to an abrupt end.

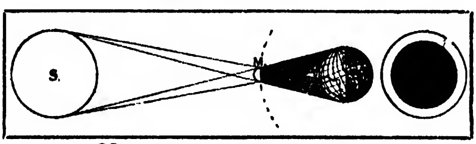
The earth's shadow is much longer than the moon's, in exact proportion to the relative size of the two bodies. Thus the moon takes a considerable time to pass through the earth's shadow, and may be totally eclipsed for as much as two hours. But the moon's shadow is only just long enough to reach the earth at all. The largest possible cross-section

of the moon's shadow where it reaches the earth's surface is about 168 miles; and as the shadow sweeps across the earth from west to east, it is only observers situated within a belt no wider than this who will see the sun *totally* eclipsed [26]. Outside this belt a *partial* eclipse will be visible over a very much greater area, its size decreasing as the distance from the belt of totality increases.

The width of the eclipse-belt, and the consequent duration of totality, vary between wide limits with the distance of the moon from the earth at the moment of eclipse. The moon's apparent size is very nearly that of the sun, each being a little over 30 minutes in diameter. But these both vary with the distance of the earth from the sun and moon, and it sometimes happens that at the time of an



27. PHASES OF THE MOON



28. ANNULAR SOLAR ECLIPSE

eclipse the moon is so far away that its shadow does not quite reach the earth, and its apparent diameter is rather less than that of the sun. At such a time we see an *annular* eclipse [28], in which at the moment of greatest eclipse a bright ring of the sun's disc is still visible surrounding the moon. It is on observations made during the brief duration of total eclipses of the sun that astronomers long depended for their chief knowledge of the solar constitution, and that they are still dependent for their study of that mysterious object, the corona.

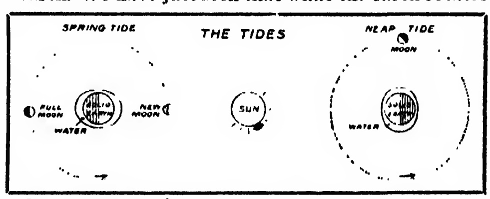
The Moon and the Tides. The gravitational attraction of the moon has a very important influence on the earth in causing *tides* in the sea. The way in which these tides are caused will be easily understood from a glance at the diagram [29].

We have seen that the attraction of one body for another varies inversely as the square of its distance. As the waters of the sea on the side of the earth nearest the moon are nearer our satellite than the centre of the earth, the moon pulls these waters towards her with greater force than she exercises upon the body of the earth; and as they are quite free to move, they are consequently heaped up in a kind of watery mound, which is highest on the spot vertically beneath the moon. In exactly the same way the moon attracts the earth more powerfully than the water which lies on its opposite side, and so draws the earth away from that water, which is consequently heaped up into a similar mound on the point exactly opposite. Thus we have two simultaneous high tides, culminating at the two points of the earth which lie in a straight line with the moon, and, consequently—since the total amount of water in the seas does not vary—corresponding low tides at two points on the earth distant by 90° from these.

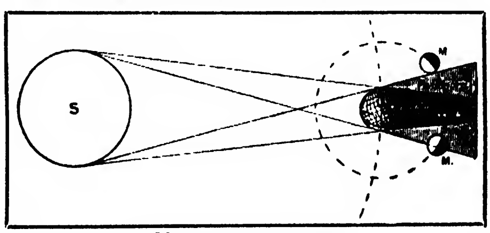
If the moon were fixed with regard to the earth the tide would always be high at one set of places and low at another, but as the earth completes a rotation in twenty-four hours, whilst the moon holds its accumulations of water in the same place, the high tide and low tide traverse every part of the seas, there being two high and two low tides at each place daily. If the earth were a perfect sphere, uniformly covered with water, this state of things would be actually observed by its fishy inhabitants. But the configuration of its surface greatly complicates the actual motion of the tides, which are greater or less, sooner or later, according to the shape of the coast line, as is explained in the course on GEOGRAPHY [page 556].

Spring and Neap Tides. The sun as well as the moon helps to create tides in our seas. Its mass is very much greater than that of our satellite, but so is its distance, and, consequently, the solar tide is only about two-fifths as high as that caused by the moon. When the sun and the moon lie nearly in the same straight line with the earth, and the moon is new or full, the solar and lunar tides help one another, and we have extra high tides, known as *spring tides.* When the sun and moon lie at right angles to one another with regard to the earth, and the moon is in its first or last quarter, their tidal forces are opposed, and moderate or *neap tides* result. It will readily be seen that the average height of the spring tide should be rather more than double that of the neap tide at any particular place.

How the Day has Lengthened. One very interesting effect of tides, as Sir George Darwin has shown, is to act as a brake upon the rotation of the earth. We have just seen that while the earth rotates



29. THE MOON'S GRAVITATIONAL ATTRACTION



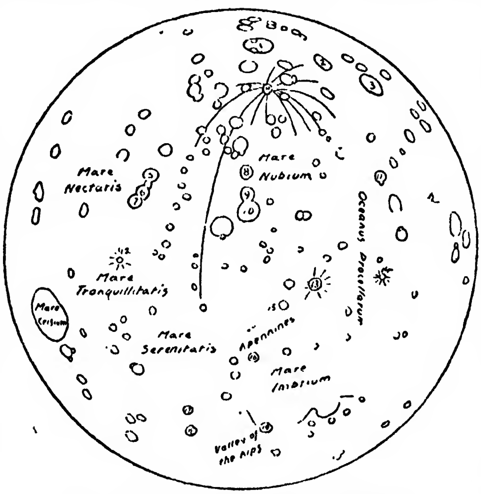
30. LUNAR ECLIPSE

a great mass of water is held still by the attraction of the sun and moon. This acts exactly like the brake which is used on the axle of a wheel, and by its friction tends to diminish the rate at which the earth rotates. In the early days of the earth this effect was much more considerable than it is at present, and Sir George Darwin has shown that tidal friction has lengthened the day from about three hours to its present length, and that the moon itself almost certainly once formed part of our planet and was thrown off from it by the centrifugal force due to this extremely rapid rotation. When the earth was still in a liquid condition, tides were caused in its actual substance by the attraction of the sun,

and afterwards possibly of the moon, and the retarding effect of these gigantic tides, which may have risen as much as 600 miles in height, must have been immensely great. At present there is ground for believing that the tidal friction is still exerting a retarding influence on the earth's rotation; but this influence is exceedingly small, and it is practically certain that the length of the day has not varied by so much as one-hundredth of a second since the dawn of astronomy 2,000 years ago.

The Physical Condition of the Moon. As we have seen that the moon was originally a fragment drawn away from the earth, it is only reasonable to suppose that it is composed of the same materials. But it differs from the earth in one very important respect. Being so much smaller it has cooled more quickly, and has probably passed through all the stages of planetary life, in the midst of which the earth is now.

Few things are more certain than that the moon is a dead world. It has no atmosphere, so far as we know, and if one exists it must be more rare than the vacuum inside the incandescent electric lamp. Such air and water as the moon must once have possessed have been absorbed into its substance or flown away into space. One consequence of its denuded condition is that the surface of the moon must undergo extremes of heat and cold. The side on which the sun is shining must be far hotter than the tropical regions of the earth, whilst the other side must endure the cold of empty space, which is very near the absolute zero of temperature. It is hardly necessary to add that the moon cannot be the abode of any kind of life which we can conceive as possible. Life may once have existed there, but it is long extinct.



31. MAP OF THE MOON'S SURFACE

The Face of the Moon. The moon is a globe about 2,163 miles in diameter, and its mass is about $\frac{1}{81.5}$ of the mass of the earth. Its density is about 3·4, that of water being taken as unity. The moon rotates on its axis in 27 days $7\frac{2}{3}$ hours, so that its day and night are each a fortnight in length. This period is the same as that in which it revolves round the earth. The moon, consequently, always presents the same face to the earth; though, as a matter of fact, we are able to see rather more than a single hemisphere of the moon because of a certain oscillating motion of our satellite known as *libration.*

But there is a considerable portion of the moon's surface, amounting to more than three-eighths of the whole, which is permanently invisible to the observer. Novelists have allowed their imagination to run riot about this invisible side of the moon, and have provided it with an atmosphere, flowing water, and inhabitants. But it is as certain as anything of the kind can be that the invisible half of the moon is perfectly similar to that which we see.

The chief feature of the moon's visible surface is the numerous and often gigantic craters with which it is pitted [32 and page 1206]. These objects, when observed through a telescope, or even a powerful field-glass, have a striking resemblance to volcanic craters on the earth. They are, indeed, on a vastly greater scale, some of them being more than 100 miles in diameter. But there is little doubt that they are the remains of extinct volcanoes which once covered the moon with violent and long-continued eruptions. Probably the surface of the earth was once in a similar condition, but the existence of the various denuding agencies which our planet possesses have entirely changed the configuration of its surface [see GEOLOGY]. No distinct evidence of volcanic activity has been seen upon the moon in modern times, though a few observers believe that they have noticed very slight changes of this nature in progress. It is most probable that the moon is a dead world, affording a kind of prophecy of what the earth will be one day, when it also pursues a frozen and lifeless journey through space.

Selenography. The surface of the moon has been studied and mapped on a large scale [31]. Its chief features are three in number: (1) the numerous *volcanic craters,* such as Tycho and Copernicus, which are mostly named after distinguished men of science: (2) the wide, dark plains which are known as *seas,* because they were formerly thought to consist of water: (3) the curious systems of *bright streaks,* which radiate from many of these craters, of which the most remarkable extend in all directions from the great crater Tycho, near the moon's south pole, and are conspicuous even to the naked eye at the time of full moon. The student will find the names and description of these various features of lunar topography—*selenography* — in any good textbook of astronomy, but they are not sufficiently important to demand fuller treatment within our narrow limits.

The Superior Planets. The *superior* planets are all more distant from the sun than the earth. They include five major planets—Mars, Jupiter, Saturn, Uranus, and Neptune—as well as a vast number of minor planets, of which nearly 600 are known at present. These outer planets differ from the inner planets, Venus and Mercury, in the nature of their apparent motion. Instead of oscillating backwards and forwards across the sun, they all move, on the whole, steadily westward in respect to the sun's place in the heavens, and consequently rise earlier and come earlier to the meridian every night. It is obvious that they can never pass between us and the sun as the inferior planets do at the time of transit.

The superior planets may appear in any part of the Zodiac, outside the limits of which, however, they never move. This is due to the fact that they all move round the sun in elliptical orbits outside that of the earth. When a planet lies beyond the sun in a straight line with the earth it is said to be in *conjunction*; when the three bodies are in a straight line, but the planet is on the opposite side of the

earth to the sun, it is said to be in *opposition.* Of course, we can never see the planet in conjunction, because it is only above the horizon in the daytime, when the light of the sun obscures it. The superior planets can be best studied when they are in or near opposition, because at such times they are nearest to the earth, and are also most favourably illuminated. They do not display phases like those of the moon. A necessarily brief account of the physical features of these various planets will now be given.

Mars, the Red Planet. Mars, the major planet which comes nearest to the earth, with the single exception of Venus, resembles the earth more closely than any other of the planets, and is most favourably situated for our observation of all the heavenly bodies, except the moon. It is a globe rather more than half the size of the earth, its diameter being about 4,200 miles. Its mean distance from the sun is 141,500,000 miles, but the eccentricity of its orbit is so considerable that this distance varies by more than 26,000,000 miles. When Mars comes nearest to the earth its distance from us is about 35,000,000 miles. At these favourable moments its brightness is about equal to Jupiter, and only surpassed by that of Venus. Mars has a very pronounced red colour, which is supposed to be due to the prevalence of a rock like our red sandstone on its surface, or possibly to the colour of its vegetation.

32. MOON'S SURFACE SHOWING CRATERS

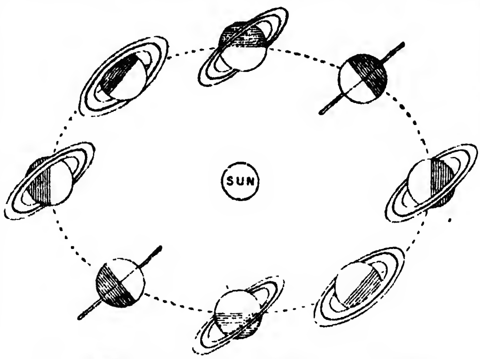
The Most Likely Seat of Extra-terrestrial Life. When studied through a powerful telescope Mars reveals itself as having a physical constitution very like that of the earth [37]. It undoubtedly possesses an atmosphere, though this is much less dense than that of the earth, so that clouds are of very infrequent occurrence in it. Mars also possesses free water, which is collected into seas on its surface and gives rise to extensive caps of ice around its poles. These ice caps are observed to dwindle in summer, and increase in winter, so that their nature can hardly be doubted. The surface of Mars is divided, like that of the earth, into continents and oceans. The most peculiar feature in its land is the presence of numerous straight narrow markings which are commonly known as canals [36]. They are not indeed canals such as we make on the earth, for they must be at least 60 miles in width in order to be visible to us at all. But there is little doubt that they represent watercourses of some kind.

The most curious thing about these canals is that they are not always visible. They seem at times to disappear from sight and then again reappear, and this in accordance with the periodical changes in the Martian seasons. It has been plausibly suggested that the marks which we see are not the actual watercourses, but the broad belts of vegetation which come into existence when the water is turned on to irrigate them, and die when it ceases to flow. It has even been suggested that this periodical flow and cessation of water is due to the enterprise of the hypothetical inhabitants of Mars. At present this theory rests on inference, but there is a great deal to be said in its favour, and the astronomers who have studied Mars most closely are most nearly convinced of its truth. We know that Mars, being an older planet than our own, is farther advanced in evolution, and that it has reached the stage at which efforts far greater than any which mankind is yet called upon to put forth must be necessary for the preservation of life on its surface. Its water supply is already becoming scanty, and some gigantic system of irrigation would undoubtedly be necessary for its surface to continue fruitful. It is possible that the markings which we call canals do really represent such a system of irrigation, but we can hardly say more than this about the great problem of the existence of life in this planet.

Satellites of Mars. Mars has two satellites, which were only discovered as recently as 1878, although their existence and many of their characteristics had been strangely predicted by Swift in "Gulliver's Travels" more than 150 years earlier. They are exceedingly small, swift, and close to the planet. The outer one revolves at a distance of 14,600 miles from the centre of the planet in a little more than 30 hours, whilst the inner one is at a distance of only 5,800 miles, and revolves in 7 hours, 39·25 minutes. Mars itself rotates in 24 hours 37½ minutes. Consequently, its inner satellite completes more than three revolutions in every Martian day. To a Martian observer it will appear to rise in the west and set in the east, completing its apparent revolution in about 11 hours; for, of course, it revolves in the same direction as that in which the planet rotates. It is impossible to estimate the size of such a tiny object with any accuracy, but we can be sure that neither of the satellites is more than 30 or 40 miles in

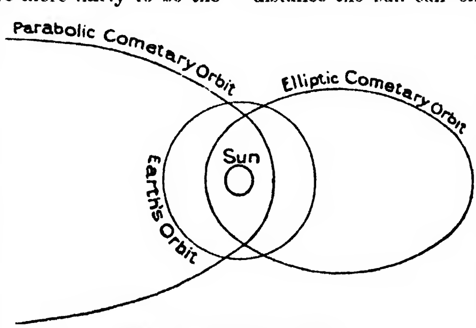
diameter, and probably they are even smaller than this. Mars completes its revolution round the sun in 687 days, so that the Martian year is nearly double our own in length.

The Minor Planets, or Asteroids. The space between Mars and Jupiter is occupied by a strange and numerous swarm of *minor planets* or *asteroids*. The first of these singular bodies was discovered by an Italian astronomer, Piazzi, on the first night of the nineteenth century. Three others were discovered within the course of the next seven years, and the number now known is upwards of 600, most of which have been recognised by the record of their motion on photographs of the sky. The four asteroids first discovered, Ceres, Pallas, Juno, and Vesta, are naturally the largest, ranging in diameter from 488 to 118 miles.



33. METEORIC RINGS GIRDLING SATURN

Vesta, though not the largest, is considerably the brightest of the minor planets, and is occasionally visible to the naked eye. None of the other asteroids has a diameter so great as 100 miles, and probably the majority of them are only 10 or 20 miles in diameter—mere " mountains broken loose," as they have been called. Most of these planets move round the sun in orbits which lie between those of Mars and Jupiter, and all of which intersect one another. There are a few exceptions to this rule, notably in the case of Eros, discovered in 1898. The orbit of this planet lies between Mars and the earth, and it is by far our nearest neighbour after the moon, its minimum distance from the earth being 13,500,000 miles. So close an approach will occur in 1931; it gives Eros a particular importance, as observations of it made at such a time should enable us to determine the solar parallax with greater accuracy than has hitherto been achieved. It was formerly supposed that these minor planets were the disrupted fragments of a planet which had been blown to pieces by some internal convulsions. It is now held, however, that they are more likely to be the remains of a part of the original nebula which never coalesced into a planet, as will be explained later on.



34. COMETARY ORBITS

Jupiter. By far the largest of the planets is the giant Jupiter, which is more than twice as massive as all the other planets put together. Its mean diameter is 88,000 miles, and its mass is about 317 times that of the earth, though its mean density is not much greater than that of water. Its mean distance from the sun is about 483,000,000 miles, or rather more than five times the earth's distance, which is taken as the astronomical unit. It completes its revolution round the sun in 11 years 10 months, though it appears to revolve round the earth in a synodic period of 399 days. Jupiter is the brightest of all the planets except Venus, which, though so much smaller, is much nearer to us and better illuminated. Jupiter rotates on its axis in rather less than ten hours, so that a point on its equator must be travelling at the rate of seven or eight miles per second. Its surface varies considerably from time to time, as seen through a telescope, and it is consequently concluded that what we see is really a surface of clouds. The great size and small density of Jupiter have led astronomers to believe that it is still in a condition somewhat akin to that of the sun—that is, that it has not yet solidified into a planet like the earth. Its temperature must be very great, though it is not so hot as to give out any perceptible light of its own. The most important marking on its surface is the great red spot which has been visible more or less in the same place since 1878, but no satisfactory explanation of its character has yet been given.

Jupiter has at least seven satellites, four of which are large enough to be seen with a good field-glass, and were among the earliest discoveries made with the telescope of Galileo. The fifth satellite was discovered by the great Lick telescope in 1892, and is very much smaller than the others; the sixth and seventh were discovered by Professor Perrine in 1904-5.

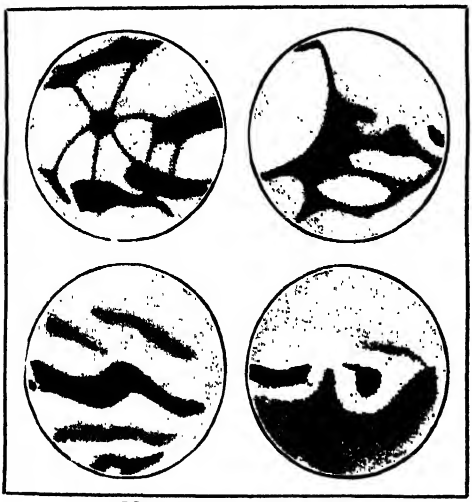
Saturn. Saturn is the outermost of the planets visible to the naked eye, and known to the ancients. Its mean distance from the sun is about nine and a half times that of the earth, or 886,000,000 miles. It is the second largest of the planets, being about 72,500 miles in diameter. Its mass is 95 times that of the earth, and its mean density is only two-thirds that of water, so that the whole planet would float if it could be immersed in a vast ocean; hence, like Jupiter, it is supposed to be still in a largely gaseous condition. Its supply of heat and light from the sun is less than one-ninetieth of that received by the earth, and at its great distance the sun can only appear as a peculiarly brilliant star. Saturn rotates on its axis in about 10 hours 14 minutes, and takes $29\frac{1}{2}$ years to complete its revolution round the sun. Its synodic period of apparent revolution round the earth is 378 days.

Saturn's Rings. Saturn is the most remarkable of the planets, and one of the most beautiful telescopic objects in the heavens, by reason of the wonderful system of *rings* with which it is girdled [33]. When favourably visible from the earth it appears like a globe surrounded by three flat thin concentric rings lying in the plane of its equator. These rings revolve round the planet, and their plane always remains parallel to itself.

It has been proved that the rings are not a solid

structure, but consist of swarms of tiny meteorites, like the shooting stars which occasionally flash into our atmosphere. They must form a wonderfully beautiful spectacle if they could be seen from the surface of the planet which they adorn —a vast arch of light stretching from side to side across the sky and brilliantly illuminated through a great part of the planet's night. In addition to these rings, Saturn has no less than ten satellites, the largest of which is about half the size of the earth. With one exception they revolve in the same plane as the rings.

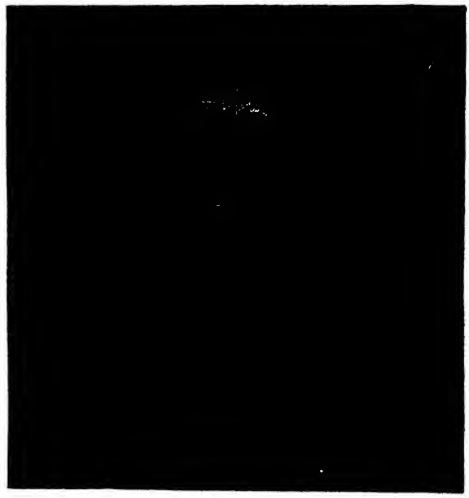
Uranus. The two outermost of the planets were not known to the ancients. Uranus was the first planet discovered in modern times, being found by Sir William Herschel, in 1781. whilst he was sweeping the heavens with a seven-inch reflecting telescope of his own construction. It had frequently been observed before, but had always been mistaken for one of the fixed stars. But when Herschel saw it he recognised by the visible disc which it presented that it must belong to the solar system, and following observations proved that it was a planet lying beyond Saturn. Its mean distance from the



36. DRAWINGS OF MARS
(From "Knowledge," by permission of E. Walter Maunder, F.R.A.S.)

sun is 19·2 times that of the earth, and it completes a revolution in its vast orbit in 84 years. Uranus can occasionally, on a moonless night, be made out by a very keen eye, as a star of the sixth magnitude, and certain early traditions about an eighth planet are supposed to imply that its true nature had thus been perceived by very primitive astronomers. Its mass is about 14·6 times that of the earth, and its density is not quite double that of water. Little is known of its physical constitution; even its diameter has not been measured with any certainty, though it is probably about 30,000 miles. Uranus has four satellites, and possibly faint rings like those which encircle Saturn.

The Discovery of Neptune. The discovery of Uranus was a happy accident, but that of Neptune was the greatest triumph of mathematical astronomy since the time of Newton. After the orbit of Uranus had been fully calculated, it was found that the actual motion of that planet did not quite agree with prediction. It began to stray from its allotted place to an extent which was almost perceptible to the naked eye, and which astronomers consequently had to explain. The only valid



39. A COMET, SHOWING TAILS

explanation was that there must be an unknown planet still further from the sun than Uranus, whose attraction perturbed that planet, and so drew it away from its predicted motions.

Shortly before the middle of the nineteenth century, the problem of determining the place of such a planet from the trivial disturbances which it caused in the motions of Uranus was independently attacked by two astronomers—Adams, of England, and Le Verrier, of France. They both succeeded in solving it about the same time, though it was the calculations of Le Verrier which first enabled Galle's telescope to be pointed to Neptune, in 1846. The discovery of this planet was a remarkable confirmation—if such had been needed—of the truth of Newton's theory of the planetary movements under the law of gravitation.

Neptune. Neptune is quite invisible to the naked eye, though it can just be seen with a good field-glass. Its mean distance from the sun is about 2,800,000,000 miles, and it takes 165 years to complete its orbital revolution. Its diameter is probably about 30,000 miles, and its mass is about

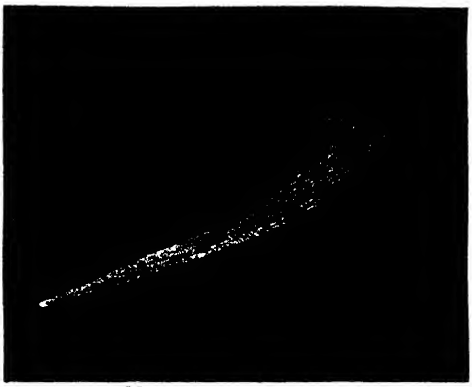
37. TELESCOPIC APPEARANCE OF MARS IN FEBRUARY, 1901 (From "Knowledge")

17 times that of the earth. Its density is about equal to that of Uranus—one-third that of the earth. Nothing is known of its rotation or physical constitution. It lies on the confines of the solar system, and if it were inhabited—which seems impossible—the sun would look to its people no bigger than Venus at her nearest approach to the earth, though the light which it gave would still be equal to that of 700 full moons. Neptune has one satellite, whose motion is even more irregular than that of the satellites of Uranus.

Comets and Meteorites. In addition to the planets and their satellites, the sun is attended by a large number of other bodies, moving with far less regularity, and generally much less conspicuous in the heavens. These are known as *comets* and *meteorites* or *shooting stars*. One of the most interesting of recent astronomical discoveries is that an intimate physical connection exists between these two classes of bodies.

Comets. Comets have been known from the earliest times, because every now and then a very large and conspicuous one hastens up to the sun from the remote regions of space, and perplexes monarchs with the fear of change. They are called *comets*, from the Latin *coma*, meaning hair, because when they are bright enough to be seen with the naked eye they look like stars attended by a long stream of hazy light, which was thought to resemble a woman's hair flowing down her back [35]. This train of light is known as the comet's *tail*. Such bright comets, of which the last visible in our latitudes made its appearance in 1893, are sometimes as brilliant as Venus; their tails have been known to stretch halfway across the visible sky.

These comets are very beautiful and conspicuous objects, which usually appear in the sky without any warning from astronomers, and invariably create a great popular sensation [38]. By far the greatest number of comets, however, are only visible through a telescope, and it is rare that a year passes without at least half a dozen of these being reported. Up to the present time nearly a thousand comets of all sizes have been recorded. Not more than one in five of these is visible to the naked eye.



38. THE COMET OF 1882

Cometary Orbits. In all cases in which a comet has been observed sufficiently often for its orbit to be calculated, it is found that it moves in one of the curves which are known to the geometer as conic sections. Less than a hundred of the known comets move like the planets in *elliptical* orbits, and consequently their periodical return to visibility can be predicted. As a rule, the eccentricity of these cometary orbits is very much greater than that of any planetary orbit, which means that the comet approaches fairly close to the sun at one end of its orbit, but at the other flies away far beyond the outermost planet, and for a long period disappears from the ken of our most powerful telescopes.

The great majority of comets have only been seen once, and their orbits appear to be either *parabolic* or *hyperbolic*. Neither of these is a closed curve, and what seems to happen in such cases is that a comet travelling in such an orbit dashes up to the sun from the remote parts of space, swings round it, often at very close quarters, and flies away again for ever [34]. Only those comets which have elliptical orbits can be said to belong to the solar system. The others are visitors from space, which in the course of their motion come near the sun and are deflected by it, but then fly away until after a lapse of ages they perhaps come within the sphere of another star's attraction. Of the comets which move in elliptical orbits, about twenty have been observed at more than one return to the sun. Some of these complete their orbits in quite a short period, like Encke's comet, which has the shortest period of all, less than three and a half years; the longest periodical comet is known as Halley's, which returns to the sun after 76 years and is due again about 1910; it is a bright and conspicuous object.

The Constitution of Comets. The nature of comets was long in doubt, and even to-day their physical characteristics are not fully understood. They are certainly formed of gravitational matter, since they move in orbits which are subject to the same laws as those of the planets. But they also appear to be acted upon by powerful *repulsive forces* emanating from the sun, to which is due the remarkable phenomenon of cometary tails. At first it was supposed that a comet and its tail consisted of what we know as solid matter. But the observed facts are quite inconsistent with this theory.

A comet's tail, which stretches for many millions of miles, is always directed away from the sun, and when the comet swings rapidly round the sun the whole of this tail follows its motion in such a way that it is quite impossible to suppose that it consists of any kind of matter with which we are acquainted. The probability is that these tails consist of highly rarefied matter thrown off from the comet under the influence of a repulsive force emanating from the sun which is probably electrical in its nature. The degree of rarefaction of the matter composing these tails is probably greater than that of any vacuum which we can produce in our laboratories, and its luminosity is due to similar causes to those which produce the glow in a vacuum tube through which an electric current is passed. The extreme tenuity of comets is proved by various facts, such as that the earth is known to have passed right through the tail of a comet without any apparent effect, that the close approach of a comet to a planet causes no apparent alteration of the planet's motion, and that small stars can be seen shining brightly right through a comet as much as 100,000 miles in diameter. Perhaps there is not much exaggeration in the statement once made by a well-known astronomer that the whole material of a comet stretching halfway across the visible heavens, if properly compressed, could be packed in a hatbox. The old fear that the earth might suddenly be annihilated by a comet striking it is throughly dispelled by modern investigation, which leads us to believe that the worst results of such an encounter would be an extremely beautiful display of shooting stars.

COATING & COLOURING METALS

The Processes of Protecting Metals. Corrosion. Coating for Ship Bottoms. Painting, Enamelling, Bronzing, Barffing, and Nickel Plating

Continued from page 6460

METALS are coated for two reasons—to prevent gradual destruction by corrosion and for purposes of ornament. Usually both reasons operate, and, consistent with the proper protection from corrosive influences, appearance is usually given the deciding voice. Some processes of protecting metals, including galvanising [page 6168] and tinning [page 6164], have already been described in detail, and we shall therefore ignore them in the present consideration. We shall notice briefly the fundamental facts regarding the other processes; and we shall consider first the protection of iron and steel by painting when protection and not appearance is the object sought.

Corrosion. Iron has an affinity for oxygen, and the result is oxide of iron, which we know as rust. Moisture accelerates the formation of rust, and precautions must be taken to avoid this. In protecting beams which are embedded in masonry lime is used to advantage, and we consider this and some other methods of treating structural steel work further on. Asphalt is the most satisfactory coating for such situations. The asphalt used should be naturally soft or may be made soft by reducing a hard asphalt with a heavy mineral oil.

For cast-iron water pipes the common protection is a coating of Dr. Angus Smith's solution [see page 5320]; but the process does not give satisfactory results with steel pipes, chiefly because steel pipes are thinner and do not retain long enough the heat necessary to cause Angus Smith's solution to form a hard, impenetrable film upon the surface. Steel pipes are best coated with asphaltum reduced to an elastic varnish by the use of oil, and baked on hard in an oven. On a large scale the work is performed most economically by dipping, the dipping tank being of a form to suit the work.

Painting Iron and Steel. Iron oxide and metallic brown paints should never be used with iron and steel. Such paints are merely iron in a more or less advanced stage of oxidation; in other words, rust. Rust promotes rust. Iron oxide, even in the form of paint, conveys oxygen from moist atmosphere to the metal, and becomes a vehicle for the spread of rust. Zinc oxide paints also are found to peel off, and salvation is found in oxide of lead paints. Red lead forms with linseed oil a hard elastic coating that adheres to the metal surface with great tenacity. Its only chemical effect is to promote the formation of black or magnetic oxide, that prevents corrosion and does not act as a communicating medium for atmospheric oxygen. Red lead in oil "sets" much as plaster of Paris sets when mixed with water; and just as plaster of Paris cannot be worked to advantage after it has partly set, so a red lead paint should not be applied when the process of setting has progressed some way. The usual practice in large shipyards—these may be selected because the work in them demands the best-known practice—is that the red lead is mixed with just enough linseed oil to form a stiff, tough paste, which will keep for several days without hardening. This paste, when required for use, is thinned down with a proper proportion of pure linseed oil and applied at once, care being taken to leave no paint in the pots overnight. By this method the lead and oil "set" on the surface of the metal, and the adhesion is thereby more tenacious than it would be otherwise. The best mixture is 5 lb. of pure linseed oil and 18 lb. of red lead, which make one gallon of paint, and can be made to cover 500 square feet as a first coat, or 600 square feet as a second coat.

The advantages of red lead as a paint for iron and steel are that it dries easily with raw linseed oil without the need for the addition of any "drier," that after it has dried it forms an elastic coat capable of expansion and contraction with the metal, that it does not impart or convey oxygen to the surface upon which it rests, and that it hardens without shrivelling, making a tough and insoluble covering.

All varieties of driers impair the value of any paint applied to iron and steel. The nature of all driers is acid, and any acid will ultimately induce corrosion or oxidation of any iron surface to which it is applied, thereby lessening the stability and protective properties of the applied coating.

Corrosion by Sea Water. Industrially, no process of coating metals is more important than when the objects coated have to withstand the action of sea-water. Utility is the first consideration, and artistic effect, while not negligible, is of much less importance. A few years ago extended tests were made upon steel and aluminium plates in Brooklyn Navy Yard, under the care of scientific authorities, in order to determine the most satisfactory coating to resist sea-water corrosion. Seventy-two plates were immersed in the sea and withdrawn. Sixty of them were left for thirteen months, and twelve of them were subjected to nineteen months' immersion. A careful examination of them after withdrawal was instructive, and led to certain definite conclusions, which may be summarised as follows: Whatever pigment is used for sea work, a more durable coating results if varnish is the vehicle than if oil be used. Further, a varnish coating, or a pigment and varnish coating, withstands sea-water action better when baked on than it does when only air dried. Zinc-white was found to be more durable than any other pigment used in the test, and finally enamel coatings, baked on at high temperatures, were proved more durable than any other coating.

Anti-fouling Paints. In the old days of wooden ships, the hulls used to be sheathed in copper to give anti-fouling properties, but when iron and steel plates superseded wood for shipbuilding purposes, copper had to be discarded. When a plate of iron or steel and another of copper are joined or in mechanical contact in any acidulated solution of water, such as sea-water, the iron becomes electro-positive to the copper, and corrodes rapidly. The value of copper lay in the fact that it protected the wood beneath it from the action of sea-water, and because it constituted a substance with anti-fouling properties; that is to say, that marine organisms did not readily attach themselves to it. The anti-fouling paints or compositions now used are legion. Many of them are secret preparations,

and others are the subject of letters patent. Most of them are sold under proprietary names.

The essentials in a paint for ships' bottoms are that it must be of a nature capable of protecting the surface of the hull from corrosive influences; it must form a smooth surface, so as to offer as little friction to the water as possible; and it must be a rapid dryer, so that the bottom may be cleaned and two coats of paint applied in one day. The compositions used must be adapted to the waters through which the ship has to make her way. For instance, the waters of the Indian Ocean are more fouling than those of the Atlantic, and a composition for use in the former ought to have a higher percentage of a poisonous ingredient. The harder the paint on a ship bottom, the longer it will last. The use of shellac dissolved in spirit gives a coating of the necessary hardness and adhesive powers. The second or external coating should contain a poisonous ingredient that will kill the marine organisms seeking to adhere to the hull surface. Zinc-white, arsenic, copper, and quicksilver have all their use in different compositions. The more scaly the composition the more frequently must it be renewed. In spite of this scaling, such compositions are usually preferred, because as they scale they carry away with them any attached organisms.

Before applying a ship paint, the surface to be treated must be cleaned. All rust must be removed. Better results are attained by a poor paint on a well-prepared surface, than by a good paint on a badly prepared surface. Among the patented anti-fouling compositions we may mention the following:

1. Bitumen, lime, fine sand or Portland cement, and flaky mica—melted together and applied hot.

2. Mix 32 parts of quicksilver with 1 part sulphurised oil of turpentine by grinding in a mortar; add 60 parts of lard and mutton tallow, working the whole into a homogeneous mass. Finally, add 20 parts of litharge which has been ground up in oil. Before using, reduce to proper consistency by stirring in gradually linseed oil, varnish, and 3 per cent. of peroxide of manganese. Any pigment may be introduced to colour any desired shade. This composition is said to be an effective deterrent to the lodgment of barnacles.

3. Tallow, 40 parts; resin, 10 parts; nitreous sand, 10 parts; arsenic, 1 part. Melt together, and mix well.

Celluloid promises to be a valuable coating material for ship hulls [see under DYEING], when the prejudice against it has been dispelled.

Protecting Structural Steel. Apart from shipbuilding work, there are many purposes for which iron and steel must have a thoroughly protective coat of paint. An important field is for structural steel buildings, which are common in other countries, and which are bound to b come common in this country whenever the restrictive building laws which prevail with us have been modified so as to make the form of construction economically possible. In structural steel work, the steel joists are almost invariably embedded in cement, or covered with wood, stone, or plaster, so that it is impossible to give them periodical coats of paint as may be done with, say, a bridge or a ship's hull. Hence the need at the time of building to make the pigment covering as durable, as impenetrable, and as free from any agent of corrosion as can possibly be done. The extent to which steel-frame buildings can maintain their strength under different methods of protection has for years been a matter of conjecture and theory. The method of construction is not old enough to furnish precise data regarding corrosion under different condition. Hence peculiar value attaches to the examination of buildings which suffered by the San Francisco earthquake and fire last year.

Lessons from San Francisco. San Francisco was a city with many steel-frame buildings, and the new San Francisco will follow this method of construction almost exclusively. From the point of view of investigation, the building which attracted most attention when the ruins came to be examined was a nine-storey insurance office, which was erected in 1893, and had therefore done thirteen years of duty. The rust or freedom from rust of the members of the steel framework after thirteen years of use was the point upon which precise information was sought by architects and others. There was very little rust indeed when the steelwork was exposed. Where the steel was covered with lime only, there was found to be a little more rust than when Portland cement and lime had been used together. Where there was rust under the paint, it is thought that care was not exercised in having the surface clean at the time of painting. But, generally speaking, the freedom from rust was so general, and the condition of the members so satisfactory, that all the columns, beams, tie rods, and bolts were sold for use in new buildings in the vicinity.

From the whole experience certain conclusions are drawn regarding steel-frame buildings, and some of these considerations are briefly as follows:

A steel frame, properly painted and buried in masonry, will not rust enough in thirteen years to affect its strength appreciably. The better the steel is coated with mortar, the less it will rust. Portland cement is better than lime mortar for imbedding steel to prevent it from rusting. Unpainted iron rods buried in mortar composed of lime and a large proportion of Portland cement rust very little—certainly not enough to impair their strength. If steel is not thoroughly cleaned before it is painted, the paint will not greatly retard the progress of rust. It is much easier to cover steel thoroughly with concrete than with brick masonry. If brick masonry is to be used, the bricklayer should plaster the steel thoroughly before the brickwork is put up. The quality of paint used, though important, is not so important as surrounding every part of the steel with Portland cement. Cinder concrete does not injure to the slightest degree a steel floor-beam that has been painted.

Paint for Tin and Zinc. In this country tin is not used as a roofing material. But in other countries—conspicuously in Canada—tinplate is an exceedingly common roofing material. A common paint for tin roofs, when they are treated with paint, is made by mixing Venetian red, Spanish brown, or yellow ochre—or these in combination according to the colour desired—with pure raw linseed oil. Such a paint attains a great elasticity, which enables it to expand and contract with the metal without cracking. As tin roofs are generally used only in countries subject to wide extremes of temperature, this property is valuable.

It is extremely difficult to persuade oil colours to adhere to zinc owing to the coating of zinc oxide. But zinc seldom needs painting for protection, as it does not corrode under atmospheric exposure. By means of a special treatment zinc is said to be made capable of taking on an oil paint satisfactorily.

This treatment consists in the application of a mordant made by dissolving 1 part each of chloride of copper, nitrate of copper, and sal ammoniac in 64 parts of water, and thereafter adding 1 part of hydrochloric acid. Under this treatment the zinc first becomes a deep black, but during the drying process this changes to a grey, to which oil colours will adhere satisfactorily.

Cleaning Metals. No matter what process of covering metals is to be adopted, it is essential that the article to be coated should be cleaned if good is to result. There is no exception to the rule. Rust, dirt or grease prevent intimate adhesion, no matter whether the coating be paint, enamel, or another metal to be deposited by simple immersion or by electric deposition. The methods employed for cleaning iron and other metals before galvanising and tinning have been considered on pages 6164 and 6169, and, generally speaking, those methods apply to all metals upon which a fine finish is desired.

The usual method of cleaning for good work is by *pickling* or immersion in an acid bath, and the usual pickle is sulphuric acid and water (1 in 20 to 1 in 30). Where sand has to be removed, as with cast iron sometimes, hydrofluoric acid is better as it dissolves the sand (silica) and is not active upon the metal. After pickling, the work must be washed well with water so as to remove any trace of acid. Where the article is greasy, a solution of caustic soda or of caustic potash in water is the best means of removing the grease. It is best applied hot. When rust has to be removed from iron or steel a good mixture to use is made by mixing 1 part of hydrochloric acid and 6 parts of sulphuric acid in 1 gallon of water; then when the rust has been removed another bath made by dissolving 4 oz. of zinc sulphate in 1 gallon of water and by adding 16 oz. of sulphuric acid completes the cleaning process. Corroded brass or copper is best cleaned by dipping it into a mixture containing 3 parts of nitric acid, 6 parts of sulphuric acid, and 8 parts of water. Corroded zinc may be cleaned by dipping into an acid bath with 1 part of sulphuric acid, 2 parts of hydrochloric acid, and 160 parts of water. For dirty lead, tin, and pewter a hot caustic soda solution is best.

Polishing Metals. For work of a high order such as enamelling and plating the mere removal of rust and grease is not enough. It must be polished if the resulting surface is to be excellent. There are many methods of polishing. Sand blasting we have described elsewhere [see page 6314]. It is used chiefly for brass and other soft alloys. Other processes are stone and emery grinding, scratchbrushing, and buffing. The methods adopted depend upon the condition and nature of the work and upon the finish desired. Preliminary processes where the surface is coarse consist of grinding upon an emery or corundum wheel [see page 6314]. For finer work polishing lathes are used. These have circular wire brushes, hair brushes, leather bobs, felt bobs, or cotton bobs revolving at high speed. Wire brushes are usually lubricated with some liquid such as stale beer, the object being to keep the brush from becoming too hot and to prevent it from cutting into the metal. With the other forms of brushes or bobs, polishing powders or polishing compositions are used. The usual best practice is to have the polishing material in the form of a cake and to apply it to the bob simply by holding it in contact as the latter revolves. The materials are composed of rottenstone, pumicestone, emery in various degrees of fineness, crocus, tripoli powder, and rouge. Tripoli is used coarse, for instance, for brasswork and small iron and steel, while if the work is to be plated fine tripoli and crocus are used. Rouge is used for finer work still—for cutlery and jewellery. Any of these compositions and materials can be used with hand polishing brushes and tools, but this practice is laborious and costly, hence seldom used in manufacturing industries.

Bluing Iron and Steel by Heat. Small articles of polished iron or steel may be blued easily by the use of heat. The most convenient method of applying this heat is by the agency of a Bunsen burner, which yields a hot flame but does not smoke. Another common method, especially for flat work, is to heat a flat piece of iron and steel—sufficiently thick to retain its heat for a long time—and to place the small objects upon its hot surface in direct contact or upon a piece of sheet iron interposed between the two. The Bunsen burner, when properly constructed, should burn with a light blue flame, having within it a blue-green flame, the apex of which is the point of most intense heat. The article being heated should be held immediately above this point of greatest heat. Watch the change in colour as the iron or steel article rises in temperature under the heat. Withdraw it from the flame before it quite comes to the desired shade of blue, hold it in the air until the desired tone appears, and at this point throw the article into oil—preferably a heavy oil, such as fish oil or lard oil—where it may be allowed to cool. When the article being treated is of uniform shape, the work is easy; but where the shape is irregular—say, thick at one part and thin at another part—greater care and practice is necessary to secure uniform results. In such a case the heat must be confined to the thicker part for a longer time than is necessary for the small parts. Another method of attaining the same result is to heat sand very hot in a pan, then to immerse the articles in the sand, and to roll them around until the desired shade appears, when the colour is fixed by the oil-bath, as already stated. By all of these methods the iron or steel passes through the following colours—pale straw, dark straw, brown, purple, blue and green, as its heat increases, and it may be arrested at any one of them.

Of the many other recipes recommended for bluing iron and steel, the following may be put on record: A solution of 1 oz. lead acetate and 1 oz. sodium thiosulphate in 50 fluid ounces of water, being used hot, imparts tones from a light brown bronze to black, according to the duration of the soaking, the intermediate tints being purple, blue, light blue, and steel grey.

Lacquering. Metals may be lacquered both to preserve them from atmospheric action and to improve the appearance. The usual transparent lacquer is made by dissolving shellac in methylated spirit and colouring matter such as dragon's blood for red, and gamboge or turmeric for yellow, while a wide range of colours is secured by introducing the aniline dyes. In applying the lacquer the article being treated should be kept warm at a uniform temperature. The work should be done where there is no dust floating about, and the operation should be performed rapidly and smoothly. The lacquers should be kept in stoppered bottles, which are best when of opaque glass. They should be applied with a thin, wide and flat brush. [See Graham's table of lacquers on the following page.]

Enamelling. Enamelling is perhaps the most common of the processes of coating small articles of iron and steel. We refer not to the vitreous enamelling such as is found on the enamelled milk saucepan and the enamelled mug, but to the ordinary enamel paints which are applied either by a brush or by dipping and afterwards hardened in an enamelling stove. Articles enamelled in this way are found in every household—the iron bedstead, the coal-scuttle, the room fender, and many other articles of domestic use. This sort of enamel is merely a fine paint, which is dried and hardened by heat.

COMPOSITION OF LACQUERS.

Number.	Shellac.	Mastic.	Canada balsam.	Spirits of wine.	Pyro-acetic ether.	Spirits of turpentine.	Turpentine varnish.	Simple pale lacquer.	Dragon's blood.	Annotto.	Saunders.	Turmeric.	Gamboge.	Saffron.	Cape Aloes.	Sandarac.

The Enamelling Stove. An enamelling stove is necessary for the work. It is best heated by Bunsen burners. Enamelling stoves may be purchased from makers who specialise in them, but any ironplate worker can make one without difficulty, and if proper precautions be taken, the home-made article is often better than the factory stove. A ventilator at the top permits a current of hot air to circulate through the stove. It is an economical provision to have the walls lined with a non-conducting material, such as fireclay, so as to prevent unnecessary heat radiation, thereby reducing the amount of gas consumed to maintain the proper heat. The sides should be fitted with angle iron bars upon which bars or shelves may rest to support the work. The door should be made the whole width of the front, thus permitting easy ingress and egress of the articles before and after enamelling. It should also have fixed to its inner side a thermometer registering up to not less than 400° F., and capable of being inspected from the outside. The usual device is to have an oblong panel cut from the door in front of the thermometer and fitted with a sliding or swinging cover which can be removed when it is desired to read the temperature. The gas supply should be in excess of requirements so that the proper heat can always be secured. The heat is regulated by raising or lowering the gas jets or by lighting or extinguishing one of the Bunsen tubes.

For many purposes—a cycle frame, for instance, or a fine cast-iron stove—a fine polish is essential. The finer the polish the finer is the resulting coat of enamel. The polish is obtained first by grinding on a grindstone, or an emery wheel if the work be rough. For work that is not rough originally, polishing with a fine emery bob and then with a leather and cloth bob is sufficient. Some work is "sweated" before having the coating of enamel applied—that is, rubbed with a cloth wrung out of spirits of tar and placed in the stove at full heat of, say, 300° F. to 400° F. for a quarter of an hour

The Coats of Enamel. Some articles may have only one coat of enamel, in which case the finishing enamel is that applied, but in most cases a first coating precedes the finishing coat. The article is either painted with the enamel by means of a brush, or dipped into a bath or trough containing enamel. If the brush be used, it must be of good quality so as to lessen the likelihood of hairs adhering to the surface. A hair cannot be removed after the enamel has been hardened without leaving a blemish. The size and shape of the trough, if dipping be practised, must be decided by the shape of the articles, but a trough is used only where enamelling is on a large scale.

The enamels are purchased from firms making a speciality of their preparation. The enameller need not think of making them for himself. The work having received its first coating, is placed in the stove, and is given the necessary heat for a period depending on the colour and quality of the enamel. For black enamel the heat is usually from 300° F. to 350° F., and for coloured enamels about 125° to 150°. Care should be taken not to give the full heat at once. The time required at this heat is usually between one and two hours, and must be decided by experience. Keeping the work in the full heat for too long a time makes the enamel easily chipped besides consuming unnecessary gas. When the gas is turned off the enamel is hot, but wet. When it has dried the article is polished with a paste made of pumicestone in an impalpable powder or crocus and water. All roughness should be carefully removed in this polishing.

The finishing coat—not of the enamel formerly used, but of "finishing enamel"—is then given. It must be applied in a thin coat or the finished appearance will be blotchy and shrivelled. The work is again put into the stove and the full heat maintained until it is slightly "tacky" or "gummy" when touched. Then turn out the gas and allow the article to cool. The article is enamelled. If a still higher degree of finish be desired, this second coat may be rubbed smooth with the paste as before, and a third coat—another of the second or finishing coat—applied, but this is seldom done.

The enamels should always be kept corked when not in use, so as to prevent dust or other extraneous matter getting into them. As much work as possible should be put into the stove at each heating, thereby diminishing the cost of gas upon each article.

Vitreous Enamelling. The process of applying a coating of vitreous enamel to articles of metal has during the last few decades spread from the field of ornament into that of utility, and an enormous industry, which flourishes especially in Germany and Austria, has grown into being. Street signs, and culinary and domestic utensils are the articles to which vitreous enamel is most frequently applied. In Continental Europe cast-iron work, such as coal stoves, is treated to this variety of enamelling, but in this country its use in this direction is limited.

Enamel is merely a coating of a glass applied with an ingredient such as tin oxide or bone ash to render the glass opaque. Into coloured enamels other ingredients are introduced, in accordance with the colour desired. White is by far the most common variety of enamel used for coating articles of metal, and blue comes second in importance. In America, however, mottled or "granite" ware is more common than white. A knowledge of the properties and composition of glass is essential to the manufacturer of enamels, and reference may be made to the article on glass manufacture [page 4531].

A *flux* is necessary to cause the enamel to adhere to the surface of the metal. Borax is the flux at once the most easy to work and that most generally employed. Other fluxes are fluorspar, broken glass or *cullet*, gypsum, clay, and broken porcelain. These fluxes are used alone or in various combinations according to the class of work under treatment.

To introduce colour into enamel many metallic oxides are used. The chief pigments in general use are as follows:

To give blue—Cobalt oxide and cobalt silicate.
,, black—Ferrous oxide.
,, brown—Ferric oxide.
,, green—Ferrous oxide (in small quantities), cupric oxide or chromic oxide.
,, red—Ferric aluminate, tin-gold chloride, sodium-gold chloride or purple of Cassius.
,, yellow—Oxides of silver, iron, uranium, and antimony or antimonate of potassium or lead.
,, violet—Oxide of manganese.

Lead in Enamels. Lead ought to be absent from enamel applied to any vessel intended to contain food. On account of the affinity of lead for silica a lead enamel is an easy one to manipulate, and makers of cheap enamel ware use it extensively. But it cannot be too strongly urged that its use is dangerous. The presence of lead in the enamel of an article may be detected by several simple methods. If weak vinegar be boiled in an enamelled vessel, and if as a result the surface of the enamel becomes dull and rough, lead is present. This test will also throw lead into solution in the vinegar. Another test is to beat up an egg in an enamelled vessel, and allow it to stand for twenty-four hours. The sulphuretted hydrogen in the egg will darken the lead oxide and cause the enamel to show a stain. For most pieces of chemical apparatus also an enamel containing oxide of lead is bad, as the lead may enter into chemical combination and vitiate or modify the results attained. There are many recipes for leadless enamels. Mr. Paul Randau vouches for one as being in use in some large Austrian enamel works, and we give the formula:

Silica	30 to 50 parts
Flint	10 ,, 20 ,,
Kaolin	10 ,, 20 ,,
Pipeclay	8 ,, 16 ,,
Chalk	6 ,, 10 ,,
Ground porcelain	5 ,, 15 ,,
Boric acid	20 ,, 40 ,,
Saltpetre	6 ,, 10 ,,
Gypsum	2 ,, 5 ,,

Enamel adheres better to charcoal iron than to coke iron, and in cast iron to "wh te iron" rather than to "grey iron." White iron, however, is rather hard and brittle for most purposes to which enamelled iron is put, hence a mixture of white and grey pigs are generally used in cast iron that has to be enamelled.

Preparation for Enamelling. To prepare iron and steel for the coating of enamel, they must be pickled in diluted acid, a process which has been described in some detail in our descriptions of galvanising and tinning [see pages 6164 and 6169]. If greasy, treatment with caustic soda removes the grease. The articles are then scoured with clean, sharp sand until quite bright. Many mechanical devices are adopted to secure economy of work and big output in large works, but we shall not stay to consider these devices here. A common one is a sand blast apparatus. After scouring, the work is dipped into boiling water, drying immediately after withdrawal, when it is ready for the enamel coating.

The under coat is then applied. The enamel is usually kept moist, and is therefore like clinging sand. Before application, it is reduced with water to the consistency of cream. The workman ladles into the vessel, the interior of which is to be enamelled, as much of this enamel cream as experience teaches him will suffice for the work, and by means of a stiff brush he spreads it over the surface to be coated. Any excess is allowed to drip off, but practice enables the workman to dispense with the necessity of draining. The work coated with this enamel is then taken into the drying-room, preferably heated by steam pipes, and after remaining there about one hour, the article is dry and ready for fi ing, for which purpose it is taken to the muffle furnace.

The muffle furnace is of the ordinary type, and must be of a capacity to suit the work. But workshop economy demands that it should be made quite full every time it is heated, hence there is danger of expense in having the furnace too large. It is better to increase the number rather than to increase the size of the furnaces; but there must always be one large enough to accommodate the largest piece of work likely to be treated. The fuel for the furnace may be that most convenient to the district. Gas may be chosen with advantage, if it be available, as it allows the temperature to be regulated perfectly.

Firing the Enamel. The object of the muffle forms of furnace is, of course, that the contents may come under the full heat given off, but may yet be secure from the dust and smoke that would surround them if there were no muffle. It is usual to have the greatest heat at the back of the muffle, so that the articles are not subject to the extreme heat immediately after insertion. The work is put into the muffle when the front of the latter is at a dull red heat, and the back portion at a bright red heat. The pieces of work are moved about by the workman into the hotter or cooler portions as they seem to require it. One expert man can attend to a round dozen of muffles, filled with work. From twenty minutes to half an hour ought to suffice for this firing. After that time, the enamel will have fused over and on to the metal. It will still have the powdery effect which it had when it entered the furnace, but the powder can no longer be rubbed off with the finger, and close examination will show that the adhering particles have lost their sharp edges. If the powder does not adhere well in the manner indicated, the enamel composition is too refractory, and must have some borax stirred into it. If, on the other hand, it be very smooth on its surface, it is too fusible, and the enamel mass must have some clay or flint added to it to make it more refractory.

The Final Coat. The covering coat is applied after the article has been withdrawn. If there be any exposed iron which was not intended to be enamelled, and was therefore not coated with enamel composition in the first instance, the firing will have made it black. This black, which is black oxide of iron, must be removed with wire brushes. The finishing layer of enamel is now applied in the same manner as the first was. The thinner it can be made, consistent with efficient covering, the higher will be the finish and the greater the durability of the finished article. The temperature of the muffle furnace for the finishing coat is kept a little lower than it was for the first layer, as the composition is more easily fusible. Also the articles are moved about in the muffle,

and turned more frequently, so as to secure uniformity in the process of fusion. When it is considered that they have had enough of the fire, they are removed, but ought to be allowed to cool gradually, otherwise the enamel may crack in the cooling. There is frequently a separate muffle at a dull red heat, into which the articles are placed and allowed to cool slowly. The enamelling is now complete.

Cheap enamel ware is frequently made with only one coating of enamel, but good work that will stand the test of use, especially if it be for articles for cooking, demand two coats. The first, or ground coating, should be somewhat porous, and the upper or covering layer forms the impenetrable glaze.

Decorating Enamel Ware. The common method of decorating enamel ware is by means of transfers as used for pottery ware. The ink with which these transfers are printed must be made of fusible oxides. To fix a transfer to an enamel surface is not difficult. It is applied, the back of the transfer is damped with a sponge, and the article is fired, so as to fix the ornamentation. Hand decoration is also practised, and is the common method when bands are being put on the outside of vessels, but for elaborate work its cost is prohibitive. Mottled or *granite* enamel ware is made by spraying upon a coating of white or yellow enamel a covering, or rather a partial covering, of coloured enamel. It is then fired in the usual way, and if a good surface be desired, it is treated with a final transparent enamel glaze.

Colouring Metals. The numerous processes for bronzing metals may be divided into three classes, depending for their action upon chemical change, electro-chemical change, and mechanical application. The first and the second might properly be classed as one, but electric deposition is such an important and such a distinct process, that it may well be elevated into a class apart.

All metal articles may be treated to an application of bronze powder, caused to adhere to the surface of the metal by a special varnish. Bronze powders are made in dozens—indeed, hundreds—of shades, and their manufacture is a huge industry in Austria, which supplies the greater part of the world with them. The so-called *bronze* powder is simply metallic brass, copper, aluminium, or other metal or alloy in a very fine state of subdivision. The particular depth of shade is usually obtained by oxidising more or less the metal in the manufacture of bronze, but with this, the man who applies the powder has no direct concern. [See also page 6310.]

The article to be bronzed is usually coated with a special varnish. This varnish, or *size*, had better be purchased from varnish manufacturers, but a good recipe for its manufacture is as follows: Boil linseed oil for two hours, and add to it gradually, when boiling, 5 per cent. of its weight of red litharge, followed by 5 per cent. of white litharge. If the first addition of red lead cause the formation of a red scum, the oil is at too high a temperature, and the further addition of red lead must be delayed until the oil has cooled somewhat. The mixture is kept for about a week, and is then ready for use.

The iron or other article to be bronze-coated is given a coat with the varnish or size, and when this varnish has become almost dry, or, as it is called, *tacky*, the bronze powder is applied, usually with a brush. Then, when the varnish has quite dried, the surplus powder is brushed off and the article is bronzed. It may be coated with varnish again, and will, after this precaution, resist atmospheric action and retain its freshness much longer than it otherwise would. It must not be forgotten, however, that any varnish applied after the bronze powder diminishes the metallic brightness, so that the manipulator must choose between brilliance and durability.

An expeditious, economical, and satisfactory method of applying bronze powder is by mixing it up like ordinary paint, with the varnish as a base, and by painting it on the surface to be decorated. Two coats are desirable, and, of course, these may be thinner than a one-coat application. Turpentine is the medium used to thin the varnish. The hardness and durability of the bronze coating is much increased if the article be dried in a japanning stove. The temperature should not be high—not more than 200° or 250°—and half an hour is about long enough time to allow.

Bronzing Brass by Immersion. There are many simple immersion baths used to bronze metals, and the tone resulting depends upon the duration of the immersion. Brass may be coloured any shade from brown to black by a bath made by dissolving 2½ oz. of nitrate or perchloride of iron in 1 gal. of water. Any shade from brown to red may be secured by immersion in a solution containing ½ lb. nitrate of iron and hyposulphite of soda in 1 gal. of water. Yellow to red demands a bath where ¼ oz. tersulphide of arsenic, and 3 oz. of pearlash solution have been dissolved in 1 gal. of water. Potassium sulphide added to water (½ oz. to 1 gal.) gives orange bronze; a mixture of perchloride of iron and water (1 gal. to 2 gal.) gives an olive green, while sulphocyanide of potassium (20 oz.) and water (1 gal.) gives a blue.

Bronzing Copper by Immersion. Bronzing copper baths, used simply by immersing the copper articles in the solutions, are as follows, the chemicals mentioned being dissolved in 1 gal. of water:

Brown to black, 2½ oz. nitrate of iron.

Dark drab, 2½ oz. nitrate of iron and 1 oz. sulphocyanide of potassium.

Bright red, 1 oz. sulphide of antimony and ½ lb. pearlash.

Red to black, ½ oz. sulphur and 1 lb. pearlash.

Steel grey, ½ oz. chloride of arsenic (must be applied at 180° F.).

Japanese Lacquer. Japanese lacquer is valuable as a metal coating, and when once the secret of its manufacture has been given to the Western world, its use will extend. But at present its precise method of preparation is held as a jealous secret. It is known to be made from the secretion of a tree, the *Rhus vermicifera*, called by the Japanese the *urushi-naki*, which grows to a height of about 30 ft. when it attains its full yielding capacity. The lac is collected by making horizontal incisions in the tree. The issuing lac is milky white and thick, but on exposure becomes first dark brown, and finally black. The lac is purified by being strained through cotton-wool, then by rubbing it on a paint slab and mixing it well with water, which is finally evaporated by heat. The further treatment in preparing the famous Japanese lac varnishes is not known outside of Japan. White and pure light colours cannot be obtained in these Japanese lacquer varnishes. The usual colours are brilliant black, impure vermilion, impure dark green, and dark grey. Drying is done in twenty-four hours in a moist atmosphere, and if the articles to be dried are placed in enclosed rooms, the walls and floors must be wetted down periodically, so as to provide the moist atmosphere. Fine lacquer work requires 18 coats; it improves in colour with age. If Japanese lacquer

were used only for bric-a-brac and woodwork, we would not give its description space in this article, but it has a much wider use than that held by general opinion. It is widely used for metal coating—the Japanese use it for acid tanks, for ship's coating, for coach and decorative panels, and for domestic articles, which it enables to resist hot water, soap, and alkaline solutions. It never splits or cracks, and has great durability. Applied to the hulls of ships, Japanese lacquer forms a coat both anti-corrosive and anti-fouling. The coats applied to hulls vary in composition, the first being almost pure lacquer, and the succeeding coats containing proportions of mica or kaolin to increase the covering power. When first used as a ship's paint, anti-fouling paints were applied over the lacquers, and this method was a failure, the urustric acid in the lacquer attacking the metallic base of the anti-fouling paint, the result being that the virtues of both were destroyed. Later, it was found that the lacquer alone is an admirable anti-fouling paint, as well as an anti-corrosive protection.

The Bower-Barff Process. The Bower-Barff process of coating iron and steel is old, the two inventors from whom the process derives its name having registered their patents over twenty-five years ago. But the process did not obtain prominence or commercial success, on account of certain inherent difficulties which gave bad results. It remained for followers of the original inventors to carry the process some way nearer perfection, so that the modification of the original process now followed by those who practice *barffing*, as it is usually termed, may be said to be both a practical and a commercial success.

The root principle of the barffing process lies in this—that when iron or steel is made red-hot, and steam is brought into contact with it, the surface undergoes a chemical change and becomes black oxide, or, as it is more properly called, magnetic oxide of iron. We need not waste space in describing the plant used by Bower and by Barff respectively in achieving their objects. Our time will be better occupied in paying attention to the modern improvements upon the original methods adopted.

No other metals but iron and steel can be subjected to barffing with successful results, hence its use is somewhat restricted. But the process is less expensive than galvanising, and, if carried out as it now can be carried out, the surface given to the metal is even more resistant to corroding influences in exposed situations. The finish is a dark slate or dead black—the natural colour of black oxide, and the depth deepens upon the length of time to which the articles are subjected to the process. The bad results in early attempts were that the magnetic oxide surface given to the iron or steel was very hard and brittle, being liable to scale. This difficulty has now been almost entirely obviated. Certainly, articles barffed to-day do not give evidence of peeling in the manner and to the extent that formerly prevailed.

The present-day practice usually followed is the Gesner modification of the original. This consists in heating the work in a closed retort, and injecting steam for some time. The steam is shut off, and a small quantity of naphtha is admitted, after which steam is again injected. Finally, the work is allowed to cool naturally, and is then finished.

The Barffing Furnace. The furnace used is much like a coal-gas furnace, consisting of one or more clay retorts, which may be made to open at one or both ends. The fuel used is immaterial, as the work is isolated from the fumes, and local convenience decides the point. Steam is led from a boiler into the retort by a suitable pipe. The steam need not be under pressure, and an ordinary house boiler is quite suitable for its generation. The steam-pipe is led along the bottom of the retort, protruded from the end opposite to that by which it entered, is returned, and its end led into the retort again. The object of thus causing the steam-pipe to travel the whole length of the retort before the steam is allowed to escape is that the steam is superheated before coming into contact with the work. This is an essential feature of Gesner's method. Another essential feature is the use of a hydrocarbon, such as naphtha, with the steam. The theory of the inventor of this process, and his claim to success, rest in the fact that the steam, passing through the red-hot pipe in the bottom of the furnace, is partially reduced, that hydrogen and oxygen are set free, and that these, acting in conjunction with the steam, give a coating of magnetic oxide containing oxygen. Such a coating is, by experience, found less liable to scale than one devoid of hydrogen. Analytical tests made have shown that the magnetic oxide coating contains about 1 per cent. of hydrogen. The door of the retort is made reasonably tight to prevent the escape of steam, and clay is plastered around it with this object. An exhaust pipe is led from the top of the furnace into a water-seal, which gives a low pressure in the retort. About 1½ in. of water is usually all that is given. The arrangement of the furnace is calculated to give as nearly as possible a uniform heat in the retort.

The articles to be barffed must be free from scale and dirt. The better and smoother the finish before barffing, the better is the resultant coat of black oxide. The castings or other articles under treatment may, if greasy, be treated with caustic soda; but if free from grease, this is unnecessary. To remove scale or dirt, they may be pickled or sand-blasted. The latter treatment is the better.

Operating the Process. The retorts in which the work has been placed are heated to from 1,000° F. to 1,200° F., and the steam admitted for about 30 minutes, and then about a pint of naphtha is allowed to enter through a pipe for that purpose. Then steam is allowed to enter alone for about another 30 minutes, and is finally shut off. When the retort has cooled to about 800° F. the articles are removed, and, to prevent marks or imperfections on the surface, they are put into paraffin or other heavy oil while still hot. They are taken out afterwards, the oil is removed by immersing the articles in benzene, and a coating of flat lacquer or wax or both is given. A little polishing follows upon a rotary bristle brush. For coarse work, such as cast-iron furnace pans, for which barffing is largely used, many of the refinements enumerated above are not practised as this would raise the cost where cheapness is of more importance than elegance; but for light hardware the process usually employed is that we have described.

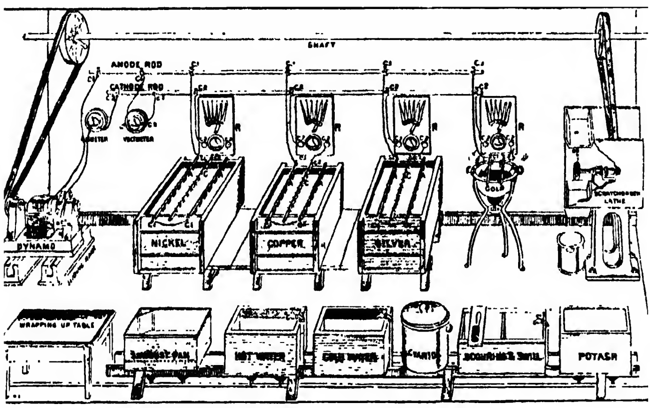
The cost of the process for large work such as furnace pans may be as low as from 4s. to 5s. a hundredweight, but for lighter and smaller articles it is much higher, and may be as much as 20s. a hundredweight. The expense in small articles is because every article placed in the retort must be deposited so that every part of its surface may be subject to the action of the steam.

The original process of barffing increased the size of the work, and as the work could not be machined afterwards without destroying the surface produced, provision had to be made in initial preparation.

The formation of hydrogen during the modified process we have described seems, however, to prevent this enlargement, and machined work—screws, nuts, valves, and other articles—may now be made to finished sizes and barffed without fear that the process will disturb the fitting.

Electroplating. The principles and the practice of electroplating are treated in the course on ELECTRICITY [page 3421], and it is assumed that the reader has made himself familiar with the instruction given there. Space may be spared here for some practical information upon the equipments required for various classes of work and for different volumes of output.

The most common form of electroplating is a deposition of a deposit of nickel upon steel or iron, and in many plating shops, particularly in the cycle trade, no other work is undertaken. We may therefore consider such a shop. A plating plant, capable of treating up to 30 sets of cycle fittings per week, would include a dynamo (6 volts, 100 amperes) driven at 1,200 revolutions, and requiring 1½-horse power; a nickel vat, 4 ft. by 2 ft. by 2 ft. deep; a copper vat 30 in. by 18 in. by 18 in. deep; and a polishing lathe. It is never wise to purchase a plant that will overtake only the amount of work available at the moment, as in the event of increase of work the plant will not be able to rise to the work. It is considered well that the capacity of the plant should be 30 to 50 per cent. higher than there is immediate occasion for. The size of the vats and the quantity of solution depends upon the quantity and size of the articles to be plated. Every square foot of surface of work being plated requires 10 amperes of current, and this forms the guide in determining the size of the dynamo necessary. The dynamo should be fixed in a convenient position as close to the vats as possible. The grinding and polishing should never be done in the same shop or room as the plating.



ARRANGEMENT OF PLATING SHOP

The Plating Plant. A complete plating plant, as arranged by Messrs. Canning, of Birmingham, is illustrated herewith. The plating vat must be lined with chemically pure lead with burnt joints. The nickel anodes should be pure cast nickel plates, having an aggregate surface at least equal to the surface of the work, and if rolled nickel plates be used at all they should not be more than one to four cast anode plates. The nickel solution is made by dissolving sulphate of nickel in water. The trade in this country usually employ Canning's special nickel salts—a double sulphate of nickel and ammonium—dissolving one pound by weight in one gallon of clean boiling water in a vessel of wood, earthenware, or enamelled iron. The solution as it becomes impoverished is brought to strength again by the addition of more nickel salts. It must be kept neutral, and if through use it becomes acid, ammonia is added in small quantities to bring it to neutrality. The anodes are suspended in the tank from brass rods as seen in the illustration, and the articles to be plated are also suspended from suitable hooks or baskets. The best practice is to have anodes at each side of the work so that with three rods the centre one carries the work and the other two the anodes, and if five rods are used the centre and the side rods carry anodes. A recent improvement in electroplating plant has been introduced by Messrs. Canning and widely adopted. By mechanical agitation of the electrolyte the current density is increased, and the time taken to form the electro deposit is reduced by as much as one half. The direct result of the introduction of mechanical agitation is to double the capacity of any plant.

Electro-brassing and Electro-coppering. The same process as for nickel plating is used in depositing any other metal, but the anodes used must be of the metal it is desired to deposit. Thus, anodes of gold, platinum, silver, brass, copper, tin, or zinc are used as required. We may take as typical electro-brassing, as after nickel plating it is the most generally practised. The electrolyte used may vary in composition, but the following is good (Canning):

Pure cyanide of potassium	1 lb.
Carbonate of copper ..	8 oz.
Carbonate of soda	3 oz.
Bisulphate of soda.. ..	1 oz.
Water	1 gal.

In making, dissolve the cyanide of potassium in three quarts of hot water, and add the carbonate of copper. In a separate vessel dissolve the carbonate of soda and the bisulphide of soda in one quart of hot water. Mix the two solutions when cold and stir well. The electrolyte may be used either hot or cold; if the latter, the temperature should be 120° to 140° F.

Before immersion the work must have been thoroughly cleaned in hot cleaning solution (hydrochloric and sulphuric acid in 10 parts of water) and swilled, then scoured with powdered pumice-stone and again swilled. The full details for depositing other metals cannot be given in this article. There are several good textbooks to guide the novice; the "Handbook on Electroplating," published by Canning & Co., of Birmingham, may be recommended.

Finishing Plate Articles. When a nickel-plated article leaves the electrolyte it has a dull-white appearance. It must be finished. It is first rinsed in hot water and then dried. Then it goes to the finisher, who, with the aid of mops made of felt, calico or swansdown, usually mounted on a polishing lathe, polishes the work, the final touches being given with a soft clean mop. The first mop is usually charged with dry Sheffield lime or with tripoli powder.

CABINET-MAKING

Veneering. Inlaying. Furniture Construction. Table Tops. Carcases. Fitting of Shelves, Backs, and Tops. Framed Work. Staining and Polishing

By W. J. HORNER

NO sharp distinction can be drawn between cabinet-making and joinery any more than between carpentry and joinery, though in each case it is easy to give specific instances of work that is within the exclusive province of one or the other Joinery occupies an intermediate position, and is overlapped at one extreme by the rough and heavy work of carpentry, and at the other by the fine and neat work of cabinet-making. Such work as plain furniture, and shop, bank, and office fittings may be done either by cabinet-makers or joiners, the choice depending chiefly on the degree of finish required. With the exception of plain deal articles the construction of furniture is regarded as cabinet work. With a few exceptions the tools employed and the methods of jointing have been described in the courses on Carpentry and Joinery.

Woods Employed. In cabinet-making, hard wood is chiefly used, and the soft varieties, in which the bulk of carpenters' and joiners' work is done are generally used only under veneer and frequently not even then. A great number of fancy woods are used, but for large articles the list is very much reduced owing to the unsuitability or cost of many of the rarer woods. Mahogany is the most commonly employed and is one of the best for furniture, owing to its small liability to shrink and warp. For many years after it came into general use it was to the cabinet-maker what oak was to the carpenter, and what deal is to the latter craftsman at the present time. There are two main varieties, the Spanish, which is valued for its rich appearance and hardness, and the Honduras, or baywood, which is softer, straighter grained, lighter in colour, and cheaper. The chief other woods used are oak, walnut, ash, and birch. The important woods have been described in the first article of the course on MATERIALS AND STRUCTURES, beginning on page 51. Soft woods, such as pine and American whitewood, are used a great deal for parts that do not show, such as backs of carcases and drawers, drawer bottoms, runners, and sides. They are used also covered with veneer, or in some cases—drawer bearers, for instance—may have a hard wood facing about ½ in. thick, glued on the front. All wood in cabinet work must be thoroughly seasoned. Artificial drying in kilns is usually resorted to. There are many varieties of these.

Furniture Designing. This is not done by the journeyman cabinet-maker, but by specialists, who make the drawings for him to work from. These drawings are usually not very elaborate compared with the drawings required in some other trades, for exact dimensions are unimportant, and many details of construction can safely be left to the judgment of the workman or his foreman. A single perspective view of an article with its leading dimensions is therefore often sufficient for a cabinet-maker to work from, and in some cases no drawing at all is made. Drawing is supplemented a great deal by written instructions. The designer must be familiar with methods of construction, or he will cause needless trouble and expense with perhaps weak and unsatisfactory results. Apart from this, he is chiefly concerned in designing goods that will best command a sale. So much variety has gone before that new designs now are new combinations of features of old designs. It might be quite possible to design something absolutely new, but the demands of utility and good appearance would almost certainly condemn it. The first essential in any article of furniture should be a design which makes it convenient for use. All ornamentation and considerations of appearance should be subsidiary.

The Value of Appearance. In cabinet work appearance has to be considered more than in other woodworking trades, and though utility should never be subordinated to it, it makes a difference between the work of the cabinet-maker and that of the joiner and carpenter. Good work is desirable throughout in an article of furniture, but only parts that are constantly visible are finished neatly, while backs and under parts are left rough. Another thing peculiar to cabinet work is that strength is in most cases of less importance than appearance. Furniture is not supposed to be subject to rougher usage than when serving its normal purpose, and the cabinet-maker constructs it on that assumption. In the jointing of light framework, for instance, stub tenons or dowels secured by glue alone are typically cabinet work. In many articles, however, the appearance of strength is desirable, and thus we have pilasters formed by gluing thickening pieces against thin sides, and the lining-up of horizontal pieces, and addition of solid-looking plinths and cornices. In some cases the purpose of an article permits of great latitude in fixing dimensions, and then proportions are adopted which look well. Thus an article of rectangular shape is not made more than twice as long, or high, as it is wide.

Changing Fashions. The design of furniture is subject to slow changes of fashion. As with dress, and other things, the style of which changes without necessarily improving, this is caused by a desire for distinction among wealthy people and desire among poorer ones to imitate them, a new fashion being adopted by the former as soon as the reigning one has become common property. Besides this, public taste varies at different periods, and the style of furniture varies correspondingly. It is possible, however, that the changes of the future will be slight compared with those of the past, because extremes in all directions have been reached and recognised as unsatisfactory. The best furniture is made primarily to serve its purpose perfectly, and secondly, to please the eye. The highly ornamental and the severely plain, alike, generally fail in both these directions.

A complaint frequently made is that furniture is less substantially made than formerly. The assertion is less true now than it was some years ago, but the time has gone past when quality and methods did not vary much from a set standard. If the best work now is not superior to any that has ever been done before, it is because better work is impossible. No one can dispute that a great deal of modern work is trashy, but as such work does not last we have no

means of knowing whether the workmen of a century or more ago were equally skilful in that direction. Probably they were not. The rank and file, no doubt, were ignorant, simple-minded men in a position to take as much time as they pleased to do anything. They had a high opinion of their manual skill, and exaggerated notions of the importance of trade secrets, in many cases not to be imparted freely to each other, and still le s to the outside public. Modern conditions are different. Work is done now much more expeditiously and consequently at comparatively far lower prices. In many cases the cost of labour is a trifle compared with the cost of material. This is not because wages are low or because manual work is done more rapidly than formerly. It is because the workman now is assisted by machines which perform all the operations that before occupied most of his time. The subdivision of labour now prevailing also conduces to rapidity of production.

Old and Modern Work Compared. Neither machine work nor subdivision of labour means inferior work, but rather the contrary. In some respects the best of the very old work was rough compared with the best modern work, and its roughness was not compensated for by its being any stronger than what is made now. We have only to notice the construction of old furniture preserved in museums to perceive that. Articles elaborately carved and inlaid are often jointed more roughly than would be permissible now. The use of wood pegs in tenoned joints, with the end grain of the pegs showing in the front faces of the work, and generally projecting about a sixteenth of an inch through shrinkage, would be intolerable in the cheapest modern articles. Old work suffered also through being done by men who were not specialists. There are few men who can do both heavy and light work with equal accuracy, and no one man can be as skilful at half a dozen classes of work as the same number of specialists assisted by machinery can be.

The Element of Time. If it be untrue to pretend that our best is not equal to the best that has gone before, it is still more untrue to suppose that our men are not equal to their predecessors. Only those whose admiration for the past is based on unreasoning sentiment can believe so. So far as we can judge of them, there is no reason to doubt we not only have their equals, but have far greater numbers of them. But in most work nowadays the element of time has attained an importance it never had before. Most classes of work are so often repeated that the time they should occupy is known or can be estimated almost to an hour, and it is to the workman's discredit if he exceeds this almost as much as scamped work is to his discredit. The test of a first-class workman is to do work of the best quality in the minimum time. If an unlimited amount of time is allowed, a far less skilful man can equal the product in quality. A first-class workman, however, has not always the opportunity to do the best work. Quantity instead of quality may be required of him. There is a large demand for cheap articles, the cost of which is cut down by employing inferior material and quicker methods of construction. Their unsubstantial character does not indicate that they were made by incapable workmen, but that their cost was not allowed to exceed a certain amount. Work of this kind is justifiable because it supplies a demand, but in the case of the cheapest work it may be doubted whether the demand would be very great if the average purchaser was capable of seeing its defective character.

Modern Subdivision of Trade. Cabinet-making, even more than most trades which have attained a high degree of development, is very much subdivided. It has first of all two natural divisions, for there is a decided difference between carcase work, such as wardrobes, chests of drawers, etc, which are boxed in, and open framework, such as that of chairs. Chairs are so different to ordinary cabinet-maker's work that people employed in their construction are known as chairmakers, and not as cabinet-makers. Chairs differ so much from each other, however, that the chair-making industry is itself very much subdivided. But even among articles of furniture which do bear considerable resemblance to each other, it is found more economical for firms to confine themselves chiefly to one, and portions of that are often purchased ready made. In no case is all the work on one article done by one person. All turned parts are done by a wood-turner. Carving is done by a carver or by machinery. Veneering and inlaying are done by specialists. Polishing and upholstering are done by men of those trades. Among the operations just mentioned the only ones that can be considered as branches of cabinet-making are veneering and inlaying.

Veneers. These are thin sheets of fancy wood ranging in thickness from that of a thin sheet of paper to ¼ in. They are used a great deal in cabinet work, and to a less extent in joinery, for gluing to the surface of cheaper wood to improve the appearance of an article. In some cases also curved parts are built up entirely of veneer by gluing a number of thicknesses together. *Ply wood*, which is now largely used for panels and drawer bottoms, is built up in the same way with the grain of the layers crossed. These, however, are not veneer in the ordinary sense, but plain cheap wood sawn thin. The most expensive furniture woods, and especially pieces of exceptionally handsome appearance, are seldom used for anything else but veneer, for it would be considered a waste of valuable material to use it in any other way unless for articles so small that the amount of material used in them is not worth considering.

Veneer is cut by special machinery, and comes into the cabinet-maker's hands ready for use. It is known either as *knife cut* or *saw cut*, according to the method of cutting it to thickness. By the knife-cut process it can be cut very thin, and there is, of course, no waste in sawdust. From 30 to 40 thicknesses may thus be obtained from 1 in. By sawing, about one-third that number is the most possible, but sawn veneer is thicker and for most purposes, better, though more troublesome to glue. Saw-cut veneer as used for most purposes is about $\frac{1}{16}$ in. thick. Very thin knife-cut is sometimes backed with paper. This prevents it from splitting and warping. Warped veneer may be flattened by damping and putting under pressure between warm, dry boards. Knife-cut veneer may be either sliced or rotary-cut in a kind of lathe. The log is steamed or boiled before cutting, and the cutting machinery is very heavy and rigid, so that a sheet of tissue paper thickness can be cut if desired.

Veneering. The methods of gluing veneer differ in some respects from those of making ordinary glue joints. This is owing to the thinness of the veneer and the large surface to be glued. There are two methods; one by means of *cauls*, which practically means cramping the parts till the glue is set. The other by the use of the *veneering hammer*, which means squeegeeing surplus glue out by sliding pressure on the veneer, and the latter in such cases is always so thin that it remains

Method of cutting grooves for shelves 31. Case or pedestal with drawer runners 32. Fitting of runners 33. Another method of fitting runners

in contact without further treatment. This latter, however, is considered only a makeshift method, to be employed when cauling is inconvenient.

The wood on which veneer is to be laid must itself be carefully chosen. A hard close-grained wood does not adhere well to a soft one. Soft woods, such as pine and American whitewood, are very commonly used beneath veneer, but in the best work Honduras mahogany would be employed as a groundwork. Knots should be cut out and pieces of ordinary wood fitted and glued in their place. Small holes should be filled with plaster of Paris. The surface, after being planed, is roughed with a *toothing* plane and sized with thin glue. A toothing plane iron is shown in **1**. It fits nearly vertically into a plane body resembling an ordinary smoothing plane. The serrated edge of the iron scratches the wood and leaves a surface on which the veneer is not liable to slip and the glue obtains a good hold. Two toothing irons of different degrees of coarseness should be kept, as a finer iron is needed for hard wood than for soft. Another method sometimes adopted is to go over the surface with coarse glasspaper on a flat rubber. The veneer is toothed also when sufficiently thick. Rounding surfaces are rasped and roughened with coarse glasspaper. Where a piece of board is cut tangentially to the annular rings of the tree and only one side of it has to be veneered, the veneer should be laid on the heart side, as in **2**.

Veneering with the Hammer. The veneering hammer is used as in **3** and **4**, to press out surplus glue. The hammer has a handle about 1 ft. long and a head about 6 in. square by 1¼ in. thick, with a piece of thin iron inserted in a saw-cut in its lower edge and secured by screws. The edge of the iron, which is used to press the veneer, is rounded slightly and made smooth so as not to injure the surface. In addition to this, soap is often used to enable the hammer to work freely without sticking. Hot water is also sparingly applied to the upper surface of the veneer, chiefly to counteract the tendency to curl when it is wetted by the glue on the other side. The glue is spread as rapidly as possible on both the ground and the veneer; the veneer is laid on the ground and pressed down, and then the hammer with heavy pressure on its head is worked about the surface to force as much glue as possible from the centre out to the edges. The easiest way to move the hammer when pressing on it is to work the handle from side to side while moving it forwards or back, thus giving the head a zigzag movement over the veneer. The veneer, as a rule, will remain in close contact after the hammer has been passed over it, but sometimes blisters may be seen or detected by tapping. In such cases the glue beneath may be remelted if necessary by the application of heat, which soon penetrates the veneer. A hot flat iron is generally kept ready for this purpose, and a damp cloth first laid on the place where it is to be applied. The blister will then generally remain down or if it is obstinate a weight may be put on it for several minutes. A bowl of hot water is placed on the bench when the veneer is to be laid, and the hammer, when not in use, is put in the water to keep its edge free from hardened glue. A sponge and one or two pieces of cloth are kept in the water, too. The gluing must be done in a warm atmosphere free from draughts, and the glue applied as hot as possible, so that the veneer may be properly laid while the glue is still quite liquid. Veneer can be removed if necessary by the application of heat and oil or water to loosen the hold of the glue, but it is never worth while to do this, as the veneer would be practically spoilt in the process. Bad places in veneer are better rectified by cutting them out and fitting other pieces in. A piece with grain as nearly like it as possible should be laid on top, and an irregular cut made through both, following the grain as much as possible to make the joint unnoticeable. An inlaid piece cut geometrically square or circular is much more conspicuous. Air can be released from a blister if necessary by making a small puncture. If more glue is required beneath a slit must be cut with the grain.

Veneering with Cauls. A caul is a piece of wood, zinc, or other material, of the size required to cover the surface to be veneered. It serves two purposes. One is to contain heat to make the glue run freely when it is cramped on. The other is that, veneer being too thin to have any rigidity in itself, uniform pressure must be applied all over its surface, and cramps alone would not do this. When a surface is large, its area may be covered equally well by a number of cauls placed side by side. For curved surfaces, cauls shaped to fit the curve are required, but in most work surfaces are flat, and the cauls are flat pieces of wood of about 1 in. to 1½ in. thick, sometimes kept specially for the purpose, sometimes selected from the stock of wood used for ordinary work. For permanent use they are better covered with sheet metal, preferably zinc. This not only preserves their edges from wear and reduces the risk of splitting and warping, but glue from the veneer does not obtain a hold on it, and consequently it cannot get stuck to the work, as is sometimes the case with wood cauls, for glue makes its way through thin veneer. Another reason why metal is preferred is that cauls have to be heated before they are applied, and, if care is not taken, the wood ones are liable to get spoilt through burning. Neither do they retain heat as well as metal cauls. Small cauls may be merely plates of zinc ¼ in. to ⅜ in. thick. Large ones are backed with wood. Cauls of irregular shape, and consequently troublesome to make, are, if constantly required, usually made of cast iron. For temporary use a bag of sand may serve as a caul on a surface of any contour, and may be heated and cramped on the veneer. Cauls are cramped to the surface by any convenient method.

For small work, hand screws are generally used [**5**], and, as in using the hammer, pressure should be applied first to the central parts to force the glue outwards to the edges. In **5**, two pieces are veneered with one caul between them. Wood cauls should always be soaped to prevent their sticking and pulling pieces of veneer away. Zinc cauls are soaped also when working with very thin veneer. In using cauls, only the dry heat of the caul is employed, and therefore the work is dry and hard in much less time than is required for hammer-laid veneer, in which the surface is wetted with hot water. The cauls and cramps are left on for several hours, until the glue is set. For work on a large scale, metal presses [**6**] with powerful screws are used, and a number of boards with veneer on are put in a pile and very heavy pressure applied, a number of presses, about 6 in. apart, being used to press long pieces. The boards are passed through machines which apply the glue very rapidly. For work on a small scale various kinds of wood presses are made by the workman, the principle being similar to the iron press shown, but wedges, instead of screw power, are the usual method of applying pressure. Joints and cracks in veneer are kept together and the glue prevented from coming

through and sticking to the caul, by pasting paper or canvas over. In some cases it is a practice to cover the entire face of veneer with paper. This is cleaned off after the cauls are removed.

Veneer is cut to dimensions by laying it on a flat surface, using a straightedge on it as a guide, and cutting with a sharp chisel or knife if the veneer is thin, or with a saw if it is thick. Joints on a surface are made by lapping the edge of one piece over the adjoining one, and then by cutting through both. Veneer should always be put on larger than required, and the edges trimmed off afterwards, otherwise there would be trouble in setting it correctly into position while gluing. The best veneer is generally put on panels, because the figure or grain of the wood is more noticeable there than on narrower parts. Often they are *cross veneered*—that is, a plain piece of veneer is first put on across the grain, and this is afterwards covered by the final veneer with its grain running the same way as the *ground* or *core*, as the interior wood is called.

Veneers on panels and other large surfaces are sometimes cut and jointed geometrically, pieces cut out from the same log being turned with grain reversed towards each other, so that similar curls and twists incline to the joint from opposite positions. Parts may be stuck down and pieces fitted in to make bad places good, as described for hammer-laid veneer.

The Scraper and its Use. The scraper is a small piece of sheet steel about $\frac{1}{32}$ in. thick. Its usual form is rectangular, measuring about 6 in. by 3 in. Often a greater length and less width is found convenient, but in any case its original dimensions soon become reduced by wear. Other forms are curved to suit hollow or round surfaces. Its edges are made very keen by first squaring and then slightly burring or turning them over, as shown to an exaggerated extent in 7.

The scraper is a tool frequently used by joiners, but to the cabinet-maker it is indispensable, and is used after the plane on almost all surfaces. The hard wood used by the cabinet-maker is often too cross-grained to be planed at all without tearing up the surface and leaving it worse than when sawn. But even when it can be planed smooth, the marks of the plane show as a series of undulations across the surface, and although these might be removed by glasspaper on a rubber, it would be difficult to produce as smooth a surface as can be done with a scraper in less time. The scraper, therefore, generally follows the use of the smoothing plane and is itself followed by a rubbing down with very fine glasspaper.

The scraper is held and worked at an angle as in 8 and 9, so that the sharp edge can be made to scrape or cut a very fine shaving when moderate pressure is exerted. Sometimes the steel is fitted into a wood block which serves as a handle [10.]

The sharpening is effected as follows: The edge is first ground or filed square and straight with a very slight amount of rounding up at each end, so that the corners will not leave ridges on the surface of the wood. Next, while still keeping the edge square, it must be made perfectly smooth. The best way to do this is by rubbing it on an oilstone [11]. The edge must be rubbed with the scraper vertical on the stone, and each face must also be rubbed [12] to remove the ragged burr which gets turned over in grinding and smoothing the edge. The edges should now be square and smooth with sharp angles. It is necessary now to burr or turn these angles uniformly so that they shall be very much keener than they are at 90°. This may be done with the scraper in either of the positions shown in 13 and 14. Another way is to hold the scraper in a vice. A short rod of steel in a handle is the proper tool to turn the edge with, but very often the back of a small gouge is used for the purpose. In 13 the scraper is shown held in a vertical position with its lower edge resting on the edge of a bench. In 14 the scraper is laid flat on the bench with the edge to be sharpened projecting slightly over. In both cases the sharpener is held at a similar angle in relation to the edge of the scraper. With the sharpener slightly tilted as shown, and pressing as heavily as possible, it is drawn sharply along the edge, turning over a slight burr as it goes. This burr is imperceptible to the eye, but is sufficient to scrape a wood surface far more effectively than would have been possible before this operation. If sufficient pressure is applied, one stroke of the sharpener is enough, but if not, more may be made. The edge soon becomes dull with use and requires re-sharpening, and after this has been repeated a few times, the edge becomes so worn that it is necessary to re-grind. In re-sharpening, the turned edge is generally rubbed flush, as in 15, before the sharpener is used to turn the edge afresh. All the edges of a scraper may be sharpened in this way so that each can be used in turn till too dull to cut.

Inlay. The inlaying of ornamental design into a surface is frequently practised to decorate cabinet work. To a person unacquainted wth the practice it might be supposed that the effect was obtained by staining or painting the design on the surface. The difference in colour is obtained by the use of different woods, and in a few cases, where such colours as blue or green are employed, by staining the inlaid wood before insertion. Wood is the chief but not the only material used as inlay. Others often employed are ivory, pearl, tortoiseshell, and metal. It is then called *buhl* work. The inlaid material is always very thin and is glued in place. This is more frequently done in veneer than in solid wood, and the thickness of the veneer usually represents the depth to which the pattern is inlaid. The forms of inlay range from simple straight lines of white or black wood about $\frac{1}{16}$ in. wide, round the edges of surfaces, to representations of flowers and scenery. Figure 16 is an example of stringing and banding round the margin of a surface. The term inlay includes all inlaid work, but different names are given to different classes of inlay. Work of complicated outline, such as representations of natural scenes and highly ornamental patterns, is known as *marquetry*. Geometric patterns are called *parquetry*, and this term is now applied chiefly to floors laid with hardwood blocks arranged in any geometric pattern. *Intarsia* is a very simple kind of marquetry in which pictorial effect is obtained by a few pieces of inlay, the grain and outline of which represents a land or sea-scape without detail. Buhl work, as already noted, is inlay of other material than wood.

Methods of Inlaying. Inlaying of the more complex character is not done by cabinet-makers, but panels or other parts are purchased already inlaid, or inlaid veneer is purchased and either laid on large enough to cover the surface it is required for, or the inlay is contained in a small piece of veneer cut to oval, circular, or other shape, and let into the body of the other veneer. Patterns of plain outline are also sold separately. Built up patterns and inlaid veneers when purchased in this way have their parts united by being stuck on a backing of paper. This is the usual method of forming patterns even when done by the person

who afterwards intends to inlay them in another surface. The paper is intended to be on the outer side when the pattern is inlaid, so that it can be cleaned off when the glue is set. If turned the other way the paper would prevent the glue from holding the inlay properly, for paper can easily be split if glued between two pieces of wood.

Fitting Inlay into Veneer. There are two methods of fitting the parts of patterns together and fitting inlay into veneer. One is to cramp or stick temporarily the pieces face to face, and cut through both with a fine saw or sharp knife to the outline required, thus obtaining an interior part which will fit into a corresponding exterior one. The other is to cut a pattern out separately, and lay it on the surface in which it has to be sunk, and mark its outline with a sharp pointed knife or scriber, and cut out to these lines. For inlaying into solid wood, this latter is, of course, the only method. Incision is made to the required depth by chisels, gouges, or a knife with a sharp point, and the recess for the inlay routed to the required depth, with a small *router* if in solid wood, or with a chisel when only veneer has to be removed. A router is a plane which can be set to cut a channel or recess to uniform depth. It will be illustrated farther on. But most of the inlaying the cabinet-maker is required to do is the insertion of plain parallel strings, the channels for which can be cut very rapidly with a double-toothed cutting gauge, similar to a mortise gauge, except that the cutters are deep and thin, to penetrate well into the surface. This gauge is set to the width of the inlay, and makes two parallel cuts in the surface at the required distance apart. The material between these can be removed at a stroke with a router. The inlay is glued in, and pressure put on it till the glue is set. The inlay may be parallel strips cut from veneer, or more frequently it is bought ready cut into strips known as *strings* or *stringing*. Mosaic bandings are also often employed. These are made up in innumerable patterns of different woods arranged in different ways. They are made by gluing up the patterns in lengths and then slicing off in strips about $\frac{1}{16}$ in. thick or less. The grain must run plankwise with the surface when the inlay is glued in place. Inlay designs are nearly always made in quantity either by gluing up a thick pattern and slicing off, or by sawing out a number of thicknesses together. In either case it is not regarded as cabinet-makers' work.

Other Methods of Ornamentation. Next to mouldings, which have been treated of in Joinery, carving is the most important of all decorative methods. Carved portions of work come into the cabinet-maker's hands already finished by the carver, and he is concerned only with fixing the parts in place or fitting them together. The same is true of turned work, which is done by wood-turners. This is generally not intended chiefly as ornament, but it is so easy to make turned work ornamental that it is done even in the simplest and cheapest work, almost the only exception perhaps being the use of plain parallel rods in some chairs and other articles. These, however, are not turned in the ordinary sense, but made cylindrical by being passed through a machine with revolving cutters. Another form of ornament on furniture is known as *ormolu*. This consists of metal ornaments with gold plated or gilded surface, attached to the wood by brass pins or fine screws. *Fretwork* occupies a position of some importance in light fancy articles of furniture. In this very fine saws are used to cut ornamental patterns in thin wood. The lines to cut to are transferred from patterns on paper. Fretwork for the cabinet-maker is cut by machine saws and comes into his hands ready to be attached to the work. *Pyrography*, or *poker* work is a rough means of ornamenting a surface by tracing a pattern on it with a red hot platinum point, which burns the required outline, making a slight channel in the surface of the wood, and showing as brown or black lines according to the degree to which it is burnt.

Furniture Construction. The method of constructing a given article may vary with circumstances. If the work has to be done as cheaply as possible without much regard for quality, the parts are prepared and put together in the simplest style, glue and nails being the chief means of union. If the best work is required the best forms of joints are adopted everywhere instead of the parts being allowed to depend solely on the medium which holds them together. The quality and amount of material used may also vary. Soft wood is cheaper than hard, does not look so well, and is less durable. Pieces of wood, alike in kind, vary in quality and strength. Thin material may be used for economy when thicker would be more suitable, or the strength of an article may be diminished by economising material in hidden parts. There are, of course, some exceptions where cheapest and best work must be done alike, because there is no other practicable way. The arrangement of the parts of an article of furniture has to be made with a view to exterior appearance, economy of material and labour, and sufficient strength to serve the intended purpose.

Dowels are employed more in cabinet work than in joinery. They are used very often instead of tenoned joints. Figure **17** is an example. In many cases it is troublesome to get the centres of the holes for them marked correctly by measurement or by gauging from an edge, and then other methods may be adopted. One very convenient way is to locate them by means of pin marks, as in **18**. Ordinary pins are placed in the joint, and pressure applied so that the pin heads leave imprints on both parts, which serve as centres on which to bore the dowel holes. Another method is to have a number of centre pops [**19**]. These might be made of wood with a steel point inserted, but are better turned in solid metal. The body is the same diameter as the dowel, and is intended to be inserted in the dowel hole, which has first been bored in one of the pieces to be dowelled. The thin flange shown at the top prevents it from going farther in. The other piece of wood is then adjusted in position, and a tap with a mallet, or a little pressure, causes the point in the centre to leave an impression corresponding exactly with the centre of the hole required in the other piece. Another method is to cut a piece of paper to the shape of the jointed surface and prick holes through at the places where dowels are required. The paper can then be laid in position on each surface, and the centres marked through the holes in the paper. Another way seldom practicable in cabinet work is to cramp the pieces of wood together and bore entirely through one piece into the other.

Insertion of Screws and Nails. Screw and nail heads are seldom allowed to show on exterior surfaces. Where possible they are put in from behind as described in joinery. Screws with rounded heads are preferred when the heads cannot be concealed. In some cases screws with flat heads are provided with metal cups which give a neater appearance. Nails are punched below the surface with a hammer and punch [**20**], and the holes filled flush with wax stopping coloured to

suit the wood or stain. Figure 21 shows a method of withdrawing a nail without injuring the surface of the wood. The blade of a square or other sheet metal is laid on the surface to receive the leverage of the pincers, and so prevent the wood from being bruised. Figure 22 shows how screw holes may be countersunk by scooping out with a gouge. This is not quite so neat a method as with a countersink bit, but is more expeditious, and is frequently adopted. Needle points are used for attaching light mouldings and other parts. They are similar to ordinary needles, but without eyes. They are driven in the required distance, and then snapped off flush with the surface, and, of course, are then almost invisible.

End grain appearing flush with a surface plank way of the grain is objectionable, and therefore tenons are seldom carried through unless at the back of an article where they will not be noticeable. Even under veneer through tenons are objectionable, because a slight amount of shrinkage causes them to bulge the veneer. In other cases end grain is generally allowed, if possible, to project beyond to avoid a flush joint. Except when they are glued, flush joints are always objectionable, even when the grain of each part corresponds, and consequently they are usually beaded, or moulding is attached to conceal them. The shooting board is used a great deal by cabinet-makers. Small pieces of wood are often sawn, and planed with the tools in an inverted position as in 23 and 24, the saw or plane remaining stationary and the wood being worked backwards and forwards.

Construction of Table Tops. The tops of tables, counters, sideboards, bureaus, etc., are frequently thickened or lined up at the edges, as described in Joinery; but there are several methods of building up the main surface. The simplest way is not to build up at all, but take solid board of the required length and width, and keep it flat by its attachment to the framework of the article, while at the same time allowing it freedom to shrink or swell without splitting. If very wide, this is usually done by buttoning. Comparatively narrow widths may be screwed or nailed with safety, but glue should never be used except in cases where the grain of the parts it is attached to is arranged in the same direction so that all these parts, if well seasoned, when put together can be relied on to shrink or swell similarly. Another method of keeping a top flat is to dowel or tongue flush cleats to the ends, generally with mitred corners. This is satisfactory if the wood is well seasoned, and the width not very great. A better way is to frame and panel the top with a flush panel as in 25. Here also the corners are better mitred, and the joints strengthened either by tenons or dowels. Another method is to half-lap the joint and mitre the upper face only.

The tops of writing-tables panelled as in 25 generally have the panel slightly below the surface of the frame, so that leather or cloth can be glued on the panel to make a flush surface. When solid tops are covered with leather, the border round the leather is veneer glued on. Veneered tops should have their edges corresponding in appearance with the veneer, so that it looks like solid wood, and as edges are generally moulded, and therefore difficult to veneer, the top is built up as in 26. A core of pine or cheap mahogany has an edging of more costly wood, corresponding with the veneer, glued round it, end grain pieces frequently being put on the ends. Both the upper and under faces of the core are generally veneered, so that the core is entirely enclosed. In such cases it is very often cross veneered, as in 26. Another method is to frame as in 25, making the frame of, say, mahogany or walnut, with a pine panel, and to cover this with veneer to match the frame, the veneer generally standing its own thickness above the surface of the frame, as in 26. Another way is to put a hardwood edging with mitred corners round a pine frame and conceal the latter by covering with veneer or leather.

Carcases. Carcases may be either panelled or plain boarded. Sometimes a skeleton framework of posts and rails is built to attach the panels or boards to, and sometimes there is no such frame, but the parts are fitted together at the corners in box fashion, either dovetailed, tongued, and grooved, or, in some cases merely nailed or screwed or secured by glue blocks. The method depends to a large extent on the character of the article. In cabinet work, parts are sometimes panelled mainly for appearance. Carcases intended to stand on the floor, without legs, usually have a few inches of plinth below the baseboard of the carcase. In heavy articles of furniture this plinth is sometimes separate, the carcase merely resting on it; but in most cases the sides of the carcase either extend below the baseboard, and the plinth is screwed against them, or the plinth is partly against and partly beneath, and secured by glue blocks or screws or nails.

A simple example of a carcase is shown in the bookcase [27], the frame of which, with plinth and cornice removed, would consist of two plain uprights with shelves fitted between. The uprights should, to make the most substantial job, continue to the floor, and the plinths be nailed or screwed against them from the inside, the plinths being simply an increase in the thickness of material at the sides. The plinth along the front would have the edges of uprights and bottom shelf to bear against, and would be secured by glue blocks in the interior angles. A plinth at the back would be treated similarly, but generally plinths and cornices are carried only round front and sides, leaving the back a plain flush surface. The cornice is built up by first covering the top ends of the uprights with a plain board, overlapping an inch or so at ends and front, and then fitting moulding beneath this attached in the same way as the plinths, by nailing the end pieces and blocking the front. The objection to gluing the ends is that the grain crosses. So far the constructive details have been illustrated in Joinery, but an important matter to be considered now is the attachment of shelves to uprights.

Methods of Fitting Shelves. There are a number of ways of fitting shelves, and, as a rule, in cabinet work they must be fitted securely without exterior sign of how it is done—that is, without nails in the ends, on cleats beneath, or rebates showing at the front. Shelves for books are often made adjustable, but at present we are considering fixed shelves of all kinds, including bearers and runners for drawers. In an article with plain shelves fitted to plain sides, as in 27, the shelf ends would be rebated into the sides by one of the methods shown in 28, A, B, C. The grooves in the sides, however, are stopped about ½ in. short of the front, as in 29, and the shelf ends notched to correspond. The shelves are inserted from the back. A plain rebate or housing, as at A in 28, affords satisfactory support for the shelf, and is more easily made than the dovetailed grooves at B and C; but the advantages of the latter are that they tie the sides and keep them tightly up to the shelf ends. Ordinarily, however, the plain housing, as at A, is used, and the sides are secured at top and bottom; 30 shows how these housings are cut. At the right-hand end of 30, a tenon saw is being

used to cut the depth, an inch or so at the front having previously been cleared out with a chisel to allow the saw to work. At the left of **30** a router is being used to cut the groove to a uniform depth. Generally, a chisel would be used first to clear most of the material out. A rebate plane might be employed in a long groove, instead of a router, but the fore part, which could not be touched by the plane iron, would have to be finished with a chisel.

The top of the bookcase in **27** would in most cases be nailed on, and the bottom shelf might be nailed as the plinth would afterwards cover the nail heads, but this could be avoided by the use of glue blocks beneath, and generally the ends of this shelf would fit in veed grooves and be glued.

Methods of Fitting Drawer Runners. Figure **31** represents a case or pedestal with runners and bearers to receive drawers. This is an example of sides tied at top and bottom, and requiring only plain grooves for the runners. At the bottom a complete frame stub-tenoned together is screwed or nailed into rebates, which may run right through to the front, as the front edge, and also the screw heads at the sides, are afterwards concealed by a plinth. At the top, *stretchers* are dovetailed in. The intermediate runners are then not required to play any part in tying the sides, but are slipped into plain rebates. Details are shown in **32** of a grooved side, and a runner with its tenon to fit into the bearer in front. The inner edges of runner and bearer are shown grooved, as would be the case if a panel or dustboard was to be inserted between drawers. Figure **33** shows another method in which the side of the article is not grooved for runners, but recesses are cut instead to receive the ends of the bearers at the front and the back ends of the runners at the back. In a few cases bearers are tenoned completely through sides, but, as a rule, a shallow recess only is cut. A rail or bearer connecting the back ends of a pair of runners is not necessary unless to serve as a tie to the sides, or stiffen a back. Runners are often made of oak or other hard wood, which will not get worn very readily by the drawers sliding on it.

Attachment of Backs and Tops. Backs are tongued into a groove as in **34**, or fit into a rebate, as in **35**, or in rough work are simply nailed on the surface. A back may be simply a plain, thin piece of wood, or it may be framed and panelled, or a middle course is to make it as in **36**. In **36**, A, it fits in grooves at the sides, but is not enclosed by top and bottom rails as panels would be. The muntin in the middle is screwed or nailed to top and bottom of the carcase, but the boards in the grooves may be left free to contract or expand. Figure **36**, B, is a modification of this, and is very commonly adopted. Instead of the edges of the thin boards fitting into grooves as at A, they are kept in position by one or more rebated bars, as shown at B. The thin pieces, as well as the bars, are generally nailed to the carcase.

Tops may be simply nailed on, or dovetailed in, or screwed from beneath, or fitted on to a dovetailed tongue, which may be nailed on the ends, as in **37**. In all these cases, when the grain of top and sides coincide, glue blocks may be used also, if there is no objection to their presence. In most cases tops lap over, as in **37**, but when the ends have to be flush, the best way is to dovetail them in with lap dovetails, which do not show on the sides. When tops are screwed on, the screws are usually put from beneath through stretchers, which themselves are lap dovetailed in, as in **31**.

In **38** we have an example of carcase work first framed and afterwards covered as required, the boarding being attached by screws put through from the inside. It represents the skeleton carcase for a chest of drawers. All the material in the framework is, say, 1 in. thick. The boarding at the ends would be, perhaps, $\frac{3}{4}$ in.; the back $\frac{1}{2}$ in., or less, and the top 1 in. As the sides of the frame are to be covered, there is no objection to carrying the tenons through the uprights, and screwing the side and back uprights together as shown. The runners are tenoned at front and back, and notched into the side uprights. The ends of the longitudinal rails at the top are dovetailed to the tops of the uprights. The uprights at the front are, say, 4 in. wide, and all the other parts 3 in. This framework is, of course, equally suitable for attaching panelled sides and back to.

As an alternative to grooving, panels in cabinet work are sometimes inserted as in **39**, a rebate being planed or a bolection moulding glued on the front, and a fillet bradded round the back to keep the panel in.

Figure **40** is a face view of a frame for a panelled side or end showing how the bottom rail is kept above the floor. The lower part is afterwards covered by the plinth, which laps about an inch above the lower edge of the rail. The joints are either all stub-tenons, or, as there is no objection to it, the back tenons are sometimes continued through, as shown.

Framed Work. This consists of rails and posts, or legs, not boxed in, chairs being the commonest example. The parts are united by dowels or tenons, or small members have their ends housed into larger ones, or, in the case of cylindrical parts, the end of a member may be reduced in diameter. Examples of these are shown at A and B in **41**. These are usually held by glue alone, but occasionally fox wedges are inserted. But if the parts fit tightly and are well glued there is little risk of their ever coming apart. An article like **42** is built up by gluing the ends of the columns into holes in the shelves, as in **43**. If the shelves are very thin pieces may be glued to the under-surface as in **44**, to increase the depth of the stud holes, the pieces glued on appearing as part of the column. If it is desired to stiffen the shelves to prevent warping, battens may be screwed across in place of separate blocks, and the stud holes may be bored through these. The stumps of drawers are fitted into blocks, as in **44**. In some cases they are screwed in. Wood drawer knobs are generally screwed into the drawer fronts.

Figure **46** is an example of framed work in which some amount of building up is involved to obtain the required curves. It is the frame of a semicircular washstand intended to be covered with a marble top. The details of its construction are shown in **47**, in which it is turned upside down. The semicircular top on which the marble rests is formed by gluing two layers of segments which are afterwards worked to the sweep on the outside and veneered, the inside being left as it leaves the bandsaw. A bead is formed on the lower edge by nailing on a thin layer of segments with outer edge rounded and projecting. The ends of the sweep are connected by a straight rail notched in flush, and forming the back of the table part. A transverse bar extends from the middle of this to the sweep, being notched flush into the under edge of the latter and covered by the bead segments, and nailed on to the edge of the back rail, the depth of the rail being less than that of the sweep. The main purpose of this transverse bar is to provide an attachment for the top of the pillar, which comes within the curved front. The base is a piece of $\frac{1}{2}$-in. wood lined up to about 2 in., and

veneered. It does not rest directly on the floor, but on projections extending about an inch below the thickening or lining pieces. The two back uprights are carried through, as shown, to form feet at the back, and one other is formed at the front by a pad, which is nailed on. The pillar is slipped in after the parts are together, and nailed from above and below.

Brackets, either of metal or wood, are often used to strengthen joints. A wood bracket is shown in **48**. These are roughly sawn, but the angle of the back must be accurately finished. They are used only in hidden parts, a common instance being the interior angles of chair seats. Where brackets are required in exposed places they must be neatly finished, generally to a more or less fanciful shape, and if of wood, the screws are inserted through the work into the bracket instead of through the bracket, as in **48**.

Chairs. The seats of these, when not of solid wood or turned rings, are usually dowelled or tenoned, and glued, and sometimes strengthened by brackets of wood or metal screwed into the interior angles. The back and back legs are in most cases continuous, and the seat notched into them and screwed or nailed. The front legs are glued into bored holes. Rails connecting the legs are glued in similarly. Cross-pieces in the back are tenoned, or dowelled, and glued. Very often some of the parts are of bent wood. Special appliances are employed for making these. It is done by steaming the wood and clamping it in an iron mould, the mould itself often being formed with a chamber and pipe for steam heating its surfaces.

Tables. The methods of framing the legs and rails and buttoning on the tops of plain tables has been described in Joinery. Small tables, such as **49**, do not require such elaborate methods. The top would not be buttoned but screwed on through the rails, or if very narrow, glue blocks might be used. The rails might be housed or tenoned into the legs, but in most cases would be dowelled. The bottom rails, to which the tray or shelf is attached, might be housed into the legs, as in **50**, and the tray notched to fit the legs. The rails then would be glued in and nailed through the inner faces of the legs, where the nails would not show, though in many similar cases there is no objection to putting fine nails through from the outside if required. In some cases the tray might be attached to the under edges of the rails instead of on top, and then would be nailed to them. Figure **51** is a heavy writing-table, which does not differ greatly in constructive details from plain tables described in Joinery. Its frame is arranged to receive two drawers in the side instead of one in the end. Its top is built as in **26**, but covered with leather bordered by veneer. Its turned legs, with castors, are a detail which does not affect the construction of the table. A general view of the frame with top removed is shown in **52**. The lower bearer is tenoned into the legs while the upper one and the end and back rails are dovetailed into them. Drawers are constructed as in **53**. In cheap work the backs are nailed instead of dovetailed.

Extension Tables. The commonest form of extending table is shown in **54**. In this there are double rails secured to the legs at opposite ends, and, when closed, the free ends of each pair of rails fit loosely into housings in the legs. They are also tied laterally by stretchers. The rails are kept in alignment by tongues and grooves, usually dovetailed, as in **55**. Large tables of this class have three sets of rails, the middle ones being supported by the others or by extra legs. The frame is usually extended and closed by a screw worked by a key, and a separate leaf fills the space left when the ordinary top is opened. Another form of table with a folding top is shown in **56**. In this the top is pivoted, so that when unfolded it can be swung round at right angles to its position when closed, the long way of the frame then affording sufficient support for both flaps. When square legs of tables or other articles are tapered, as in this example, all the taper is cut from the inner faces.

Flap Tables. Ordinary flap tables have their flaps supported by brackets, swinging legs, or slides which draw out from the frame. Figure **57** shows methods of attaching brackets to the rail of a frame. The simplest is to hinge them, as at A, but for appearance the joints at B and C are preferred, C being considered the neatest; B is known as a finger joint, and C as a knuckle joint. Another way is to pivot a piece in the top of the rail, as at D, which can be swung out to support the flap. The point in favour of this is that it lies flush with the rail when closed. Swinging legs are hinged, as in **58**, sometimes with a tie near the bottom as dotted. The rule joint [**59**] is the usual method of hinging flaps.

Articles with more than three legs sometimes require levelling to prevent them from rocking, due generally to inaccuracy in the superstructure. The exact amount to cut off may be marked as in **60**, by standing the article with three of its legs on blocks of equal thickness on a true surface, and setting a fourth block against the fourth leg, which should be the one which requires cutting. The top surface of this block represents the correct length to cut the leg to. Another way is to mark from the floor with dividers instead of getting the depth from a fourth block.

Writing-tables and Desks. These are generally of the pedestal type, with a kneehole between. A table in which the top and pedestals are in separate parts is shown in **61**. The construction of a pedestal has already been illustrated in **31**; **62** shows how the top is framed. The grain of the ends runs horizontally, but in this example the table is veneered and the grain of the veneer on the upper part is made to correspond with that of the pedestals.

More frequently pedestal tables are made in one framework. Figure **63** is the carcase of a cylinder fall-desk. The sides are shown plain, but in many cases would be panelled. The table generally fits in grooves in the ends and is made to draw out several inches beyond the front. Figure **64** is an end view of the fall. It is pivoted at the centre from which its curve is struck, the connecting pieces generally being of hoop-iron. It is staved up on a block as in **65**, and the staves should be dowelled or tongued as well as glued. The back of table and back of fall are usually connected, so that the fall opens when the table is drawn out and closes when it is pushed in. Figure **66** is another form of roll-top desk with a flexible fall. This is an improvement on the cylinder fall, and is now in more common use. In this the fall slides in grooves in the ends. It is formed by gluing strips of wood on canvas, as in **67**. The pedestals are panelled and connected by a panelled back and by a stretcher in front secured by metal angle brackets. The drawers lock automatically by means of catches which clip their backs. These catches are released by pressure of the fall when it is pushed back as far as it will go. The lock on the fall is of a kind which locks itself when the fall is drawn down, and requires a key only for unlocking. These desks are usually made of oak. The table is solid board screwed directly on the pedestals. A writing bureau is

shown in 63. The cover is hinged, and when opened is supported by two slides which draw out from the carcase. On writing-tables with level tops loose desk slopes are often used. These are very simple in construction, sometimes consisting only of a piece of board tilted by two tapered battens screwed to its under surface.

Bookcases. Sometimes these consist merely of an open carcase with shelves, but to keep dust from the books the best cases are fitted with glass doors. A common type of bookcase is shown in 69. In this the upper doors are glazed and the lower ones wood panelled, as there would be some risk of glass getting broken in the latter. The parts are made separate, as in 70, and the lower part is wide enough to project 4 in. or 5 in. in front of the upper, thus providing a useful ledge and being better proportioned for the larger books it is intended to contain. The upper part should have a vertical partition in the middle behind the meeting stiles of the doors. If the length of the shelves exceeds 4 ft. the lower part would be better with a similar partition. The upper part is lap dovetailed at the corners, and the partition housed in and screwed. The lower part has two stretchers lap dovetailed in at the top, and its bottom may be housed and nailed if covered by plinth, or fitted into a dovetail groove and glued, and in either case may be further strengthened by glue blocks in the angle beneath. The front edges of the sides may have pieces glued on to form pilasters, thus giving the sides an appearance of greater thickness than is actually the case. A top is screwed on to the stretchers of the lower part, and the upper part is screwed on to this. The doors of the upper part are hinged on the face of the frame.

Shelves are generally made adjustable in height. A common method of doing this is to screw saw-toothed strips about ⅜ in. thick against the sides, as in 71. Bearers of similar thickness are made to fit between, and on these the shelf ends rest, the ends being notched at each corner to clear the saw-tooth strips. The alternative to this method is to have two columns of holes corresponding with the saw-teeth in the last example, and to insert pins in these to support the shelves. These pins are of metal, and there are several varieties of them.

Sectional bookcases have become very popular and are best where the number of books is constantly increasing. Bookcases like 69 look well as an article of furniture, but they are suitable only for a fixed quantity of books. Sectional cases consist of a number of separate boxes each with a capacity, say, for twenty average books. These sections are all alike and provided with simple means of uniting them end to end or one on top of another. A glass door may be fitted to the front of each section. A convenient arrangement is to hinge the doors at the top, and make them so that when lifted into the horizontal position they can be slid back into the case, leaving the front clear and the books uncovered.

Wardrobes and Cabinets. Wardrobes are a common example of large carcase work. They are usually made in three parts, the plinth and cornice being separate from the body, and these parts fitting together loosely with blocks or dowels as guides, and in some instances screwed together. Figure 72 is an illustration of an ordinary plain wardrobe. It has a drawer at the bottom, and the door in the middle is panelled with a mirror. The sides are lap dovetailed to the top and bottom similarly to the bookcase in 70. In the best work, backs are panelled, but generally matchboarding, ply board, or a number of panels between muntins, as in 86, are put in the back. As the doors of wardrobes do not extend across the entire front, pieces, either panelled or plain, must be put on. In many cases these are nailed or screwed directly on and the holes plugged. Where this is objectionable they are glued and dowelled, or screwed from the inside, and sometimes glue-blocked. Figure 73 shows a joint between front and side. With a drawer at the bottom, as in 72, the parts of a large wardrobe would generally be jointed at the bead above the drawer, and the plinth would generally be solid with the lower part, as in the bookcase [69]. The methods of constructing more complex wardrobes do not differ much from what has already been described. Doors, whether in the middle or at the sides, close against the front edges of the frame, as in 74, which is an example of a door hinged to a side. Drawers in the lower part generally work between pilasters formed as in 70, guides of course being required flush with the pilasters, and the width of the latter representing a corresponding reduction in drawer width, the space behind the pilasters not being utilised. Beads are often formed as in 73, where joints occur on the outer faces of front and sides.

Figure 75 is a cabinet with glass doors, and drawers and table above. Its carcase is framed with bottom, shelf, bearer and runners for drawers, and stretchers dovetailed in at top to screw the table on to, none of which differs essentially from what has already been described. The back portion, which forms the main support of the upper shelf, is panelled and screwed on behind. Figure 76 is another form of cabinet, veneered, inlaid, and decorated with ormolu. It has three doors, the middle one containing a mirror, and the two side ones being curved, with glass panels. The curved rails of these doors might be of solid wood worked to the sweep and veneered, but the best way is to form them of a number of layers of veneer bent round a block and glued together. The base and top may be built up as in 77, and the four uprights which enclose the doors may be halved in flush with the outside faces, and the outstanding blocks put on after.

Glass in Furniture. The ordinary methods of inserting glass are shown in 78 to 80. In 78 the glass drops into rebates and is secured by wood fillets behind. The method shown in 79 is suitable only for mirrors. In this the glass goes into a rebate as before, but is protected behind by a backing of flannel and board, the flannel being flush with the back of the frame, and the board screwed on. In 80 the glass fits loosely in the rebate, and is centred and secured by glue blocks as shown. Glass divided by ornamental bars into a number of panes is fitted similarly to that in ordinary windows, except that wood fillets are more generally used than putty. When these have to be bent to curves they are generally of birch or other flexible wood. Where the bars form a very ornamental pattern they are sometimes merely stuck on the surface of a single sheet of glass. Plain and bevelled mirrors may be purchased in great variety of size and shape, or can be obtained to order.

Miscellaneous. Figure 81 is the frame of a couch. The feet are supposed to be dowelled to the under part of the frame. An alternative is to tenon the rails in similarly to those of a table. The upper parts which form the back and end are tenoned or dowelled and glued in the most convenient way to produce the outline desired. Figure 82 shows the

usual method of fitting the feet of circular tables and other articles into the centre post. Screw heads are sometimes concealed by gluing buttons [83] over them. Three methods of forming rounding interior angles in frames are shown in **84** to **86**. Figure **84** is satisfactory, but involves either gluing on a piece or cutting out from one of the members. Figure **85** is a good method when the parts are mitred. Figure **86** has the advantage of allowing the straight pieces to be planed up parallel.

Glue blocks, as illustrated in Joinery, are very commonly used in cabinet work. In many instances, where widths are not great, they are used across the grain. The union of rails to table legs, for instance, is often strengthened in this way. Wire nails are very often used on exteriors without any attempt at concealment, while in other cases they are punched in and the holes stopped, but their presence can, of course, be detected if they are looked for. Metal connections, such as brackets and thin plates or strips, screwed on, will often make a substantial job of what would otherwise be weak owing to slender proportions of wood or a difficulty in making a sufficiently strong joint between parts.

All parts of furniture that are either ornamental or standard in form may be purchased ready made at not much higher prices than the cost of the material. Thus, prepared and carved panels, pediments, brackets, trusses, plain and embossed mouldings and beadings and pressed wood ornaments, can be more economically purchased than made. All kinds of turned work, such as legs, spindles and knobs, are kept in stock by turners and seldom require making to order. There are also so many designs in inlay available that the cabinet-maker never needs to do anything more than select from them. All these articles may be purchased either from specialists or from large firms that stock all of it.

Glass-papering. On a large scale this, and scraping also, are done by machines. Glasspaper is used first to remove tool marks and other slight inequalities and secondly to make surfaces smooth. It is necessary to rub down with glasspaper after the first coats of varnish or stain have dried, to remove the roughness caused by the raised grain. Surfaces, therefore, have to be glasspapered two or three times in the course of finishing the work, and each time paper of finer grade, or paper that has been worn finer by use, is required. A flat surface is done with the glasspaper, kept flat on a rubber as in **87**, and the direction of the rubbing must be with the grain or the surface will appear scratched. Cork rubbers are best, but often a block of wood is used instead. Rounding surfaces are done with the hand, as in **88** and **89**. Hollows are generally managed similarly, though in some cases rubbers of the correct shape are made. Quirks and narrow places may be rubbed with paper simply folded, as in **90**, or wrapped on a thin piece of wood or metal.

Staining. This is done to improve the colour of soft and cheap woods and make them resemble more expensive varieties. The resemblance, however, is chiefly in colour, for in most cases the grain shows unmistakably what the wood actually is. In staining, any inequalities in the shade of the natural wood are corrected. Some parts are generally lighter or darker than others, and this looks especially bad when two pieces are glued together, and the joint is made conspicuous by a sudden change of colour. This, of course, is avoided as far as possible in selecting the wood, but it is further corrected by applying an extra quantity of stain to light parts to make the colour uniform. This matching of the colour of parts is done more or less in nearly all polished work, even when the natural colour of the wood is supposed to be showing. Stains are sold in liquid form ready for use, and are applied with a brush. Hard woods may sometimes be improved in appearance by having their natural colour darkened. Wood darkens with age, but is done artificially by oiling, by staining, or, in the case of oak, by fumigating with ammonia.

Polishing. This is the usual method of finishing cabinet work. There are several ways of doing it, but by far the commonest is known as French polishing. In this the polish is simply shellac varnish (which is shellac dissolved in methylated spirit) applied with a rubber instead of a brush. In order that the polish may be permanent it is necessary to ensure its not becoming absorbed into the wood surface and losing its lustre. The pores of the wood, therefore, are filled by rubbing in a filling medium to economise time and material in applying the polish. There are many fillers employed, plaster of Paris and whiting being common ones, made into very thin paste with oil, water, or turpentine. The filler should be coloured to suit the wood. After this has dr ed and been rubbed down the process of *bodying in* beg ns.

The rubber with which polishing is done is a pad of cotton-wool damped with polish and wrapped in a piece of soft linen rag, one thickness of linen only covering the wool. The polish is rubbed evenly and quickly with light pressure of the rubber over all parts of the surface to be polished. The movements of the rubber are unimportant as long as all parts are treated equally. As the rubbing proceeds, the polish dries and the pressure then may be slightly increased. A little linseed oil is applied to the linen when it does not move freely over the surface, but too much oil will make it impossible to get a good polish. This bodying in should properly be done three or four times, with intervals of several days between each, otherwise it is likely to sink in and diminish the lustre of the polish. The coat of polish should be as thin as possible, to show up the figure of the wood and avoid the yellow colour of a thick coat of shellac. The bodying in is followed by a concluding process called *spiriting off*. In this a very thin polish and finally methylated spirit alone is used to remove oil, smears, rubber marks, and any inequalities. It is, in fact, polishing the surface of the coat of shellac, and, if carried too far, will dissolve and remove the shellac and so spoil the work. The final rubbing should follow the grain of the wood. The pressure should be light and the rubber kept moving. Intricate parts are difficult to polish, and are generally given four or five coats of thin varnish with a brush.

The mediums used in other kinds of polishing are chiefly wax and oil. They give comparatively dull results and are used only for special purposes.

WOOL AND COTTON WOVEN FABRICS: FOUR REPEATS SUITABLE FOR WEAVING

DESIGN FOR WOVEN FABRICS

Pattern Made by Interlacing Warp and Weft. Reversing and Other Repeats. Designs for Madras Muslin, Lace Curtains, Chenille, and Silk Fabrics

By H. NAPPER

TO the designer the amount of different materials and the variety of methods of weaving offer such an enormous field for his invention that it is difficult for him to keep in touch with the changes in production and vagaries of fashion to which the market is subject. Unlike other forms of material that require pattern, such as carpets and printed goods—where there is very little in the way of change in method of production—tapestries, silks, and other woven fabrics are constantly undergoing change in the desire to get different mixtures in wearing so as to give new features to the material and to compete with other firms in producing something new.

The Basic Pattern in Woven Fabrics. The simplest form of woven fabric, which must be made by the interlacing of warp and weft, immediately begins to give texture or pattern. Ordinary matting gives a good idea. There you have the pattern made by the material. This makes designing for woven materials interesting to the craftsman because the design becomes a part of the material, and in some cases the beauties of the fabric must have pattern before they can be seen.

Patterns are made for wool, cotton, polished cotton, silk, satin, chenille, etc., and an endless variety is made, again, from mixtures of one, two and three of these together. The many uses to which these can be applied also make a great demand for variety in style and size of design. It is not necessary for the designer to have a thorough practical or inside knowledge of the way in which these fabrics are woven or to put his productions on to ruled paper, for, with the exception of Madras and the coarser forms of tapestry, the actual drawing can be reproduced with the most delicate forms copied exactly.

Repeats Economical for Weaving. It is necessary to bear in mind that a drawing, even for the finest damask, must be put on ruled paper (before the cards for weaving are cut) inside the factory, so the size of the design becomes a matter of cost in the production, especially regarding the height. There are shown in illustrations four methods of weaving, which give some idea of economy in repeat. The first [11] shows the ordinary "reverse drop." It will be noticed that in the lower right-hand corner is a part enclosed within dotted lines, within which are a few alterations; centre leaves are not the same—a line is introduced across the stem. These things might be done in designing to ease the effect, but to get it would mean that the cost of production would be increased. In 12 is shown a very useful method of weaving. Although this looks like a long pattern, it is really only half of what it seems. When the cloth is woven, say, to the top of the flower, the cards are reversed or turned over, and the pattern runs again the other way. Various names are given to this repeat—"chasing," "turnover," "bosom," etc. A reversing side-repeat is shown in 13, and another form of chasing or side-repeat in 14. These present the only methods of getting large-looking patterns in small repeats. The third is, of course, economical in that it reverses exactly. These repeats apply to almost every form of weaving. There are, unfortunately, no set sizes for widths of design, as in printed papers and fabrics. This makes it difficult for the designer. Some English and most of the Continental manufacturers use 25 in. width, making 12½ in. for reverse, again divided into 6¼ in. Other looms are only used for sizes of 9 in. to 18 in. reverse, thus making material into divisors of yards, similar to carpets.

Madras Muslin Designs. The simplest form of weaving for which the designer can start is Madras, or lace muslin. Madras muslin is used for curtains hanging in windows, etc., as for the greater part of the time light is seen through them.. Experience will teach that solid masses should be used sparingly, and if the design contains large objects they should be broken with half tones so that the lightness of the material is not destroyed. In single cover—that is, with ground work woven in fine yarns of warp and weft—with heavy second weft to make the pattern by interlacing with the ground yarns, where this weft is not attached to the ground to make pattern, it is afterwards cut away by means of a clipping machine. Although the effect of this is one colour in white, cream, or ècru, a great variety of effect can be obtained by using the weft in horizontal lines, with ground showing between, or by dots [15]. The more even the weight is the better the curtains will hang. It is not necessary to work the design elaborately with lines; a half-tone wash will show what is intended. Make the design on thick tracing paper or ordinary brown paper, so that the effect is always seen light on dark, and keep the detail large to allow for easy rendering on the ruled paper. In describing this, one warp and two wefts have been mentioned, but the designer need only think of the material as in the one weft or shuttle. The ground is not counted, it being a necessity; merely the net in which his pattern is woven.

Various qualities of this material are made, coarse and fine. Other shuttles are added, making it two, and sometimes three cover. For two, a good way is to use one for outlines

MIXTURES AND PLANTING IN WOVEN FABRICS

and half tones, using the second for "chintzing" or "planting" (described later in the heavier fabrics). These can again be mixed, giving a great variety of effects by the use of silk, cotton, and tinsel. Almost any width can be used for the repeat from 8 in. to 24 in., and any reasonable height. Should borders be necessary, keep the same height as for filling or a divisor of same.

Lace Curtains. Curtains allow much more freedom in design than Madras, and also more effects, which are best represented by flake white and washes of various depths on a dark blue or black ground. The great scope allowed is shown in illustrations **16** and **17**, by different borders on either side, free and reverse dados, etc. Almost anything can be represented in this material, as a glance at the various windows in any street will show. The beautiful qualities of hand-made lace do not concern the maker of patterns, as all the woven fabrics described in these articles are made by machinery.

Mixtures and Planting. In nearly all fabrics composed of wool or cotton, generally termed tapestry, the pattern or colour parts are made by the weft, the ground by the warp. This is always the case with the best qualities, and in the English makes. The better the material the easier it is to make designs suitable for showing the beauties of the material. Some rich effects are obtained by the use of two, three, four, and sometimes more wefts; this gives a free use of any of these colours in any way wished, sometimes mixing two together to give extra colours, if required. Of course, every extra weft adds to the cost of production. The weft having to pass at the back of warp when not required in front to make the pattern, gives a heavier and richer effect to the hanging. With a material composed, say, of two wefts and one warp, the richness of appearance can be obtained, with great saving in material and weaving, by changing the one shuttle. Both wefts can be changed if necessary, but it is better to keep one for the building up of pattern, otherwise the colouring becomes too complicated in getting different ranges. By referring to the illustration of weft "planted," it will be seen how, by a little ingenuity in arranging the design, bloom, fruit, and birds can be changed into three distinct colours, and still be counted as only one weft [**20**].

From these, again, other colours can be obtained by the mixing of the two wefts in the way shown in **18**. If a green weft be used for leaves and stem, the turnover part, when in line with the bloom, can be mixed with it, if of yellow colour the green would become lighter and greener; the same would occur with bird and fruit colour. Great care must be taken that only two colours are in a line, and that the colours do not look like bands, unless the design has been made to get this effect, and the ground is the richest or best material. There is a great variety of cloths made in this way, some of very fine quality, others coarse; but the same rules apply where more wefts are used. It is usual only to "plant" or "chintz" one of them, and three to four changes in the length of repeat will be sufficient for all requirements.

Mixtures for Cheaper Materials. In other illustrations [**19** and **21**] will be seen another method of mixtures, the same again combined with planting. This is generally a cloth of cheaper quality, but capable of giving a greater variety of effect, and is useful for coverings and general hard wear, owing to its presenting a harder surface when well made. In this fabric the colours are generally derived through the warps, the wefts in most cases being a black and cream. These are apparently only used for outlines, and should never be in large masses, as they are generally of poor quality. Their great feature is that when used for tying down or mixing with the warps, two effects of colour can be obtained. In examining the illustration **19**, it will be seen that in part of the leaf black lines cross, in another white lines. This explains the method; although the lines are tied, it is not exactly in this way, it being impossible to show in black and white, but it will serve to show how two colours are made. It is not necessary to show either the black or cream in the drawing. Two tints of the same colour, but different weight, and that the mixture with black always gives the best effect in cloth only have to be considered.

It will be seen that, given three warps and two wefts, eight distinct tones can be used, but the six colours will consist of two shades from the three warps. Sometimes a fourth is added for ground; in this case it is generally of wool, serving to give a richer material. This is used solid, and not mixed to give a double effect with the wefts. Many varieties of this cloth are made with the black suppressed, except for mixing purposes, and the same with the cream. It can also be "planted," as shown in **21**, getting almost endless varieties. The drawing for this should be kept on the large side, as there is a slight straightness or stepped effect when carried into the squares, resembling the effect of Brussels outline.

Silk Wefts and Cotton Warps. A very beautiful and rich material of modern invention is made, in which the wefts are of silk, mixed with warps composed of cotton threads, generally in white and red. These are only perceptible on close examination, but the result given to the fabric is amazing in its variety of colour when folded. The outline is a weft and plays no part in affecting the appearance of the silks. It can, therefore, be made white, black, or any colour the weaver wishes. In the more costly productions chenille is used, adding another contrast in surface. The colour effect is obtained from the floating surface of silk wefts; so if one, two, or three wefts are used, two colours can be made from each by the white cotton coming on to the surface to give the light shade, and the red showing in the other parts to give the deeper shade. With three wefts six colours can be produced.

Chenille. This is a very beautiful fabric of cut pile, composed of fine wool dyed in every conceivable shade. It is used principally for curtains, but sometimes in mixtures with

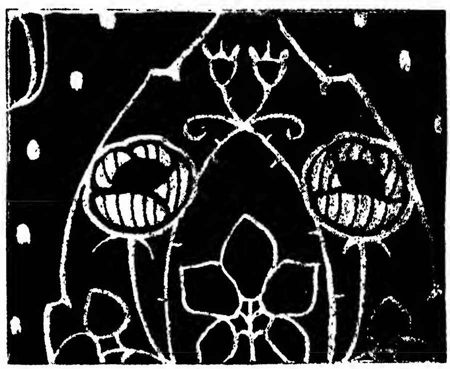
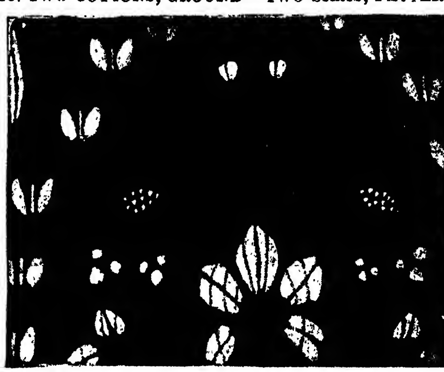
23. DAMASK—SHOWING EFFECTS BY MIXTURE OF WARP AND WEFT

24. BROCATELLE, SHOWING BOLD DRAWING



25. TWO COTTONS, GROUND—TWO SILKS, PATTERN



26. BOTH SIDES OF REVERSING CLOTH

DESIGN FOR WOVEN SILK FABRICS

silks for outlines, etc., in other fabrics. For hangings, it is an ideal material, as it is practically the same in colour and design on both sides. There is no limit to colour or scope in arrangement of design. The same freedom exists as in lace curtains. Unlike any other fabric, there are no technical difficulties in the matter of warps and wefts; the colours are woven on to a continuous weft, which passes backwards and forwards in the width of curtain, falling exactly over each other, and building up the curtain with loops and ties in the warp. The sizes to bear in mind are the widths of curtain, which should always be in yards—from 1½ yd. to 2 yd. in width, and 3 yd. to 4 yd. in length. Borders 9 in. in width, and always repeating in the same height as filling.

Make the design on thick cartridge paper, in solid tempera colours, so that it will bear rough usage when passing through the factory. This advice applies to designing for every purpose. The drawing is looked upon as for a practical purpose, not as a work of art, and in most cases is cut up and marked in such a way that it becomes unrecognisable.

Silks. The most simple and beautiful form of silk to design for is damask. Whether it be made in pure silk (though called silk, it is generally a satin ground) or in polished cotton the result is invariably pleasing. In nearly every case in which the effect is obtained by one warp and weft, the ground is the most expensive part of the material, and should always have the larger portion of the repeat. Mixtures can be obtained by lines or dots of the pattern giving effects of tones from the ground as shown in 23. They need not be carried out in this way, as a wash in the shape required will do; but it must be used sparingly, otherwise it will tend to destroy the brilliancy of the fabric, and the sharpness of the design.

Damask fabrics are used for a great variety of purposes, the finest being for dress material. Some of these are so fine in quality that a line drawn by pencil can be reproduced. In making a design for them it is usual to draw it with pencil on white paper, giving the effect of shading with slight washes of colour. In all silk materials requiring pattern the imagination has to come into service, for it is impossible in the design to give an imitation in any way of the fabric and at the same time make a practical drawing. Coarser qualities are used for furniture coverings, hangings, tablecloths, etc. Widths in general use are 21 in. or divisions up to 31½ in. or 63 in. Care should be taken in regard to height, as even in the finest quality the pattern must be put on ruled paper, as with a carpet, and cards cut and laced together, forming an endless band, the whole of which must be turned over in making a repeat.

Brocatelle and Brocade. This is a heavier fabric than silk damask, backed with a solid substance which gives to it a full or rounded effect. The raised figure or design is in this the richest part of the material. It is usual, therefore, to show but small portions of the ground. The drawing must be bold [24] and keep the quality of roundness so that the richness of the surface is aided. The sizes usually follow those given for silk damask, but, of course, small divisors or small repeats would not give the large effects required, 10½ in. side or reverse making 21 in. or 31½ in. reversing to make 63 in. width.

Brocade is a very elaborate and costly fabric. Many wefts are used to give a great variety of colours and mixtures, and its best form is seldom used, unless for very special purposes, as in some cases only a few inches can be woven in a day, owing to the fineness of material composing the pattern.

Silk Mixtures. A great variety of silks are made with mixtures of silk, satin and cotton. The ground in these, as in the case of silk damask, is always the richest part. A small piece with two silk wefts—one for outline, which can also be mixed with ground, giving half-tone, and the other for colouring the pattern—is shown in 25 and 26. This can be "planted" or "chintzed" when carefully arranged, two, three, and four changes being given to this weft, adding to its variety.

It is necessary for the silk to float or come away from the ground, otherwise the gloss or sheen would not be retained. This cannot be done in large masses without tying them to the ground by the warp in some way, because the silk would fray or get away from its original shape. To obviate this and to keep some of its natural beauty, ties are introduced as shown in 22, about a quarter of an inch apart, which are made by the warp. These must be put into the design, following, if possible, the drawing in the design, helping to give it more expression. Care must be always taken to keep them as near as possible to perpendicular lines in order to cut the weft in fairly equal proportions.

Cheaper Silk Fabrics. The ground can also be planted, if a striped effect is desired, by making on the edges of different colours, a small trailing pattern in the outline weft. This will soften the contrast and give the fabric a lighter appearance. Sometimes three wefts are introduced so that two colours for all-over purposes, and one to change or plant, are obtained. In cheaper qualities cotton is substituted for the cream outline, and if used sparingly gives a very good effect. Owing to the dulness of cotton the silk or satin looks much brighter by contrast. Some silks are made with the patterns showing equally on both sides, but, of course, reversed [see 25 and 26]. For these, like all cheaper forms of silk, it becomes more difficult to make satisfactory patterns owing to the complications in weaving. Generally there are two ground colours, cottons, which dovetail into one another. Outlining and making pattern on these are two silks, which can be mixed with the cotton, giving other effects, serving to hold the fabric tighter, and giving a more varied surface. It is impossible in this cloth to give extra effect by "planting," as what fills in a shape on one side becomes outline on the other. This reversing quality must always be borne in mind.

THE CHURCH AS A CAREER

The Church of England and Nonconformist Denominations. The Roman Catholic Church and the Jewish Ministry. Examinations and Colleges

THE CHURCH OF ENGLAND

By R. Mudie-Smith

THOSE who wish to become candidates for Holy Orders should apply for entrance into one of the theological colleges of the Church of England [see list below]. Every application is considered on its merits, regard being taken as to the evidence of personal piety and promise of fitness for the ministry apparent in the candidate.

The full course of preparation sometimes occupies three years (or two years if the Central Examination is taken before entering college). Two examinations, the Central Examination for non-graduates and the University Preliminary Examination for Holy Orders, have to be encountered in the course of preparation, besides the personal examination of the ordaining bishop.

Entrance Examination. The "Central Examination" is required by all the bishops before admission to a final course of two years' study in a theological college. It is an entrance examination in the sense that it admits to the beginning of the two years' theological course, but it is not intended to debar candidates from previously entering a theological college for preparatory training.

The following are the subjects of this examination prescribed for 1907 and 1908:

1. Xenophon's Anabasis, Book III.
2. Cicero, De Senectute.
3. Outlines of Scripture History.
4. The gospel of St. John, Chapters I–XII for translation and interpretation.
5. Outlines of English History: Text books recommended—*Outline of English History* and *Oman's History of England* (Gardiner).
6. The first book of Euclid (the paper will include easy deductions), or Elementary Logic or Modern Geometry.

Candidates are exempt who have passed any of the following examinations: (*a*) The Oxford and Cambridge Senior Local; (*b*) Examination for Higher Certificates of the Oxford and Cambridge Joint Board; (*c*) the London University Matriculation, provided that the candidates shall have passed in Latin and Greek; (*d*) Responsions at Oxford; (*e*) Previous Examination at Cambridge, Parts I. and II.; (*f*) one examination after Matriculation in Trinity College, Dublin; (*g*) examinations for the title of Associate in Arts of any of the recognised University Colleges in England; (*h*) Matriculation Examinations in Colonial and other Universities: provided that in all cases the candidate shall have passed in Latin and Greek, and that the certificate of having passed any one of the specified examinations shall have been obtained within three years of the examination from which he desires to be exempted. In examinations which do not include Scripture subjects, the candidate will be required to pass in the outlines of Scripture history and in the selected gospel.

Method of Application. Examinations are held three times a year—viz., in the first week of December, in the second week before Holy Week, and in the last week of July.

CHURCH OF ENGLAND THEOLOGICAL COLLEGES

Name of College.	Terminal charges inclusive: (1) Tuition (2) Board.	Average length of residence required.	Principal.
Chichester Theological College	(1) £35 per annum; (2) £55 per annum	For non-graduates two years. For graduates one year	Rev. Preb. Rickard, M.A.
Wells Theological College..	(1) £30 per annum or £10 per term; (2) £75 per annum	Four terms..	Rev. H. L. Goudge, M.A.
St. Aidan's Theological College, Birkenhead	(1) and (2) resident students £24. Non-resident, £14 per term	Six terms. Three terms for graduates	Rev. A. J. Tait, M.A.
Cuddesdon Theological College	£30 inclusive	Five terms (if possible) ..	Rev. Canon Johnston, M.A.
Lichfield Theological College	In college (1) and (2) £30 per term. In lodgings, £13 16s. 8d. per term	For non-graduates two years. For graduates one year	Rev. Preb. E. Elmer Harding, M.A.
Salisbury Theological College	(1) and (2) £30 per term. Four terms	For non-graduates two years. For graduates one year	Rev. Canon D. Whitefoord, D.D.
London College of Divinity (Highbury)	(1) £10 per term; (2) £45 per term	Non-graduates two or three years. graduates one year	Rev. A. W. Greenup, D.D.
Lincoln Scholæ Cancellarii	(1) and (2) £81 per annum inclusive	Non-graduates two years. Graduates one year	Rev. Canon Crowfoot.
Ely Theological College ..	(1) and (2) £30 inclusive ..	One year	Rev. Canon B. W. Randolph, D.D.
Leeds Clergy School ..	(1) and (2) £27 10s..	One year	Rev. J. G. Simpson, M.A.
Wycliffe Hall, Oxford ..	£25 inclusive per term	One year	Rev. W. H. G. Thomas, D.D.
Ridley Hall, Cambridge ..	(1) and (2) £25 per term	Three terms	Rev. T. W. Drury, B.D.
St. Stephen's House, Oxford	(1) £5; (2) £16 ..	Graduates one year ..	Rev. G. H. Brown, M.A.
St. Michael's College, Aberdare	(1) and (2) £70 ..	Non-graduates two years. Graduates one year	Rev. H. R. Johnson, M.A.
House of Sacred Mission, Kelham	(1) £20; (2) £40 ..	Six years	Rev. H. Kelly, M.A.

Candidates for examination, and candidates who present a certificate of an equivalent examination, must apply through the principal of the college at which they propose to enter or of which they are already probationary members.

These applications must be made on or before November 1st for the December examination, on or before March 1st for the March examination, and on or before July 1st for the July examination. Each applicant must state in his application which of the alternative subjects, Euclid, geometry, or logic, he intends to take.

A fee of 15s. is charged to every candidate, and the fees as well as the application must be sent to the principal of the college. The papers set in previous examinations can be obtained from Deighton, Bell & Co., Cambridge, price 1s. 1d. for each year.

The University Preliminary Examination. The University Preliminary Examination for Holy Orders is taken at the end of the student's complete course. It is conducted under the control of a council consisting of the divinity professors of Oxford and Cambridge, two graduates in divinity from each university nominated by the Archbishop, and examining chaplains, one being nominated by each of the bishops, who accept the results of the examination.

The examinations begin on the Tuesday in the second week before or after Easter which is nearest to April 3rd, and on the Tuesday nearest to October 8th.

The examinations are open to (*a*) graduates of the English universities; (*b*) members of theological colleges in connection with the Church of England who have at least entered on the last term of the complete course and are recommended by the principal; (*c*) any other person who may be nominated by a bishop with a view to ordination in his own diocese.

The examination consists of the following subjects:

1. A general paper on the contents of the Bible.
2. Old Testament: selected portions:
   (*a*) Psalms i.-xli. (for 1907); xlii.-l., lxxiii.-lxxxix. (for 1908).
   (*b*) Northern Kingdom and Amos for 1907-8.

The paper in these books will contain questions on their subject matter, criticism, and exegesis, together with questions on "Introduction." An opportunity will be given of showing a knowledge of the Hebrew text on the set books.

3. New Testament (in Greek).
   (*a*) St. Luke.
   (*b*) Romans.

The paper on these books will contain passages for translation and questions on the subject matter, criticism, and exegesis of the books, together with questions on "Introduction." Candidates will also be expected to show a general knowledge of the Lord's life and teaching as contained in the four Gospels. Passages from English Version will be given to be rendered into the original Greek.

4. (*a*) The Creeds and the Thirty-nine Articles; history text and subject matter:
   (*b*) Apologetics.
5. The Prayer Book: history and contents.
6. Ecclesiastical History:
   (*a*) History of the Christian Church to the Council of Constantinople (inclusive).
   (*b*) History of the English Church from the earliest times to the Accession of Queen Anne.
7. A selected work or works of a Latin ecclesiastical writer (1907), Cyprian, De Oratione Dominica.

A passage will also be set for translation into English from some ecclesiastical Latin author not previously specified.

8. A voluntary paper on elementary Hebrew with passages for translation (1907): 1 Kings xvii.-xix., 2 Kings iv., v.; Amos.

Candidates are required to satisfy the examiners in each of the first seven subjects.

A fee of 25s. is charged to every candidate who enters the examination.

Candidates are required to send in their names with certificates of moral character and particulars of their degrees, or written forms of nomination from bishops in cases where such nominations are required to Rev. Dr. King, Gayton Rectory, Blisworth, R.S.O., before March 1st for the Easter examination and before September 1st for the October examination.

The papers given in previous examinations, with the regulations, etc., may be had of Deighton, Bell & Co., Cambridge and London, and Parker & Co., Oxford, price 1s. each set, or by post on receipt of 13 stamps.

Candidates, in sending in their names, must give a permanent address.

The Student's Expenses. Students at Oxford and Cambridge can, if they are economical, limit their terminal charges in some colleges to £30. The annual expenses, including subscriptions to college clubs, need not exceed £100. The three-year course, consisting of nine terms, would cost, therefore, about £300. The expenses of a non-collegiate student in the universities who is willing to live frugally and who keeps only the minimum residence in each term, can be kept under £55 per annum on an average of the three years. This sum includes university and non-collegiate charges. The course for arts in the B.A. degree at the University of Durham consists of two years of three terms each.

At University College the average terminal charges are £26 5s., and at Bishop Hatfield's Hall £24. The total, therefore, at the former for the two years is on the average £157 10s., and at the latter £144.

The Ordination Candidates' Exhibition Fund aims at helping young men of thoroughly good qualifications whose means are insufficient to enable them to complete what is required for college training. For full particulars apply to Rev. Canon Petit, M.A., 39, Victoria Street, Westminster.

The following is a list of other funds designed for a similar purpose, and the name of the clergy and others to whom communications should be addressed:

The Cambridge Graduates' Ordination Fund. Professor Stanton, Trinity College, Cambridge.

London Clerical Education Aid Society. Rev. H. F. S. Adams, The Vicarage, Streatham Common, S.W.

Cambridge Clerical Education Society. Rev. G. A. Weeks, Sidney Sussex College, Cambridge.

The Elland Society. Rev. Canon Lamb, Clapham Vicarage, Lancaster.

Bishop Clerical Education Society. Rev. P. A. Phelps, 29, Berkeley Square, Bristol.

Dr. Robinson's Exhibitions. Rev. W. Allen, St. Mary's Lodge, Loughton.

The Society of the Sacred Mission undertakes (where necessary) the whole cost of the student's six years' training at their Theological College, Kelham, but students are expected to repay a sum not exceeding £250 by instalments after ordination. There are a large number of applications—over 300 every year—of which only 20 are accepted.

The Bishop's Examination. Persons desirous of being admitted as candidates for Deacon's Orders must make a written application to the bishop three months before the time of ordination. A paper of questions will be forwarded to any person so applying, which he will be required to answer. After due investigation the bishop will fix a time for seeing him. It is not necessary that a person so applying should at the time of his application be provided with a title, which may be sought for afterwards upon the bishop's permitting him to become a candidate.

Candidates for ordination must be under thirty years of age. No candidate can be ordained deacon who has not completed his twenty-third year.

Candidates for Deacon's Orders must supply the following papers:

1. Certificate of baptism.
2. (*a*) If the candidate is a graduate of Oxford or Cambridge—Certificate of his having taken B.A. degree, and also having attended two courses of lectures by divinity professors, one of which must be a course by the Regius professor. (Such certificates are not required if a candidate shows that he has taken honours in the Theological School or has spent a year at a diocesan theological college, or has passed the University Preliminary Examination of Candidates for Holy Orders.)
   (*b*) If the candidate is a graduate of Dublin University—The certificate of his having taken the B.A. degree and also the Divinity Testimonium.
   (*c*) If the candidate is a graduate of Durham University—The certificate of his having taken the degree of B.A. and also the Licence of Theology.
3. College testimonials.
4. Testimonials for the time elapsed since the candidate left college.

Examination for Deacon's Orders. The subjects of examination for Deacon's Orders differ somewhat in each diocese, but the following are the subjects prescribed for the London Diocese, 1907. The books suggested for the course of study are given in italics:

1. The Old Testament:
   (*a*) General knowledge of the contents and interpretation. *Old Testament History* (G. W. Wade), *Old Testament History* (Edersheim), *History of the Jews* (Ottley), *The Cambridge Companion to the Bible*, *The Divine Library* (Kirkpatrick), *Introduction to Old Testament* (G. H. H. Wright).
   (*b*) Subjects for special study: Book 1, Ps. i., xli. *The Psalms, Book* 1 (Kirkpatrick).
   (*c*) The Hebrew Text of Psalms i.–ix. (optional).
2. The New Testament:
   (*a*) General knowledge of the contents and interpretation. *Life and Times of Jesus the Messiah* (Edersheim), *Introduction to the Study of the Gospels* (Westcott), *Introduction to the New Testament* (Salmon), *The Books of the New Testament* (Pullan).
   (*b*) Special subject for study in the Greek text: the Gospel according to St. Luke. *International and Critical Commentary* (Plummer), *Cambridge Bible* (Lias).
   (*c*) Oral examination on the contents of the four Gospels. (The Greek text required.)
3. (*a*) The Book of Common Prayer, history and contents. *Prayer Book Commentary* (S.P.C.K.), *A New History of the Book of Common Prayer* (Proctor and Frere), *Teachers' Prayer Book* (Barry).
   (*b*) Ecclesiastical history. The history of the English Church from the earliest times to the accession of Queen Anne. *The Students' English Church History* (Perry), *History of the Church of England* (Wakeman).
4. The Articles of Religion.
   The Thirty-nine Articles (Bishop Gibson), *The Thirty-nine Articles* (Bishop Harold Browne).
5. Latin.
   (*a*) S. Cyprian, De Oratione Dominica. *Edition issued by G. Bell & Son.*
   (*b*) A piece of English to be translated into Latin.
6. Evidences of Christianity.
   Evidences of Christianity (Ragg), *Manual of Christian Evidences* (Row).

The papers required by a candidate for priest's orders are these:

1. A testimonial from three beneficed clergy similar to that which is required for deacon's orders; but only for the time which has elapsed since the candidate's ordination as deacon.
2. Nomination to a curacy, or presentation to a benefice—unless he be already licensed in the diocese, in which case a nomination is not required.

Examination for Priest's Orders. The following are the subjects of examination for priest's orders for the London Diocese, 1907.

PART I. (Advent and Lent)

1. The Old Testament.
   (*a*) General knowledge of the contents and interpretation. *Old Testament History* (G. W. Wade), *Old Testament History* (Edersheim), *History of the Jews* (Ottley), *The Cambridge Companion to the Bible*.
   (*b*) Subject for special study: Jeremiah. *Cambridge Bible* (A. W. Streane), *Expositor's Bible* (C. J. Ball), *Jeremiah: his Life and Times* (T. K. Cheyne).
   (*c*) The Hebrew Text of Jeremiah xxvi–xxviii. (Optional).
2. Dogmatic theology, based on the Prayer Book and Articles.
   Prayer Book Commentary (S.P.C.K.), *A New History of the Book of Common Prayer* (Procter and Frere), *The Thirty-nine Articles* (Bishop Gibson), *The Thirty-nine Articles* (Bishop Harold Browne).
3. Butler's Analogy.
4. Pastoral work. *Parish Priest of the Town* (Gott), *Self Discipline* (Gibson).

PART 2. (Trinity and September)

1. The New Testament:
   (*a*) General knowledge of the contents and interpretation. *Life and Times of Jesus the Messiah* (Edersheim), *Introduction to the Study of the Gospels* (Westcott), *Introduction to the New Testament* (Salmon), *The Books of the New Testament* (Pullan).
   (*b*) Subject for special study in Greek text: the Epistle of St. Paul to the Romans. *International and Critical Commentary* (Sanday and A. C. Headlam), *Cambridge Bible* (Moule), *Practical Exposition* (Gore).
2. Ecclesiastical history. The history of the Christian Church to the Council of Constantinople. *The Student's Ecclesiastical History*, *History of the Christian Church to* 461 (Foakes-Jackson), *History of the Christian Church* (Robertson).

3. Hooker's Ecclesiastical Polity. Book V.
4. Foreign Missions (Bishop Montgomery), published by Longmans.

The Declaration. The following declaration must be made and subscribed, and oath taken and subscribed, by all persons who are to be ordained deacon or priest:

"I, M. N., about to be admitted to the Holy Order of ——, do solemnly make the following declaration: I assent to the Thirty-nine Articles of Religion, and to the Book of Common Prayer, and of the Ordering of Bishops, Priests, and Deacons. I believe the Doctrine of the Church of England, as therein set forth, to be agreeable to the Word of God; and in Public Prayer and Administration of the Sacraments I will use the Form in the said Book prescribed, and none other, except so far as shall be ordered by lawful authority.

"I, M. N., about to be admitted to the Holy Order of ——, do swear that I will be faithful and bear true allegiance to his Majesty King Edward, his heirs and successors, according to law. So help me, God."

Every clergyman about to be licensed to any curacy has to take the oath of canonical obedience to the bishop, and make the Declaration of Assent.

The Oath of Canonical Obedience. "I, A. B., do swear that I will pay true and canonical obedience to the Bishop of ——, and his successors, in all things lawful and honest. So help me, God."

Lectures. The bishop requires deacons during their diaconate to attend courses of lectures, of which they will receive notice. The bishop also desires that the younger clergy in the diocese should attend.

THE JEWISH MINISTRY

By Nathaniel Lazarus

The Jews occupy a singular position amongst the nations of the world. They have no official national government of their own. Their only recognised heads are the ministers of their ancient congregations, who are also in many cases the most prominent leaders of the community. It is, therefore, by no means surprising to learn that the Jews pay special attention to the training of their ministers. Above all, no Jew would tolerate a clergyman who, in respect of his religious and moral life, could be regarded as unfit for his post.

Course of Training. Candidates for the Jewish ministry have more than one course of study open to them. The various methods of attaining their object in view generally depend on their age and opportunities. The chief theological seminary for Jewish ministers in the United Kingdom is undoubtedly the Jews' College, of which the Chief Rabbi is president; 99 per cent. of the Jewish ministers in England were trained at that college.

The college course consists of three distinct divisions—preliminary, junior, and senior.

Candidates for the preliminary class must be fourteen years of age, and pass an *elementary* Entrance Examination in two secular subjects (modern language, or mathematics, or science, or Latin), in English and in Hebrew and theological instruction. The course of study in the preliminary class is so arranged that pupils, on leaving it, attain the grade of the Matriculation Examination of the University of London and of the first theological college certificate. On passing that stage successfully, candidates join the junior class of the college. During that period of their training the students are attached to the Faculty of Arts at University College, University of London, where they pursue an internal course, reading for the B.A. Honours degree in Semitics. At the same time the students are required to attend a series of lectures in Hebrew and religious knowledge at the Jews' College, for the purpose of enabling them to pass the Second Theological Examination.

On completing the intermediate course, candidates devote themselves entirely to the study of Semitics, Arabic, Aramaic, Syriac, homiletics, theology, Jewish history, and literature. At that stage they attain most of the knowledge they ultimately require in discharging their duties as ministers. The curriculum nominally extends over two years, at the end of which successful candidates obtain the B.A. degree and the third theological certificate. The title of Associate of Jews' College is granted to such students.

With those qualifications in hand, candidates are generally regarded fit for the ordinary work of a minister, provided they are not too young. The age of twenty-five is considered to be a reasonable one for beginning duties.

The Diploma of Rabbi. Ministers who decide on entering communal life at that stage postpone for an indefinite period their chances of promotion. Though in possession of the third theological certificate, they have yet to work for the greatly esteemed and extremely valuable Rabbinical diploma. Ministers in possession of an English University degree and of the above-mentioned diploma are assured of successful careers. A special class is attached to the Jews' College for the preparation of students for the Diploma of Rabbi. Before entering that class students must have passed the third theological examination, together with the degree examination of some recognised university. The course of study in that class comprises Talmud and Responsà. It extends over two and a half years. The examination for the diploma is a very strict one, and it is conducted by the greatest Jewish authorities in this country. The title of Fellow of Jews' College is granted to successful candidates.

Scholarships. The Jews' College not only charges no fee for the education received within its walls, but it also bears the cost of the course at University College. Students are, however, expected to use their own books. There are about ten valuable scholarships attached to the college in support of the poorer class of students.

Needless to state, students are not restricted to starting their course of study in the preliminary class. They can join the junior or senior classes on passing the necessary examinations.

A few valuable scholarships are given to graduates of English universities in possession of the third theological certificate who wish to continue their studies at famous Continental seminaries. During that period of their study students can also avail themselves of this opportunity to obtain the German Ph.D. degree, which is a very good qualification for an Anglo-Jewish minister. Though they are often called upon to sit in the Beth-Din (Jewish law court), where various disputes are settled in the light of Jewish law and custom, very few ministers have found it expedient to read for the LL.B. degree, London.

Those who enter on the career of a minister when they are advanced in years must make every effort to pass the Third Theological Examination and to obtain the B.A. degree as soon as possible. Such students may also find it expedient to go abroad in order to obtain a rabbinical diploma from foreign rabbis. They can afterwards return to England as fully qualified ministers. It may prove

interesting to note the fact that such a diploma is almost essential for ministers in the Jewish districts of the East End of London and other foreign communities which are not so much in need of university graduates.

Aria College (Portsea, Hants) and Judith Montefiore College (Ramsgate) are two other theological seminaries conducted on the same lines as the Jews' College. At the former, preference is given to Hampshire men. Young ministers, as a rule, start work in a provincial town. Eventually they make every endeavour to receive an appointment at one of the more famous West London congregations. There are, however, a few exalted posts to which many a Jewish minister looks forward. Such are the positions of Chief Rabbi, Haham of the Spanish and Portuguese Jews, and Dayan (judge) of the Beth-Din (law court). The work of a Jewish minister can be divided into two distinct parts—congregational and charitable. He has to deliver sermons on Saturdays and all other important occasions. He is, to a certain extent, responsible for the religious and moral spirit of the members of his synagogue. He is also expected to take an active part in the charitable and communal affairs of the district under his care. In connection with his latter duties there is a ministers' committee which regulates their work in the East End of London.

The duties of a Jewish minister entail a great deal of very hard work.

THE ROMAN CATHOLIC CHURCH

By Henry Brassill

People outside the Catholic Church do not, in many instances, realise the solemnity attaching to the dignity of a priest. By his spiritual subjects the priest is recognised as the Lord's Anointed.

One would cease to be a member of the Church without formal excommunication if he did not believe in the doctrine of the Real Presence, and the chief reason for peer, as well as plebeian or peasant, for saluting a priest after the manner of a gentleman saluting a lady is that the passing clergyman may be on a sick call and have in his possession the Adorable Sacrament. There is another reason why Catholics pay public respect to a priest—viz., that he is empowered to consecrate, to adjudicate in the tribunal of penance and to discharge other sacred functions.

It is indeed an arduous trial for young or old to be raised to the sacred office. When we use the words "young or old," we mean that age is no impediment. Cardinal Manning had been an archdeacon of the Church of England and a married man before his future Eminence "went over to Rome"; the late Rev. Lord Thynne was father of the Dowager Countess of Kenmare, and officiated at the marriage of his grandson, the present earl, with the Hon. Miss Baring. Cases of this kind may be multiplied. We can name twenty priests in and around London who had been Anglicans, some by profession medical doctors, some military officers, and others who might have made their mark in the professions of which they were originally members, but the call to the sacerdotal office having come, they loyally obeyed, and are at this moment ideal workers in the vineyard.

Newman, the author of "Lead, Kindly Light," was a great Anglican divine; the late Dr. Luke Rivington was a Cowley Father and a strong Freemason; Father Fletcher, son of a baronet, now Master of the Guild of Ransom, was an Anglican clergyman; Monsignor Walter Croke Robinson, a present day preacher of fame, was at one time an Anglican clergyman also, but all had had to take the usual steps to qualify for the Catholic ministry.

The Priest's Oath. To do this it is essential that the candidate, before entering college or house of study, is prepared to make a solemn oath or vow with regard to celibacy. If going in for one of the monastic orders he has to take the triple vow of poverty, chastity, and obedience. Every nun does likewise, and some Orders are very strict with regard to the creature comforts of their members.

There is no distinction of class as to the eligibility of the aspirant to the sacred office, but persons born out of wedlock are objected to. This is especially the case in Ireland, which verily is the cradle of the bulk of English-speaking Catholic clergymen.

The great college of Maynooth has, perhaps, turned out more priests from its hallowed walls than any other. In order to enter, there is held yearly in each diocese a concursus, at which the aspirants are examined in Latin, Greek, and English. The examiners are divines of learning and erudition, and the candidates are dealt with according to merit. There are also colleges at Thurles, Carlow, Waterford, and numerous seminaries throughout Ireland, not the least of which are St. Brendan's, Killarney; Holy Cross, Tralee; St. Michael's, Listowel; and Blackrock, Dublin.

All over the world care is taken that the future priest shows a vocation for the sacred calling. With rare exceptions in Ireland the aspirants start at an early age. The intending secular priest remains all the year round, with the exception of a short holiday, in his *alma mater*. This is also the case of students in English colleges, but many in this country are fully fledged, staid men who know a great deal of the world before they resolve to embrace the sacerdotal calling and enter Stonyhurst, Oscott, or St. Edmund's. Students for the religious orders such as Franciscans, Dominicans, Servites, Carmelites, Prémontré, etc., pursue their course in their respective houses of study until pronounced eligible for Orders.

Cost of Training. The education of a student entering Maynooth College costs some £600, but those by ability who pass into the Dumboyne Establishment get through at a considerably lesser figure.

Another great ecclesiastical college in Dublin is that of All Hallows. It is situate at Drumcondra, and year by year sends to foreign parts, such as Mill Hill, London, priests for missionary service. All Hallows men may be found all over the globe. The pension, or collegiate fee, is considerably less than that of Maynooth, and when the student decides where to carry out his ministrations, in Australia or other distant lands, the bishop of the particular diocese which he selects to be attached to contributes largely to his expenses—in fact, he pays his college fees.

But the most expensive college in the world is that known as "The Pontifical Roman Seminary," in the Eternal City. Only Italian students are admitted to it, as it is the great seminary for the whole of the country. There are minor colleges, but Italian students are never considered to have completed their education without spending a time in the "Pontifical Seminary." A student may be ordained after twelve years' study in this establishment, during which time he may qualify for degrees such as D.D., Ph.D., LL.D., etc. Before getting a degree one must be at least three years in the college, and he must win his laurels by hard work and study.

The Priest's Salary. The salary of a priest both in Ireland and in England is merely nominal. His emoluments in this country, as a rule, are not on a par with a boy's wages. Many have private means—we are alluding to seculars—but the majority are gentlemen who possess little more than the raiment upon them, and who care nought for the world's goods.

The religious orders, or communities, should, perhaps, be referred to. The noble work of the Franciscans, say at Peckham and Forest Gate; the Dominicans at Haverstock Hill; the Servites at Fulham; the Canons Regular of Lateran at Stroud Green; the Passionists at Highgate; the Jesuits at Farm Street and Stamford Hill (Father Bernard Vaughan, S.J., and Father Donnelly, S.J., being perhaps the two most prominently before the public just now); the Salesians at West Batersea, cannot be overrated, and is something difficult to describe if not to conjure with.

Priests live in London from, as it were, hand to mouth; they have consecrated their lives to their duties, and go to their graves penniless—that is to say, they have no money at their death to will away.

Take the case of the *Soggarth Aroon*, who spends his life in Ireland. Often he is summoned in the middle of the night to attend a sick call in a mountain home, miles away. He leaves his bed, goes to the sanctuary where the Blessed Sacrament is reserved, takes the sacred species with him, and, regardless of the dangers of hill-side passes, finds his way to the humble cabin in which a poor soul is throbbing for solace so as to fittingly prepare to appear before its God.

Speaking of Ireland, the clergy hold what they call "stations" twice a year; they are generally held in the homes of the well-to-do. This is a very old custom, and the object is to enable the aged, infirm and feeble generally to comply with the obligations of the Church by going to confession, assisting at Mass, and receiving the Bread of Life. Lent and Advent are the periods of the year when the "stations" are held, and the results are fruitful. An improvised altar is erected at which the service takes place.

A Catholic ecclesiastical student undergoes severe examinations. Humanity, rhetoric, philosophy, logic, and theology, stare and confront him as he leaves the preliminary school before venturing to face the ordeal of being examined in the minor subjects. He is taught in a seminary or a private school before venturing to appear in the presence of the Board of Examiners, and in the event of being successful—"getting a place," as it is called—he enters, say, Maynooth College. Here he studies, and in some four years receives Tonsure and Minor Orders. All well, in a year, he receives Full Minors; a year later he is raised to the sub-Minor. Twelve months after he is raised to the subdiaconate, and possibly another year may roll by before he is made a deacon. The conferring of the Order of the Priesthood, as a rule, follows immediately that of the diaconate, although in some instances students receive the three orders—subdeaconship, deaconship, and priesthood—in the same week. The reason assigned for this is that once a candidate is raised to subdeaconship he has to read his Office, which occupies two hours each day—a rather severe strain upon some who have to study very hard during the remainder of their course. The recital of the Office is obligatory, and a divine is only excused from complying with the mandate in case of illness.

After being raised to the priesthood the newly ordained is immediately sent to work. His rector or P.P. is a reverend brother of experience and mature years. The curate's "salary," if such it can be called, is barely sufficient to provide for clothing and holiday money.

The newly ordained priest says precisely the same Mass as the Holy Father who is supreme head of the Catholic Church. The writer has been in five different countries outside his own, and has had the privilege of attending Mass in each—even on the high seas he has assisted at the Holy Sacrifice—and no matter what the nationality of the officiant or celebrant was, the service was exactly the same as that which in the days of his childhood the writer assisted at in the little chapel at Irremore, County Kerry.

Chances of Promotion. Promotion is very slow in the priesthood everywhere. But a humble curate may be raised to the dignity of bishop. The present occupant of the See of Limerick—Most Rev. Edward Thomas O'Dwyer—was not even a parish priest when the crozier and mitre of his illustrious predecessor, Most Rev. Dr. Butler, were placed in his hand and on his head. The chapter in each diocese in England nominate three ecclesiastics, whose names are placed on what is called the *Terna*, and submitted to the Holy See. In Ireland the parish priests meet, and, as is the case all over the world, Mass of the Holy Ghost is celebrated. After, this the chalice used at the Mass is placed upon the altar. No one is present except those entitled to vote, and the cathedral, or pro-cathedral, doors are barred. In England each member of the chapter, and in Ireland each parish priest, writes the name of the cleric whom he believes to be fitted for the distinguished office. The archbishop of the province presides, and two scrutineers in his presence count the votes.

Three names are sent to Rome, the one having the highest number being described as *dignissinus;* the second, *dignor*, and the lowest, *dignus*—most worthy, very worthy, and worthy. The Sacred College, as in the case of the late nominations for the bishopric of Southwark, may appoint one who was not on the *Terna*, so that elevation or promotion cannot with safety be predicted by anyone.

CONGREGATIONAL AND BAPTIST CHURCHES

By R. Mudie-Smith

A candidate for the Congregational or Baptist ministry must be a member of some church belonging to the denomination, and must have completed the sixteenth year of his age. Upon applying for training to one of the theological colleges he is required to adduce the testimony of one or more ministers and of the church with which he is in fellowship to his consistent piety, mental ability, and general fitness for the work of the ministry. A general statement is also required from the candidate as to his previous history and the chief books he has read, giving his exact age, the nature of his education, his business or profession, and the period of his church membership. Other requirements are a full statement of his theological views and one or two written sermons of his own composition.

The Entrance Examination. The entrance examination includes the elements of classics, mathematics and Scripture history, and the following may be taken as a guide to the subjects prescribed:

Division I.

1. General knowledge of Scripture.
2. Knowledge and use of the English Language.
3. Preaching ability, so far as it may be tested by a sermon to be written on a given theme.
4. Speaking power, voice, etc.

DIVISION II.

1. Latin: Cæsar, de Bello Gallico, Book V., cc. 1 to 27; Macmillan's Shorter Latin Course, by A. M. Cook, M.A.

2. Greek: Xenophon, Anabasis, Book II., cc. 1 to 3; Smith's Initia Græca (any edition after 1898); Exercises 1 to 50, with the grammar of the whole book. Accuracy in Latin and Greek Grammar is essential.

3. Mathematics: Charles Smith's Arithmetic (Cambridge University Press); J. M. Wilson's Elementary Geometry (Macmillan), Book I., to page 80, with exercises.

There is also an oral examination before the College Council. This is directed chiefly towards finding out what the candidate is rather than what he knows, and testing his ability to express his views on Scriptural and theological subjects, and on other subjects relating to the work of the Christian ministry.

The Student in College. A successful candidate enters the college as a probationer. At the end of six months or sooner special reports of his work and progress are made to the committee. If these are favourable, he is then received as a student for the usual course, subject always to the receipt of satisfactory reports. The term of study is from four to six years. The curriculum is divided into a literary course of two or three years, and a theological course of two or three. In cases where a student has taken a university degree the first term is dispensed with and the student admitted at once to the theological course.

All students receive a free education with use of rooms, and, when necessary, free board. It is expected, however, that the cost of board be met wholly or in part by the student or his friends where practicable. There are also a number of scholarships open to competition, by means of which a student of promise may obtain a sufficient income to defray the whole cost of his college training.

Candidates seeking admission into colleges now recognised as university schools, and marked in italics in the list on the last page of this article, are required to matriculate that they may be registered as internal students of the university, and pursue the course prescribed for graduation in divinity. Candidates should matriculate, if possible, before entrance; if not, they must pass this examination at the end of their first, or at the latest their second. session.

The Intermediate and Final Examinations. After matriculation a year's work prepares for the intermediate examination for the B.D. degree, the subjects being Hebrew, Greek Testament, classics, psychology and ethics.

The *final B. D.* requires a two years' course, and comprises these subjects:

1. Hebrew, with Old Testament exegesis and introduction.
2. Biblical Greek, with New Testament exegesis, introduction and textual criticism.
3. Systematic theology.
4. Church history.
5. Philosophy of theism (apologetics).
6. History of religions.

THE WESLEYAN METHODIST CHURCH

A candidate for the ministry must be a baptised member of the Wesleyan Methodist Church, and a fully accredited local preacher. The first stage of his candidature is the vote of the March quarterly meeting of the circuit in which he resides. He must be nominated at the meeting by the superintendent; and if he has not resided for two years continuously in his circuit, the superintendent must present to the meeting a written report concerning him to cover the previous two years.

An untrained man of twenty-five or over is not likely to be accepted unless there be evidence of quite exceptional ability. Still more is this the case with married men, since they cannot be sent to the Theological Institution. In the rare cases where married men are accepted a financial guarantee must be forthcoming, since such a minister would receive only the income of an unmarried man until the four years of his probation are completed, and no children born before that time are chargeable on the connexional funds.

The Church takes no responsibility for the maintenance of a candidate until he has been accepted by the Conference. It is therefore important that he should not give up his employment until after Conference. Moreover, it must be understood that every accepted candidate supports himself to the best of his powers while at the institution. The charge for maintenance there is £30 a year, and for education, £35. If unable to pay these two charges, the candidate must, before acceptance, sign a declaration to this effect, to be counter-signed by his parent or guardian, and his superintendent, promising (*a*) to meet the maintenance charge, or (*b*) to pay some defined part thereof, (*c*) to find himself in clothes and books—the latter condition being assumed in the other classes. Should he be unable, through poverty, to make even the last promise, he must apply for a grant—which will not exceed £10 a year—to meet the expenses.

The Conference expects to be satisfied on certain points before accepting a candidate for the ministry: Firstly, that he believes himself called by the Holy Spirit, that his preaching has been owned of God, and that his personal character is high; secondly, that he believes and preaches the doctrines of the Wesleyan Methodist Church; thirdly, that he has competent abilities and health for the work.

Preliminary Examinations. The candidate's first examination, known as the preliminary, is elementary in character, and takes place about the middle of April. It consists of two parts:

(1) A paper on the English Bible, requiring a general knowledge of Scripture history, and of the nature and contents of the Old and New Testament.

(2) An English paper, in which simple questions in grammar, geography, history and arithmetic are set, and also a short exercise in English composition.

Those candidates are exempt from the literary paper who have passed the entrance examination of any university in the United Kingdom, or the Oxford or Cambridge Senior Local Examination, or obtained the King's scholarship as candidates for admission into a training college. No candidate is on any ground excused the preliminary examination on the English Bible.

The candidate who has been recommended by his circuit Quarterly Meeting will be duly informed by the chairman of the district as to the time and place of the first trial sermon, and of his oral examination before the Synod. The sermon is preached in the presence of three ministers of the district, and a written report of the service is presented by these ministers to the Synod.

Oral Examination. The first of the candidate's oral examinations takes place in the presence of the ministers of the Synod during its sessions in May, and the questions put will test his acquaintance with the main features of Christian theology. When the vote of the Synod has been taken, if the candidate has passed, he is informed of the arrange-

ments made for his second trial sermon. He is also informed of the date by which he must send up his MS. sermon to the General Examination Secretary.

Final Examination. Further examinations await the candidate during the second or third week in July. These take place at one of the theological colleges, where the candidate is accommodated for two or three days. Two papers, consecutive upon the preliminary papers, are now set, the first of which bears on Christian doctrine and knowledge of the leading truths of evangelical theology as taught in the Methodist Church. The second paper embraces subjects of general education.

During this time the candidate appears before a select committee of ministers for an oral examination, to test his ability of expressing his views on general, scriptural, and theological subjects.

From this committee the candidate's case is formally remitted to the Conference, which meets a few days later, for final decision; and if accepted by the Conference, the candidate is sent in the September following his acceptance to one of the theological colleges of the Church for three, or in some cases four, years' training. The distinctive studies proper to the direct work of the Christian Methodist ministry occupy the chief place in the student's attention; but facilities are also provided for pursuing a university course, if this is considered desirable.

THE PRIMITIVE METHODIST CHURCH

A candidate for the ministry of the Primitive Methodist Church, if not a minister from another community, must be a regular member and a local preacher of at least twelve months' standing. If under twenty-one years of age, his parents or guardians must give their consent to his becoming a minister.

If the candidate is a minister from another community, he must be a member of the Primitive Methodist Church for at least twelve months prior to his application, unless proof be given that he is specially useful in the conversion of sinners, and that he has fairly and honourably resigned his connection with the ministry to which he formally belonged.

No candidate must be recommended by the station with which he is connected "unless his constitution is sound and healthy, his piety unquestionable, his mental powers good, his temporal circumstances unembarrassed; nor unless he is of industrious habits, and will use prudent and successful efforts to save souls." The station must also carefully examine him concerning his views of Christian doctrine, reading and writing, and his knowledge of English grammar, history, geography, arithmetic, theology, Church history, evidences of Christianity, and the history and polity of the Primitive Methodist Church.

If such examination be satisfactory to the Quarterly Meeting, the candidate will be recommended to the Secretary of the Candidates' Examining Committee for further examination.

Oral Examination. The Oral examination is held at one of the three following centres—London Leeds and Birmingham. The examiners, time and place of examination, are arranged by the Candidates Examining Committee, appointed by the conference.

The examination is divided into four sections:

1. Reading aloud a passage selected by the examiners.
2. Writing a paragraph from dictation.
3. English grammar, geography and arithmetic.
4. Questions as to the conversion of the candidate, present Christian experience, call to the ministry, his knowledge of experimental theology, the history, doctrines and polity of the Primitive Methodist Church, his methods of study and preparation for the pulpit, of pastoral work and visitation, dealing with penitents, the conduct of religious services and the holding of official meetings.

If successful in the oral examination the candidate must conduct a public service and preach before the district representative on the Candidates Examining Committee, with the chairman of the district meeting and the General Committee delegate. The candidate must also attend the district meeting for the purpose of taking the written examination.

Written Examination. The written examination consists of these subjects:

1. *English Grammar:* Oxford and Cambridge (Gill's series).
2. *Arithmetic:* Pendlebury's up to p. 3369, omitting the following chapters: XVI., XXXV., XXXVI., XL., *e* to *k*, XLI. to XLVI.
3. *English History:* Ransome's "Short History."
4. *Theology:* J. R. Gregory's "Theological Student," and Wesley's twelve sermons, called "The Marrow of Methodism."
5. *Christian Evidences:* Prebendary Row's "Manual of Christian Evidences."
6. *Ethics:* W. T. Davison's Fernley Lecture, "The Christian Conscience."
7. *The History and Polity of our Church:* H. B. Kendall's "Short History," and "Handbook of Church Principles and Polity," the "Consolidated Rules and Deed Poll of the Connexion."

The total number of marks for the whole examination is 900; 100 for each of the seven subjects or books, 100 for the oral examination, 50 for the preached sermon, and 50 for the written sermon. The minimum for the reserve list (candidates for the ministry not applying for a college training) is 725 marks, for the college list, 630.

The written examination begins at two o'clock on the Tuesday preceding the District Meeting.

Each candidate must supply a written sermon, which must be signed by the president and secretary of the Quarterly Meeting, and sent, along with the recommendation from the December Quarterly Meeting, to the Secretary of the Candidates Examining Committee. This will be valued and marked by that committee.

Candidates who pass successfully either for the college or the reserve list, but who have neither been appointed to a station nor received into college, must attend the ensuing District Meeting for examination upon their labours and studies during the year. Should any candidate on the college list wish to take the written examination at the district meeting with a view to improving the position gained by him at the previous examination he is at liberty to do so; otherwise he must take his place on the college list, according to his number of marks.

Candidates who have graduated in arts or matriculated at any of the universities in the United Kingdom shall be exempt from taking English grammar, history and arithmetic. For the remaining subjects they must gain 475 marks for the reserve list, and 400 for the college list.

There is a scholarship (the Lamb Scholarship) which secures the advantage of the college course of training for young men who are unable to pay the usual fees and whose parents or guardians cannot assist them to do so.

THE PRESBYTERIAN CHURCH OF ENGLAND

Candidates for the ministry of the Presbyterian Church of England are not in ordinary circumstances received into the theological college until they have completed their preparation for entering on the study of theology by graduating in arts at some recognised university. With a view to assist men during the undergraduate years, a number of scholarships have been at various times founded by the generosity of benefactors. Men who have thus prepared themselves at some university are admitted to the theological college, Westminster College, Cambridge, after examination in the beginning of October in each year.

The Course of Study. The minimum curriculum of study in the college extends over nine terms or three academic years. At the beginning of each year of attendance two scholarships are awarded to students obtaining honours in the October examination. When required, pecuniary assistance of a limited amount may also be obtained in the form of "Barbour Exhibitions," also a certain number of "Hewley Bursaries" of the annual value of £40.

The college is residential. The fee of £15 per term covers all the expenses of a student for residence, board and tuition with the exception of some small extras, which together need not amount to more than £2 per annum.

Every candidate for admission is required to send his application, with the following certificates, to the principal, not later than July 31st.:

1. A certificate that he is a member of the Church of Christ in full communion.

2. A certificate of character from the minister of the congregation of which he is a member.

3. If he be a candidate from the Presbyterian Church of England, a certificate that he has satisfied his presbytery respecting his motives, religious character, and probable usefulness in the ministry. If he be a candidate from another Presbyterian Church he is required to produce such a certificate from his own presbytery as will satisfy the board of examination on the matters specified in the regulation.

4. A diploma of Master or Bachelor in Arts from chartered university of approved standing. Candidates who have completed that attendance at a university which is required for the graduation, but have not taken their degree, may be admitted to the entrance examination on satisfying the board respecting their reasons for non-graduation.

A candidate who has not completed that attendance at a university which is required for graduation must make special application to the board of examination through the principal. The application should contain a full statement of his case, with evidence of his qualifications for Christian work or of his success in preaching the gospel. The board will inquire into the exceptional circumstances, and the reason assigned for seeking admission, and has power, should it be satisfied, to admit the candidate to the entrance examination, subject to the confirmation of the college committee.

The Entrance Examination. The examination comprises the following subjects:

1. Latin.
2. New Testament Greek.
3. Mental and Moral Philosophy, including logic.
4. Elementary Hebrew grammar.
5. The English Bible; also a short essay on a biblical subject.

Graduates in arts who are not competing for a scholarship will be exempted from examination in those of the above subjects included in the final stage of their degree examination.

THE UNITARIAN CHURCH

The colleges at which students for the ministry of the Unitarian Church may receive their training exist for the purpose of promoting the study of religion, theology and philosophy without insisting on the adoption of particular doctrines.

The chief college is Manchester College, Oxford, and the full course is three years; but the committee may admit special students for shorter periods.

Entrance Examination. Before entering the college, students must have graduated at an approved university, and must pass the following examination:

1. Old Testament: Prescribed books (in English).

2. New Testament: The four gospels in Greek. Questions on subject matter of the Gospels and the Acts.

3. History: "Retrospect of Religious Life in England," by J. J. Tayler.

4. Philosophy: James's "Text Book of Psychology" (Chapters I. and II., and XI. to XXII).

Cicero's "De Officiis" is prescribed instead of the philosophy paper for all graduates who have not taken Latin in the Intermediate or Final examination for their degree.

Under special circumstances the candidature of non-graduates is allowed. These must be over twenty-four years of age.

Both the above entrance examinations are held early in October of each year.

The committee offer exhibitions of £50 for the year to students who reach a high standard in the entrance examinations. It is understood that the exhibitions will be continued for the course of three years.

Every candidate for admission to the college as a regular student for the ministry must send with his application a medical certificate and a recommendation signed by three persons who can testify to his character and abilities, one of whom must be a minister of religion.

To assist students who are unable to bear all the expenses of a university education, exhibitions are offered to undergraduates who fulfil certain conditions. The grants are £75 per annum for undergraduate students in a college of the University of Oxford, £50 for non-collegiate students at Oxford or for students studying elsewhere than at Oxford.

NONCONFORMIST COLLEGES

CONGREGATIONAL. *New College, Hampstead, London*; Western College, Bristol; Yorkshire United Independent College, Bradford; Cheshunt College, Cambridge; *Hackney College, Finchley Road, London*; *Lancashire Independent College, Manchester*; Mansfield College, Oxford; Congregational Institute, Nottingham; Congregational Memorial College, Brecon; Bala-Bangor Independent College; Theological Hall of Congregational Churches in Scotland, Edinburgh.

BAPTIST. Bristol College; Nottingham College; Rawdon College, near Leeds; Regent's Park College, London; Pastors' College, Metropolitan Tabernacle; Manchester College; Cardiff College; Bangor College; Theological College, Glasgow; Dublin College, Ireland.

WESLEYAN METHODIST. Richmond College, Surrey; Headingley College, Leeds; Didsbury College, Manchester; Handsworth College, Birmingham.

PRIMITIVE METHODIST. Hartley College, Manchester.

PRESBYTERIAN. Westminster College, Cambridge.

UNITARIAN. Manchester College, Oxford; Unitarian Home Missionary College, Manchester; *Presbyterian College, Carmarthen.*

SALVATION ARMY. Training Home, Congress Hall, Clapton.

Printed particulars of college curriculum and conditions of entrance may be obtained upon application to the Principal of any of the above.

THE TRADE IN FEATHERS

The Various Uses of Feathers and the Processes Involved in their Preparation. Bed Feathers. Feathers for Millinery Purposes. Quills and Ospreys

By J. P. MILLINGTON

FEATHERS, like hair and nails, are products of the epidermal portion of the skin.

A feather consists of three parts: (1) A *barrel*, or *calamus* which is the hollow, translucent part used for writing; (2) a *shaft*, or *rachis*, which is opaque and filled with pithy substance (this is roughly quadrangular in transverse section with a longitudinal furrow along its inner side—that is, the side turned towards the body; the rachis, together with the calamus, form the quill); and (3) the *barbs*. These are subdivided into *barbules*, and the latter again into *barbicels*. The barbs and their subdivisions constitute the web or *vane*.

Feathers are of different natures according to the parts of the body in which they occur. The contour feathers, or plumes, come chiefly from the wings and tail, and are the most important for ornamental purposes. Besides the plumes there are smaller, softer feathers which are classified into downs, half-downs, and hair-like feathers. Finally, there are the small nesting feathers.

The plumes are the largest of the feathers, and sometimes show magnificent markings and colourings, as in the case of the peacock and pheasant. The downs, on the other hand, are covered by the plumes, and are smaller, more fluffy, and more numerous. In aquatic birds—especially in those inhabiting high latitudes—the fluffy down is highly specialised, and is so elaborate as to form an important feature of the plumage.

Uses of Feathers. The principal uses to which feathers are applied are these:

1. The manufacture of bedding, cushions, etc.
2. Ornamental and decorative purposes.
3. The manufacture of pens, toothpicks, light brushes for dusting and other domestic purposes.

Sometimes not only the feathers, but the whole bird is used as an ornament. This is notably the case with birds of paradise and various tiny humming birds. In other cases some part of the bird—for example, the wing, or the head and neck—is employed, while frequently the long contour feathers are plucked out and used.

The list of birds which serve for ornament is a long one. Among them are:

Birds of Paradise:	Jungle cocks
Black	Kingfishers
Green	Merles
King's	Orange oriels
Bustards	Osprey
Crested pigeons	Ostrich
Grebe	Peacock
Heron	Pheasant:
Humming birds:	Common
Amethyst	Japanese
Emerald breasted	Seagulls
Ruby	Starlings
Indian crows	Terns

There are others, but these are the more common.

Of the feathers usually seen, the best-known are those of the ostrich, while the most valued are those of the egret. The real home of the ostrich is Egypt and the North African States, and these countries still provide a certain quantity. The bulk of the supply, however, comes from South Africa, where the birds were introduced some thirty or forty years ago. The rearing and farming of ostriches has been attended with such marked success that the killing of wild birds has been almost, if not quite, abandoned. The profits from ostrich farming vary from year to year, and are determined by two main factors—namely, supply and demand depending upon the dictates of fashion, and the prevalence of disease to which the birds are particularly liable unless allowed practically unlimited space in which to roam.

The birds are clipped every eight months, and each yields an average of about 20 ounces. The first crop consists of chicken feathers, which are known commercially as *spadonas*.

The ostrich feathers are sold by public auction in London, and for the last five years the quantity sold has averaged about 600,000 pounds per annum. This represents an annual value of £1,200,000 to £1,500,000. About nine-tenths of the total amount comes from South Africa.

The raw material is then distributed for manufacture to various parts of England, France, Germany, Austria, and the United States of America. The main processes of manufacture are known as dyeing and bleaching, laying or preparing, sewing and curling and finishing. In addition to the manufacture just mentioned, there is a large industry connected with the making of boas and feather trimming.

Ospreys. Egret feathers, known to the trade as ospreys, are taken from the long-winged birds of the heron family. In character they are exceedingly soft and silk-like, yet remarkably stiff. The barbs are very fine, long and filiform. These are largely used as ornaments for the hair, generally in conjunction with diamonds. The price is exceedingly high, sometimes reaching as much as £8 per ounce

Considerable feeling has been shown by humanitarians concerning the slaughter of these birds, which are usually killed during the nesting season, as the plumage is then at its best. It is recorded, however, that egrets flourish in confinement, and that the feathers taken from such birds are of just as high a quality, and command the same prices, as those taken from wild birds. It is possible that this industry may be developed so that the reproach of wearing "murderous millinery" may be taken away from those who decorate their hair with these beautiful feathers.

of many different kinds is collected in country districts, and from poulterers in England and the various countries of Europe, and the manufacture of these constitutes a very considerable industry.

Another branch of the feather trade is that of fan-making. In this ostrich feathers are largely employed, though at present these articles are not much in vogue.

Preparation of Feathers. The preparation of feathers consists mainly in the cleaning and dyeing of them. It is usual to dye only those which are intended for ornamental use in boas, trimmings, ladies' hats, etc., but in the case of all feathers a preliminary cleaning operation is necessary, since when taken from the bird they are impregnated with various substances such as blood and natural grease, which, unless removed, would undergo decomposition and give rise to unpleasant consequences. We may consider the treatment according to the three main purposes to which feathers are applied.

Bed Feathers. For the making of feather beds those feathers are used in which the quill is reduced to a minimum and is as pliant as possible. Such are obtained from the domestic fowl, ducks, geese, swans, etc., and the best of them are plucked from the living birds in spring. This kind is preferred to those taken from the body after death, as they are cleaner, freer from blood and animal fats, and less liable to become tainted. They are also rather more springy and elastic, and so better adapted for this particular purpose.

The feathers are first dried in stoves by means of hot air, and then beaten with sticks to render them free and light. The dust is removed by shaking them in sieves, and the feathers are then ready for the manufacturer.

For bed quilts the down of the eider duck (*Somateria mollis*) is unequalled, because in addition to its extreme softness it possesses the property of great lightness. The down is supplied by the female, who, while sitting, lines her nest and continually adds to the warm, soft lining, so that by the time the young are born there is sufficient down to cover them completely during her absence.

Each nest yields about one-sixth of a pound of down, valued at 12s. to 15s. per pound.

Quills. Like the down used in the making of feather beds, the best feathers for quill making are taken from the living bird in spring. The most suitable, and at the same time the most expensive, feathers are obtained from the swan, but large quantities of quills from the albatross, heron, pelican, hawk, owl, etc., are used. For fine work feathers of the crow are employed; but the main source of supply is the goose, which, in certain parts of Europe, is bred almost entirely for this purpose. To all these feathers the following treatment is applied.

The feathers on removal from the body are heated in a bath containing fine sand to an average temperature of 60° C. A portion of the grease and other adhering foreign materials is thereby softened and partly absorbed by the sand, while the remainder is removed by scraping the still warm and pliable feathers. If desired, any pattern or design may be then impressed; on cooling the quill is left as a dry, horny substance, ready for cutting to the shape of pens, toothpicks, etc.

Feathers for Ornamental Use. The feathers intended for millinery purposes are first sorted according to quality and colour, the best colours and the purest whites being retained for use in the natural state after they have been subjected to proper cleaning. Those which are not to be dyed are washed in hot water in which soap has been dissolved. This removes grease and other objectionable matter. After this process they are thoroughly rinsed in warm water, and those that are to be kept white are then bleached. Formerly this was always effected by moistening the feathers and placing them in closed chambers where they were exposed to the fumes of burning sulphur. Now, however, hydrogen peroxide is largely employed as a bleaching agent. It is more convenient to use, and possesses the further advantage of leaving a purer and more permanent white. Feathers and other articles that have been "sulphured" are apt to return to their original yellow tint on long exposure to the atmosphere, or on coming into contact with any alkaline material, such as soap. Bleaching with hydrogen peroxide is not open to this objection.

Even after this treatment some feathers retain their yellowish cast, and to correct this defect they are often dipped into a dilute solution of indigo or some other blue dyestuff. This process is based upon the same principle as the one adopted by the laundress in "bluing" linen after washing, for the added blue neutralises the yellow, leaving a much purer white.

Feathers, the colours of which are unsuitable for natural use, are dyed. Dyestuffs such as logwood and indigo are much used, though a far wider range of colours is afforded by the various so-called aniline dyes, artificial colouring matters derived from coal-tar products.

Before dyeing, the feathers must be well cleaned with soda in order to get rid of every trace of grease, and then carefully rinsed to remove the alkali, which would otherwise affect the ultimate colour.

According to the dyestuff chosen the treatment must be varied, since some—for example, malachite green, auramine, magenta, methyl violet—require a neutral bath, while others must be used in a bath made acid with either sulphuric or acetic acid.

After dyeing the feathers are well washed and then carefully dried in revolving drums.

Curling. After dyeing the feathers usually require a certain amount of curling. This is effected by pulling them over a blunt knife, or by the cautious application of a hot iron. Some plumassiers employ various curling liquors, with which they moisten the feathers before dyeing. These liquors frequently contain small quantities of ammonia, and in some cases substances of a gum-like nature are added, as these help to fix the curl.

LARGE GUNS & AMMUNITION

Construction and Manufacture of Large Guns. Making and Charging Cartridges. Shells Percussion and Time Fuses

By JOHN W. WAINWRIGHT

Small Calibre Q.-F. Breech-loading Guns. This type [26] is built up from steel forgings and an inner tube with jacket shrunk on them. The inner or "A" tube forging is first rough turned and drilled, simultaneously from both ends, the tube revolving After this it is tempered and annealed and tested, then opened out to a larger diameter, with a D shaped boring tool working from the muzzle end, and then fine bored with a built up boring tool, with several inserted cutters with burnishers between them They are then lapped out when rapidly revolving by lead laps After this they are finished, turned, and shrunk up Then the rifling operation takes place, the tool used being somewhat similar to that described under Rifle Manufacture

Jacket. The jacket is then tempered and annealed, and then drilled through and second bored and second turned The trunnions are grunched down out of the rough forging, by vertical tools, a number of cutting tools in a bell chuck But in field guns the tendency of later years has been to give all field guns a longer recoil, and to provide them with a large spade at the end of the trail This design has caused radical difference in manufacture of the gun jacket Figure 27 is a Vickers 3 in gun and 28 is an Armstrong Whitworth 3-in. gun The trunnions are done away with on the jacket and a slide or grooved way extends the whole length of the gun Thus, practically, no portion of the outside from breech to the muzzle can now be turned in the lathe, but has to be planed longitudinally, the gun being supported and partially revolved and the tool box arranged to copy the contour of a template fixed upon the machine

The breech is then slotted out in a slotting machine (when of the Hotchkiss or Vickers wedge breech type), the rear face faced and the hole flared out to give easy insertion to the shell cartridge The action holes are drilled through jigs, and a dummy mechanism fitted, to test accuracy, also backsight holes bored. The jacket is then fine bored to a somewhat smaller diameter than the barrel or "A" tube, and this is called a shrinkage allowance In several cases there is a locking ring with bayonet joint which is duly machined.

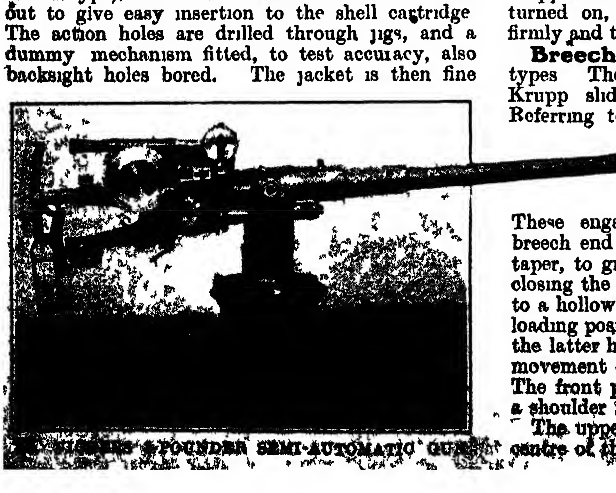
The gun is then ready to be shrunk up. For these small guns a gas fired furnace of simple construction may be used, using forced draught and town gas through standpipes and nozzles This jacket is fixed on a revolving table perfectly upright, and gradually turned round, to get an equal distribution of the heating The jacket is tried over the top of the barrel before heating to ensure it getting into the correct position When the jacket is expanded sufficiently by heat, it is tested by gauges

27 VICKERS 3-IN FIELD GUN

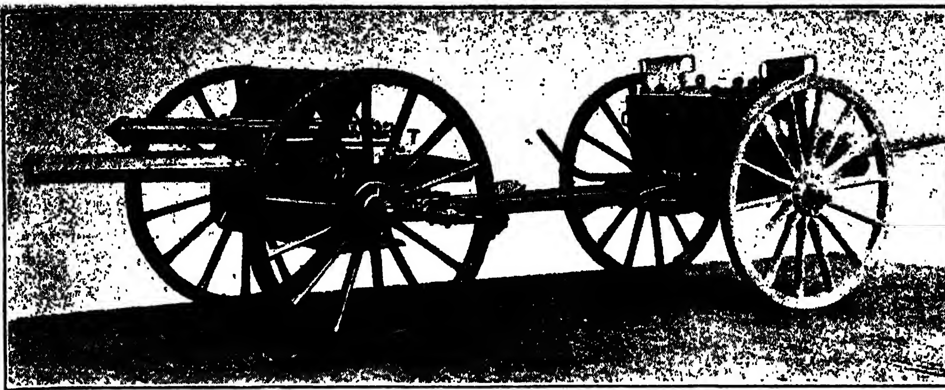
The barrel having been already lowered, and secured on to a plate, into the bottom of a pit alongside, has a taper plug placed in the muzzle to form a lead, and to give protection The jacket is then carefully lowered vertically on to the barrel to avoid making a burr on the locking ring When it is home to the shoulder the locking ring is turned, and the key inserted, the key fitting on the sides only Should there be other reinforcing hoops they are expanded in a like manner and dropped over In each case the water jets are turned on, causing the outside portions to grip firmly and thus to form an integral whole.

Breech Blocks These are of three principal types The vertical wedge, A, the transverse Krupp slide, B, and the screwed breech, C Referring to detail of manufacture of "A," the breech block is of the vertical sliding type and is retained in the breech end of the gun by means of a series of serrated projecting guides, milled in These engage in corresponding grooves in the breech end The block is machined with a slight taper, to give it a slight forward movement when closing the breech The top of the block is milled to a hollow curve to clear the cartridge case in the loading position, and the front is bevelled to press the latter home in closing the breech—the forward movement of the block completing this operation The front portion of the block is stepped to form a shoulder for actuating the extractor.

The upper portion of the block in line with the centre of the gun is bored out to receive the bush



VICKERS 3-POUNDER SEMI-AUTOMATIC GUN



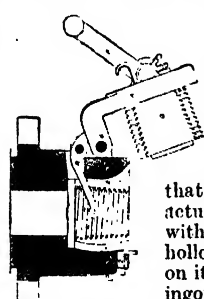
28. ARMSTRONG-WHITWORTH 3-IN. FIELD GUN

for the striker, the former having been previously machined and hardened. This is screwed into the front face to admit the firing pin. At the rear end is provided a sliding cover, a stop pin being provided to limit the opening movement. The striker opening near to the cover is recessed at the top to allow the striker to be removed when the mechanism is assembled. The centre of the lower portion is hollowed out and drilled and end-milled to take the cocking lever, trigger, and mainspring. A wibbled-out slot between this space and the striker opening admits the cocking lever to the latter. Transverse holes are drilled in the lower portion of the block to receive the axis pins for the trigger and cocking lever. The other components, such as the cranks, crank shaft, and sleeve, are machined from steel forgings and hardened.

Semi - automatic and Screwed Breech Blocks. In the semi-automatic type there is also a steel spring of the clock type fixed in a machined-out bronze cover. The extractor, when machined, is pivoted on a hinge pin screwed into the breech of the gun. A cylindrical striker with detachable point and a key is fitted into it. A hole is drilled through the striker for the head of the cocking lever. The cocking lever is forged bell-crank form, and pivoted on an axis pin in the space in the centre of the breech block.

In the Krupp type the breech consists of a transverse slide block with a circular hole through it registering to the chamber when open, but presenting a solid surface when moved across to the closed position.

Referring to the screwed-breech type, there are numerous types of this class. Taking one simple type [29], the screw, which has interruptions (or gaps between), is swung round on a carrier arm, which also has a bevel gear to rotate the screw, so that its threads, which have entered the somewhat radial gaps in the breech screw of the gun, are now threaded, so that they enter and lock into the threads of the gun screw. In this particular type the threads are cut all round and then shaped off to form two interruptions. But a much superior screw breech—namely, the "Welin" type, which has been much improved by Messrs. Vickers—is used for the larger guns.



29. SIMPLE SCREWED BREECH BLOCK

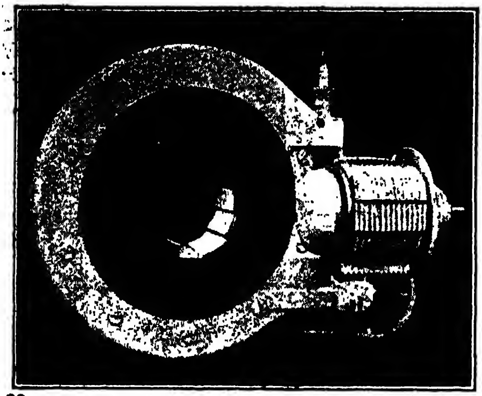
Welin Breech Blocks. This type [31 and 32] gives a much larger thread contact, and therefore support, and for the same reason it is enabled to be shortened, and the gun breech does not need to be radiused for the plug to be swung out. This arrangement of a short plug also enables a very considerable saving in weight to be made in the gun itself at its heaviest portion—namely, the breech end.

The contact area gives as much as 75 per cent. of the circumference as useful support. The thread is of the step-up type. Each segment has a different radius. This would appear to be a very difficult piece of machine work, but the result has been obtained by an ingenious arrangement brought out by Mr. Douglas Vickers. The interruptions, or gaps, are first milled through longitudinally, also narrow tool clearances between the threaded segments. It is then turned, and afterwards screw cut in a lathe, which has an attachment to the cross slide of the saddle, acuated by a cam and strong spring. This enables the tool to snap back quickly to meet the advancing larger radius during the period of passing the clearance groove.

In machining some of the smaller breech plugs, instead of using a forging for each plug, the screw is cut from end to end on a forged bar and then parted off into a number of breech screws, thus saving cost and material. Further, fewer test pieces are required.

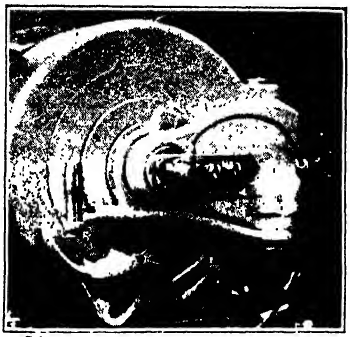
Large Guns. The steel ingots are cast with a large head to ensure soundness. This is cut off in a face-plate lathe by a square, revolving frame, with cutters that are moved forward by transverse screws actuated by a star wheel feed coming in contact with a fixed pin. They are trepanned out by a hollow, annular boring tool with cutting tools on its front face. This, on being fed into the ingot, takes out the centre, thus saving a large cylinder of metal. The ingot is then taken to the large hydraulic forging press and swaged out on a mandrel. Special mechanically-moved turning gear slung from the crane overhead is used. The hollow forgings are then rough bored out from both ends with D-shaped bits, with tooth-shaped cutting edges well supported and backed off to give clearance to the turnings, a copious supply of soapy water under high pressure being carried up to the cutting edges of the tool. They are then rough turned, and taken out to be oil-hardened or toughened and annealed.

The oil-hardening plant is of gigantic dimensions, consisting of high gas-fired furnaces, with firebrick



30. VICKERS 12-IN. BREECH MECHANISM (OPEN)

linings and with hinged front-door opening outwards all the way up, and a table at the base revolved from below by worm gear. Above this, and spanning over the furnaces and oil-tanks, is a 100-ton goliath crane worked by hydraulic power. The oil-tanks are large enough for 16-in. guns, and contain some 15,000 gallons of rape oil. They are partially sunk in the ground, and water is circulated round the annular chamber surrounding the inside shell of the tank, to keep the oil at a fairly equal temperature, and to prevent its firing. The tube is heated to about 1,500° F., and soaked at this heat for some time. Further, to ensure equable heating, it is revolved on the table before mentioned. The top doors are then opened, and the clips put on the tube, which is then lifted by the overhead crane, and plunged into the oil-tank. When ready, it is then taken out and replaced in the re-heating furnace for some time and maintained at a temperature of 700°F. to anneal it. Afterwards it is slowly cooled, and a further tensile test is taken. If correct, it is then taken to the boring lathe and second and fine-bored, and also lapped out. The various jackets and hoops are treated in a similar manner, an allowance being made for shrinkage.



31. 6-IN. BREECH MECHANISM (CLOSED)

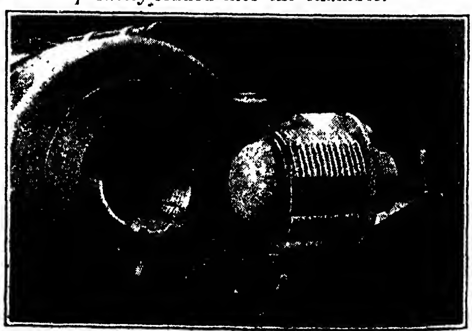
Wire-winding. As the larger guns are wire-wound, they differ somewhat in construction. There is an inner tube, which is second-bored inside, but finished turned outside, and over this is placed the "A" tube proper, and on to this is wound, in the case of the 12-in. gun, some hundred miles of steel ribbon wire under great tension. This winding on tension is regulated by grippers, held towards each other by weighted levers. The weights of these are adjustable in order that the tension may be increased or diminished, as required by theoretical construction. The gun revolves, winding on the ribbon in advancing steps or layers. The reel and apparatus traverse the bed longitudinally by a long feed-screw worked by hand. The wire is driven home by a workman with a copper drift, who also carefully examines the wire in transit and *in situ* to detect any defect.

When completely wound, should there be any rough edges on the wire or on the clamp rings, they are trued up in the lathe by spring cutting tools, or, in other cases, ground by emery wheels. Then the jacket and chase hoops which have previously been fine-bored, with a small shrinkage allowance to suit, and also finished turned, are dropped over, and shrunk on. The somewhat contracted bore is finished inside by lapping out. It is also chambered by a built-up broaching-out tool, or, in some cases, bobbed out by an emery wheel on a former. It is now inspected and measured up carefully in the bore, a micrometer gauge being used which registers the dimensions on a dial outside the muzzle end. It is then rifled in a tangent bar rifling machine somewhat similar to that described in our consideration of rifles.

In the meantime, the breech bush has been machined. To make this, an ingot is trepanned and hollow forged under the press in a length suitable for making twenty bushes. It is then rough-turned and bored, and hardened in a similar manner to a gun tube. It is now parted off into lengths and a thread is cut on the outside, and, further, the interior has the interruptions and stepped segments cut into it by special machinery.

When the gun has been rifled and lapped out, the breech bush is screwed in and fixed. The gun is again inspected minutely; to do this in the interior, electric lamps and mirrors are used to detect any defect. Also, internal impressions are taken by wedging inside plastic gutta-percha, which clearly reproduces any roughness or irregularity, and can be examined at leisure when withdrawn.

Obturator. In the case of large calibre guns, no metallic cartridge cases are used, but the efflux of the gases is prevented by the obturating pad. This consists of a plastic pad of asbestos with an unguent kneaded thoroughly into it. This mixture is formed into a pad between dies, under intense pressure, and covered with canvas. When in the gun, the pad is contained between front and rear metallic discs, but is free to expand at the circumference. On firing, the pressure forces back the front mushroom plunger. This compresses the pad longitudinally, and forces it outwards against the chamber, to make a gas-tight joint. The plunger has a hole drilled through its centre, in order that the flash from the primer may communicate with the charge. This charge lies in rear of the shot, each having been separately loaded into the chamber.



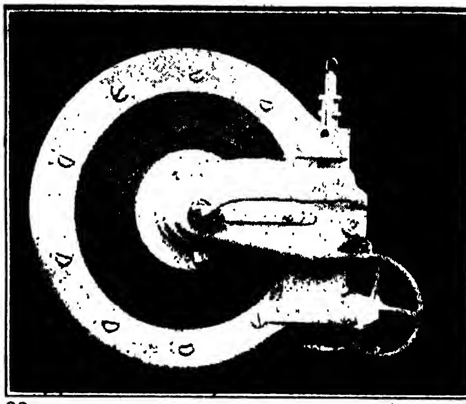
32. 6-IN. BREECH MECHANISM (OPEN)

The breech mechanism is now mounted [30 and 33]. The mechanism is arranged so that, by turning the hand wheel, the breech plug is first rotated and unlocked, then drawn out longitudinally. The obturating pad being now clear, the whole is swung out from the breech of the gun. These motions are obtained by means of a pinion and actuating lever, which rotate the breech plug with gradually increasing rapidity, unlocking it. By a combination of the sliding bar and roller stud, a sleeve is turned, causing the plug to have a longitudinal rear motion. On this movement being continued, the actuating arm swings out the mechanism clear of the gun.

Proof of Guns. After the final inspection of the guns as regards machining, they have to be tested by proof charges at a suitable range. The range, if required for large size of guns, must be in an isolated position near the sea, and should have a railway siding right on to the mounting ground, so that the largest ordnance can be conveyed there. To try the guns they are mounted on heavy, cast-iron surface plates, anchored down to a massive concrete bed. Usually an overhead gantry crane of 50 tons capacity spans the railway siding, so that the heaviest ordnance can be mounted with facility. The targets for armour plate trials are usually erected some distance away against a huge bank of sand, while fixed targets are erected on piles some thousand yards to seaward, and floating targets can be moored at any practical range. The buildings include the magazines for explosives and a handling house, chronograph house, workshops, a splinter-proof shelter, look-out shelter, etc.

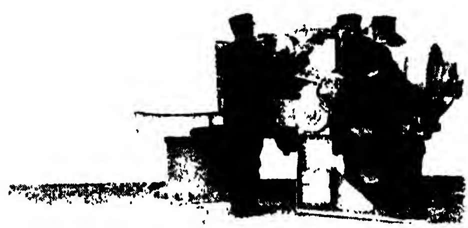
As the proof charges give pressures much in excess of those of the service charges, it is necessary to obtain information on this matter. To do this a crusher gauge is used for the direct measurement of pressure. The powder gases act on the base of a piston exposed to them, transmitting this, and compressing cylinder of copper. The amount of this compression is an index of the maximum pressure acting upon the piston base. Several crusher gauges are used to obtain an average. The copper cyinders have had given to them an initial compression, which is recorded; also, from the same rod from which they have been taken, others are compressed to an amount greater than that likely to be obtained by the maximum pressure in the gun, and each increment of load is recorded with the equivalent compression. Therefore it is necessary only to measure the length of the cylinders, as compressed in the gun, and refer them to the table obtained by the hydraulic pressures above referred to.

Chronograph. To measure the velocity of the shot an instrument called the *chronograph* is used. This is a time measurer, and is used to record the time taken by a shot traversing from



33. VICKERS 12-IN. BREECH MECHANISM (CLOSED)

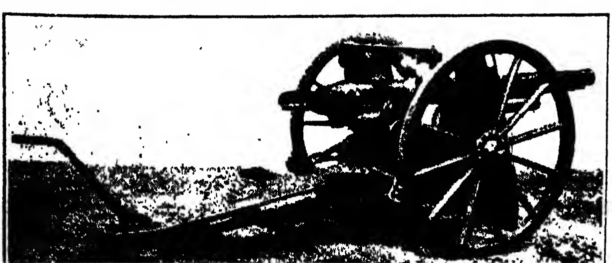
the muzzle of the gun to a point some distance ahead. Two electromagnets are supported vertically. When the circuits are complete they are magnetised and each one sustains a brass rod. One rod is called the *chronometer* and is a long one, the other is shorter and is called the *register*. On the register falling, it causes a knife-blade to indent the falling chronometer rod. Forming part of the circuit to the magnet holding up the chronometer rod is a fine copper stretched across the muzzle of the gun, while a certain distance ahead,



34. 6-IN. QUICK-FIRING GUN ON PEDESTAL MOUNTING

directly in the path of the shot, there is placed a screen of fine copper wires laced across, and insulated from the screen. This wire forms part of the register circuit. Further, a switch is arranged that can break both circuits simultaneously, called the *disjunctor*. When this is thrown over, both rods are released at the same time, and a mark is indented on the chronometer rod. On firing, the shot breaks the first circuit, causing the chronometer rods to fall, and the shot in passing through the screen breaks the second circuit, causing the register rod to fall. The mark now made is measured to that made by the disjunctor simultaneous release, and the average velocity is obtained therefrom.

The above is an improvement on the Boulengé type by Colonel Holden, R.A.



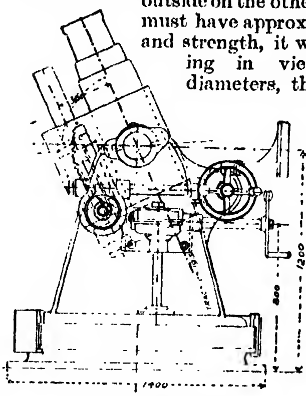
35. VICKERS 75-MM. FIELD GUN AND CARRIAGE

Field Carriage. The trunnion and axle bearings of a field carriage [35] are in one forging, and are riveted on to the trail by ample flanges. The traversing plate which supports the cradle is a steel casting. It has two trunnions which stand out horizontally upon it. These are turned on the journal part on the collar. By means

of these trunnions the gun is elevated or depressed. The trunnions lie in bearings in the trail and are kept in place by cap-squares. The boring bar is passed through the bearings to true them up with the trail. The recesses are slotted out, and the cap-squares fit in sideways. A socket is formed in the traversing plate, in which the traversing pivot rests, and around which the gun is traversed. This traversing pivot is provided with horizontal bearings (for the ranging drums) round which the gun and cradle can be elevated.

The traversing plate extends to the rear in two arms with a cross member to form a bearing for the traversing segment. The latter is machined to radius, and carries the ranging gear. The elevating gear is telescopic, and is arranged for independent, or for simultaneous elevation of the gun and sight. The separate and independent elevation are placed one on the left and one on the right side of the carriage. The one on the left elevates the whole system of the gun, cradle and sights, and is used for pointing. The gear on the right-hand side is for ranging the gun and does not influence the sight. An indicator shows the range of the gun corresponding to the elevating with degrees with line of sight. The machining of this work with internal and external threads is done on a screw-cutting lathe. All the gears are cut to conform to theoretical lines, as lost motion must be avoided. A hand wheel is on the right-hand side with a spindle and worm upon it. This gears into a segment of a worm-wheel, to give some degree of traverse in either direction.

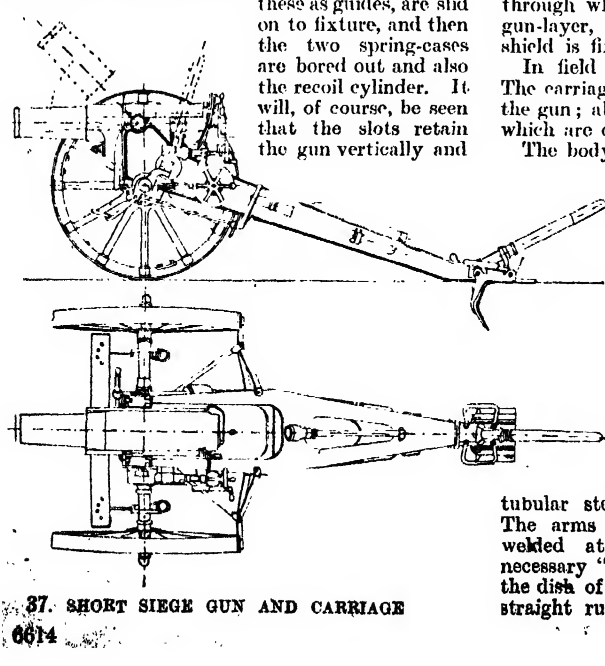
Cradle and Cylinders. These are made of manganese bronze and contain the recoil arrangement and running-out springs. A lug is formed on the under side. These are difficult castings to make, owing to the thin walls and long slides causing contraction difficulties, but this has been skilfully overcome by careful moulding. As in other castings, the runners and fins have to be removed, also the cores. They are then sent to the machine shop. The long grooves on each side are planed out on a special machine, and using these as guides, are slid on to fixture, and then the two spring-cases are bored out and also the recoil cylinder. It will, of course, be seen that the slots retain the gun vertically and laterally. In the recoil cylinder, a liner is forced in with an orifice which controls the flow of the liquid past the piston, through a gradually closing port. The spring-cases that are on each side of the recoil cylinder each contain two springs, enclosed one within the other, but separated by a tubular casing having a rim on the inside at one end, and at outside on the other. As these springs must have approximately equal range and strength, it will be obvious, having in view the different diameters, that the section and pitch of the coils must be carefully calculated to obtain a satisfactory result. The inner spring bears against the enlarged end of a rod which, after passing through the spring, is securely attached to the lug under the gun, and at the other end it pulls on the inside rim of the tubular case, enclosing this spring, while the outer spring bears against the outside rim of the tubular case: its rear end presses against the cradle itself. By this telescopic arrangement the compression of each spring is about half the distance travelled by the gun in recoiling. A large initial compression has to be given to these springs by screwing up. Suitable wheel brakes are attached. The bullet-proof shield is bent in such a manner that a horizontal portion forms the seat, the rear vertical portion of the back, while the front is continued down below the axle, thus screening the men well, and at the same time forming a seat when limbered up for travelling. The shield is flanged all round the outside edges and reinforced by right angles round the opening through which the gun projects. To protect the gun-layer, in these long recoil guns, a protecting shield is fixed at the rear end of the cradle.



36. HOWITZER

In field equipment there are three limbers. The carriage-limber, as shown in 28, travels with the gun; also the carriage and ammunition limber, which are coupled up and travel together.

The body is made of bullet-proof steel and contains a number of pigeon-holes, into which are inserted and tightly fitted baskets to contain the made-up rounds. These baskets have a wicker cover with a strap fastening. The end door has to fit up very tightly against these covers, and is padded with felt and leather. In the under-frame, corrugated and flanged plates are used which at once give strength and lightness. The limber hook is made of a steel forging, into which is welded a wearing-strip of special high-grade steel. The pole is made of straight-grained ash, well seasoned and free from defects. The axles are tubular steel with collars formed upon them. The arms are swaged down, turned in, and welded at the ends. These arms have the necessary "hollow" and "lead," the one to suit the dish of the wheels, and the other to ensure straight running on the conical arm. The arms



37. SHORT SIEGE GUN AND CARRIAGE

are slotted through to receive a lynch-pin, which retains the wheel in place.

Wheels. The spokes are of cleft oak, well seasoned and selected. They are turned in a copying lathe, and the nave ends are carefully tapered. The spokes are shouldered down to a round section where they fit into the felloes. The felloes are in some cases sawn out of ash with the grain running round the circumference. They are bored for the end of the spokes to fit into and are dowelled together at the joints. In other cases of recent practice, they are made of bent ash. The ash, having been steamed, is bent while hot by screwing on to moulds, and left for some time until it retains the required shape. These are bent in longer lengths in the old system.

The wheel-boss flanges are sometimes cast in bronze, or malleable iron, or of pressed steel, with projecting mid-feathers into which the nave of the spoke is inserted. Outside and socketing on to the boss-washer is the outside disc-washer, which is bolted up to it. Before insertion, the nave ends of the spokes are well-coated with white lead paint. The felloes are driven on to the spokes, and the spoke ends wedged. Then the welded tyre is placed over this, and in modern practice the shrinking on is done by means of a series of hydraulic rams all round the circumference and acting radially inward simultaneously. Inside the socket of the boss-washer a pipe-box, previously bored out and with oil grooves cut in it, is inserted to form a bearing. Some of the European nations use forged iron or steel wheels.

Siege Guns and Howitzers. The tendency since the Boer and Japanese wars is to use a siege gun [37] with high velocity, and consequently longer gun, for field service; therefore the weight has to be kept down.

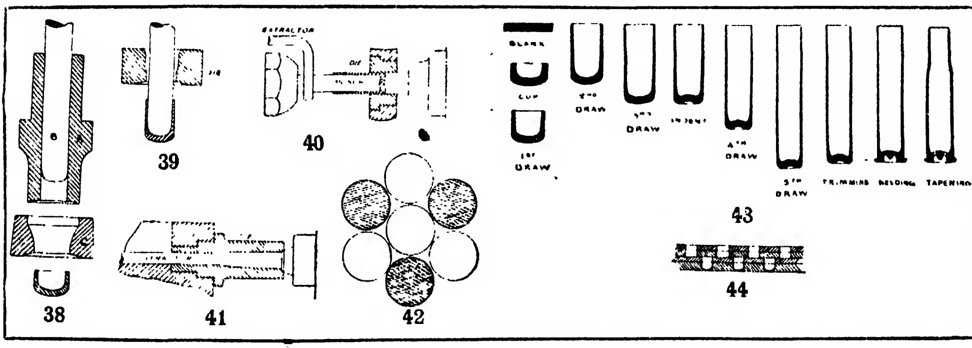
For plunging fire, howitzers [36], with high angle fire are used for field, siege, and garrison purposes.

Mountings. These features cover a multitude of designs—for instance, naval mountings, field carriages and limbers, howitzers, fortress artillery and barbette mountings. It is impossible to go fully into the manufacture of all these, so the 6-in. pedestal mounting [34] is given in detail, and the others are lightly touched upon. This mounting consists of the following principal parts—namely, pedestal, pivot and carriage, cradle, and shield.

The Pedestal. The pedestal is of forged steel, being flanged at the bottom, and is secured to the deck of the ship with bolts. It is bored and bushed to receive the pivot stem of the carriage, and has at its base a horizontal ball bearing on which the whole training mass revolves. The top of the pedestal is bored out to receive the training worm wheel, the lower part of which forms a bush, this latter fitting closely to the pivot stem of the carriage. The upper part of the wheel has teeth cut in it for the training worm to gear into, and is provided with a circular facing for resting on the top of the pedestal. The clamping gear is fitted for controlling the mounting, and consists of a friction block, set screw, two Belleville washers, clamping screw, clamping handle, and two stop studs. The ball race consists of a steel block fitted to slide in and out of the pedestal from the rear.

Pivot and Carriage. The carriage is a steel forging of two side cheeks and a bottom, with the pivot projecting down. The pivot is a solid steel forging. It is faced on four sides in the planer, then two holes are drilled through it, and the metal of the centre portion is taken out by saws, meeting the drill clearance holes. It is then finished slotted inside. Recesses are formed on the inside on the cheeks for the reception of trunnion blocks, and are constructed so that the gun may be drawn inboard after the blocks are unlocked, without any lifting. The trunnion blocks are forged steel, and provided with locking blocks operated by links and rocking lever on the toggle joint principle. Suitable handles are provided for operating the links and locking blocks, so that the latter may be moved in order to engage with the recesses in the carriage when locked. One block moves upwards, and one downwards into oval recesses in the cheeks in the pivot. On each side of the carriage is bolted a steel side-bar, the left-hand one carrying the elevating and training gear and platform, the right-hand one carrying the training gear and platform. Steel stays are provided, one on each side of the carriage to support the shield.

Cradle. The cradle is made of steel plate, and is shaped to take the gun. It also carries the recoil cylinder, spring cases, sighting gear, guard plates, reserve oil-tank, and cover plates. Bronze bearing strips running circumferentially, are provided at front and rear end of the cradle, on which the gun slides: and at the trunnion end a cap of forged steel, also having manganese bronze bearing strips, is bolted to the cradle. Two key ways, running longitudinally, and bushes with bronze are provided, one in the cap and one in the bottom of the cradle, forming guides for the keys on the gun. The trunnions are of steel, screwed and secured into the cradle.

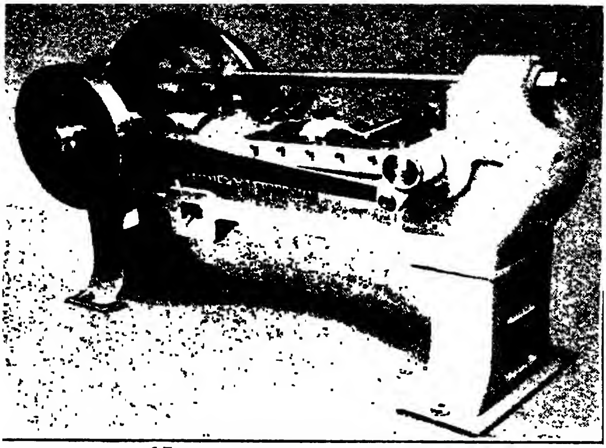


MANUFACTURE OF CARTRIDGES

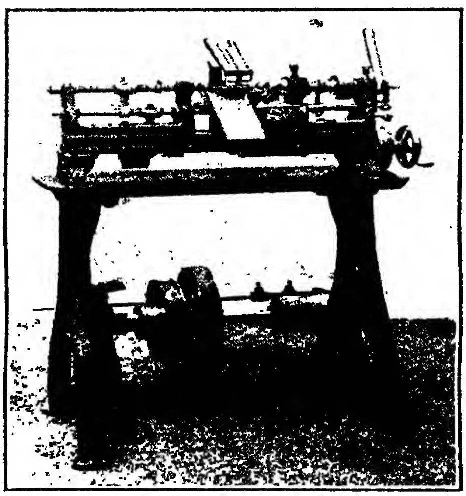
38. Blanking and cupping punch and dies 39. Stripping the case 40. Indenting tools 41. Necking or tapering
42. Plan of punch and strip 43. Various stages of drawing from blank to fin 44. Fulminate plates

The compressor bolt is secured to a steel crosshead, which is fixed to the lug on the breech end of the gun. In addition to the spring-case being supported at the ends of the crosshead, steel supporting straps are provided, binding cases to the cradle and recoil cylinder.

Sighting Gear. The sights are fitted one on each side of the mounting, and are arranged to be actuated by a separate sight setter on the left side. A special feature of the sight are the dials with spiral grooves: these give large and clear readings for range and deflection on the circumferences. The grooves are formed in a milling machine with vertical spindle, free to revolve and with downward feed, but with a fixed vertical axis, the dial being placed horizontally on a revolving table with a cross-traverse. Thus, as the dials revolve, the cross-feed motion continually decreases, the relative distance between the centre transversely of the dial and that of the vertical milling cutter, thus forming a spiral groove of equal pitch. Backlash, due to the wear of the working parts, is eliminated by the use of divided spur gear, one-half of which can be advanced to compensate the wear. A variable power, day and night sight telescope, is provided on each side, and, in addition, open sights are fitted when required. The rocking bar and carrier arms are machined out to channel section, and gauged. Mandrels representing the telescopes are accurately placed, and bedded into the clip brackets. To test the gear for accuracy, it is fastened alongside the true surface table, and the relative heights are tried by scribing blocks with a clock face micrometer containing multiplying gear which enables it to give large, clear readings for minute measurements.



45. INDENTING MACHINE



Ammunition. The manufacture of metallic ammunition, or cartridges, involving as it does severe punishment to the metal cases in their production, by successive pressings, drawings, and squeezings, together with a number of annealings, necessitates the use of a most ductile metal, which experience has shown to be an alloy consisting of 70 per cent. of copper and 30 per cent. of zinc. The metal, which is melted and cast into strips, is by successive rollings reduced to the required thickness, and cut into strips of a suitable width.

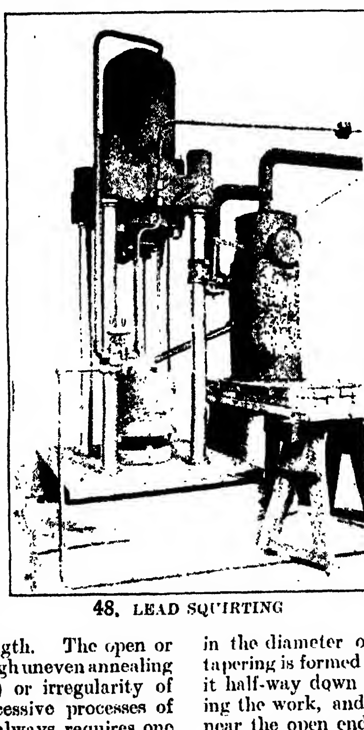
In the production of small cartridge cases, the first operation consists of cutting-out the blank and cupping it in a die press. The strip of metal is automatically fed into the press by a pair of rolls, which receive an intermittent motion from a ratchet wheel and pawl. When the metal is at rest over the

die the outer or hollow punch [A in 38] descends, cutting out the blank or disc. When this punch reaches the bottom of its stroke, the inner punch, B, then descends, pushing the disc through the die C, and thereby forming it into a cup.

Making Cartridge Cases. To use the strip of metal in the most economical manner, and avoid an excess of scrap metal, three blanks and cups (or any greater odd number) are made at each stroke of the press, the position in plan of the punches being indicated by the dark circles in 42, the metal being fed forward a distance slightly in excess of the blank diameter after each stroke. By the three succeeding operations the cup is drawn or extended, each one reducing its diameter and the thickness of the sides or walls, and at the same time increasing the length. In the machine for this purpose the cups are fed or placed by hand into recesses in a horizontal intermittently revolving table, each in its turn coming over a die, upon which it rests. The punch, then descending therein, carries it through the die, squeezing its sides, which reduces the diameter, and at the same time extending the length. On the return stroke, the case, which at the open end expands somewhat, is stripped or pulled off the punch by the die which it previously passed through [39]. The wall of the case or shell is required to be taper, or otherwise it is necessary for the metal of the shell to be thicker at the closed end and thinner at the open end. To attain this, the drawing punches are made taper, being smaller in diameter at the end entering the shell.

47. HAND CAP-PRESSING MACHINE

Indenting and Extending. The thickness of the metal in the end of the case has not been materially reduced, and it is now necessary (before proceeding with the drawing or extending operations) to indent the end of the case. This at the same time acts also as a preliminary heading operation, or forms the end so that an excess of metal is left therein, which will be required later. A machine for this purpose is illustrated in 45. The cases are placed into an incline shoot by the attendant, and are automatically taken therefrom upon a punch or mandrel when it is coming forward, which, when at rest in the forward position, receives a blow or squeeze from a die which is held in a toggle-slide, thus forming the indent. Upon the return stroke of the punch the case extracts itself and falls into a receiving box below. The tools for indenting are shown operating in 40.



48. LEAD SQUIRTING

Following the indenting there are two further operations of drawing or extending to obtain a case of the required length. The open or thin end of the case or shell, through uneven annealing (which will be described later) or irregularity of the metal caused by the successive processes of drawing, becomes ragged and always requires one or more trimming operations, an excess of metal being allowed in the blank for this purpose.

A machine for this process is illustrated in 46. The cases are placed in an incline shoot, and are automatically taken therefrom upon a revolving —and reciprocating—mandrel, a revolving cutter coming into contact with the case when the mandrel has carried it forward a set distance, trimming or cutting off the surplus metal at the end, thereby leaving the case its correct length and with a clear end. Upon the return stroke of the mandrel, the case is extracted therefrom, falling into a suitable receiver.

"Heading" and "Necking" Cartridges. The next operation consists of pressing or forming the head on the case, otherwise known as "heading." In working the heading machine the cases are fed by an attendant into a shoot, from which they are automatically taken upon a punch when making its forward stroke. As the punch with the case upon it comes to rest in the forward position, the toggle-jointed slide containing the die comes towards it from the opposite direction, giving it a powerful squeeze and forcing the metal to flow into the required form. Upon the return stroke of the punch, and the release of the die, the case is self-extracting and falls into a box. The form of the end of the case before and after the "heading" operation are shown in section in 43, which also shows the various stages from the blank to the finished case. It is sometimes necessary to have a final indenting operation after the heading so that the anvil contained in the head and upon which the cap is struck when firing may be properly raised, and the chamber for the reception of the cap properly formed.

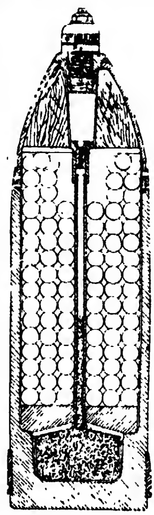
Tapering or reducing, commonly known as "necking," consists of closing in the open end of the case to a smaller diameter than the main portion of the body. In the machine for this process the cases are fed down an incline shoot in the usual manner, the one to be operated upon falling into a recess at the bottom, and being taken therefrom by a pair of fingers projecting from a rocking shaft actuated by a cam, placing it in the direct line of punch, which upon the forward stroke extracts the case from the fingers, and at the same time forces the open end into a taper fixed die. A mandrel which enters the die from the opposite end following up the punch on its return stroke, positively extracting the tapered case from the die, allows it to fall into a receiver. The tools are shown in action in 41.

In some instances, where there is considerable reduction in the diameter of the open end of the case, the tapering is formed in two operations, the first taking it half-way down the die, and the second completing the work, and forming the short sharp curve near the open end.

Piercing and Annealing Cartridges. Piercing consists of forming two small holes in

the head of the case, for the fire or flash from the cap. This operation is sometimes performed in a horizontal, automatic drilling machine, but more frequently in a special machine. The cases are fed by hand into holes in the intermittently revolving table, and are carried under the piercing tool fixed in the top of the frame, which descends and pierces the holes. An ejector worked from the crosshead below extracts the case after piercing. Sometimes the piercing is performed by two independent punches working from opposite sides of the case. The mouth or open end of the case now requires rimering out a little, so that the bullet may readily enter. Not the least important part of the production of the cases is the numerous gauging tests which are necessary to assure accuracy.

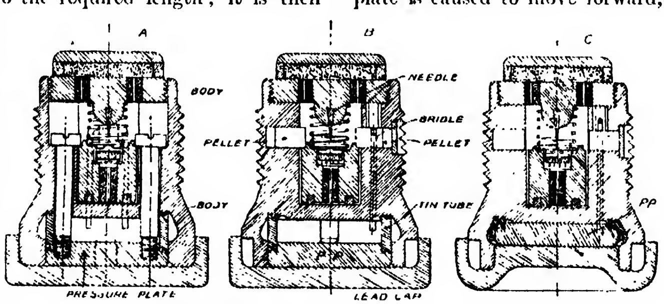
Annealing may be defined as the release of strain in the metal which has been produced by mechanical treatment. The effect on the metal cases set up by the various drawing, heading and tapering processes causes it to become brittle; for this reason there is a limit in the amount of work in reducing or altering the form of the area of the metal it is possible to perform at each operation. These defects of homogeneousness of structure may, however, be removed by heat treatment. The cases are heated with care, and then allowed to cool gradually. The operation of annealing may be performed either in a revolving gas-blast furnace, or in larger quantities by a coal-fired furnace, the temperature of which should be between 550° and 650°.



49. SHRAPNEL SHELL

When the cases have been annealed there is a layer of oxide on their surface, due to being heated in contact with air. This oxide is removed by dipping in acid liquids and finally by swilling in water. The corrosion may also be due to sulphur and other foreign bodies derived from the fuel. If strong and hot aqua fortis be used, the metal is liable to be dissolved and present a rough surface; for this reason a weak solution should be employed for cartridge cases.

Bullet-making. The next process consists of the bullet-making proper, the lead rod, which has been formed in a lead-squirting press [48], being automatically fed into a special machine. The rod is first sheared to the required length; it is then taken by a punch, and forced into a die which is the correct shape and form of the bullet, the finished bullet being finally extracted automatically from the die. The envelope for covering the bullet—the metal for which is an alloy of copper and nickel, better known as *cupro-nickel*—is made in a similar manner to the cartridge case—that is, the blanks are cut out and the cups formed at one operation. They then require extending, being drawn four times in succession; this leaving a rough edge at the end, a trimming process is necessary to complete the envelope. The lead cores are now placed in the envelopes and taken to the coring machine, being placed in a shoot, from which they are automatically taken between a punch and die and the lead core being forced tightly into its envelope, the whole being self extracting, and a completely encased bullet is delivered from the machine. In some instances two or more operations are required, the form of the conical end being thereby somewhat reduced.



Before firing During flight

50. 4·72-IN. BASE PERCUSSION FUSE

The cap is made of copper, and it is necessary that the metal employed be as nearly pure as possible, and perfectly soft, so that it may be formed to the necessary shape without fracture. The metal strip generally used is from ·010 to ·014 of an inch in thickness, and is cut out and formed at one operation, in a similar manner to that adopted in producing the caps for cases. In some instances the caps are trimmed or faced, this operation being performed automatically in a special cap-trimming machine. After this they are polished in a shaking or tumbling machine.

Charging Caps. They are now ready for charging, the composition employed for this purpose being fulminate of mercury, combined with other ingredients in order to ensure the ignition of the powder charge by the blow struck upon the cap. The fulminate is highly dangerous to handle, though comparatively free from danger in charging when the work is performed in a suitable machine. The caps are placed by hand into a copper plate which is provided with a number of holes of a suitable size. The plate is then put into the lower part of the charging machine, and has three brass plates above it. These plates are accurately ground together and work with little friction. The plates are all perforated with holes corresponding in size to those in the caps [44]. The perforations in the lower plate are exactly opposite those in the caps, while those in the upper one are half-way between or over the blank portion of the lower plate. The middle plate—which is a sliding one—has its blank portion below the holes of the upper one while the latter is being charged. When the holes of the upper plate are filled with the composition, the middle plate is caused to move forward, so that its holes come under those of the upper one, taking therefrom the composition. Thus, when the holes of the lower plate communicate with those of the middle one, the caps are filled with a quantity of composition corresponding to the thickness of the centre plate. It is now necessary to press the composition in the charged caps. For this purpose they are taken to a pressing machine. A small machine for hand use is illustrated in 47. A larger power-driven machine is, however, more frequently used, and consists of a frame having a crosshead working vertically through

the intervention of belts, gearing, and a crank shaft, and also having a table which is recessed to hold the plates containing the caps; each plate contains 1,000 caps arranged in rows of 25. The table has an automatic intermittent feed, arranged so that each row of caps is brought in its turn directly under the plungers contained in the crosshead, which then descends and presses the fulminate tightly into the cap. The row of caps, being compressed, rests upon a number of movable bases which are kept up to their work by counter or balance weights, so that the pressure on each cap is regulated by—and cannot exceed—that exerted by the balance weight, which can be varied to suit conditions and may be as much as 1,000 lb. on each cap.

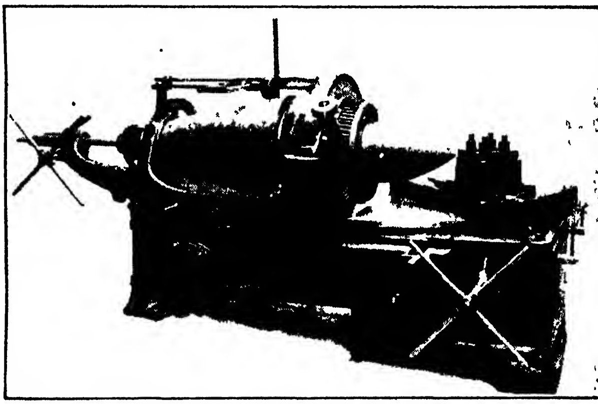
The surfaces of the compressed fulminate—the caps still being in the receiver plate—are now covered with a small piece of tinfoil, and then varnished, the apparatus for varnishing having a plate which is covered with a solution of spirit and shellac. A number of small vertical plungers are caused by the operator to descend on the plate, each taking up a thin layer of the varnish; the plunger plate is then raised, and the varnish plate removed, the receiver containing the caps being substituted; the plungers are again brought down, and leave a thin coat of varnish on the surface of the compressed composition or fulminate. The cardboard or felt wads are made in a cutting-out press, the sheets of material being self-feeding, and the blanks are cut therefrom by a punch and die.

Assembling Cartridges. The various parts are now ready for assembling. The caps are embedded into their cases by a machine. These cases are placed in the long incline shoot, and the caps in the short one, a cap and case coming together at each stroke of the machine, the cap being tightly forced in. Upon the release of the pressure, they fall into the box below. In loading the case with cordite, about sixty pieces of which—somewhat resembling fine twine—are required to fill each case, the pieces are automatically cut to length, filled into the case, and pressed home. The cartridge is now ready to receive its wad and bullet, and the final operation of securing the bullet.

The complete cartridge is then cleaned and passes through the inspection stage of gauging and rectifying, and is finally weighed in an automatic machine having three receivers, one each for those of correct weight, one for lighter and one for heavier, the limit of variation being about two grains.

Shrapnel Shell. This is principally used for field and naval purposes, and one type is shown in **49**. It consists of a hollow steel case, with a solid base, filled with lead bullets. In the case of the 6-in. there are over 500 bullets. On the inside, near the base, is a shoulder for a steel diaphragm to rest upon; below this is the bursting charge, which is in communication with the fuse and head of the tube. The contact head is of brass, and contains the time fuse at its nose. This type of shell is fired out of the gun, the fuse having previously been set, and when in the air over the object—such as infantry, cavalry, or boat flotillas—the flash from the ignited fuse passes down from the fuse to the bursting charge. The bullets, etc., then fly forward with accelerated speed. The hollow forging is bored out to the larger diameter for the bullets, and the diaphragm; and to the decreased size for the powder chamber. Then the open mouth towards the head is enlarged, and into this the finished brass head is inserted, and riveted with brass rivets. Inside the head is a wood filling plug, and at the point the time fuse is screwed in. The body is turned in the ordinary way, and the driving band compressed into the recess. The lead bullets are machine moulded, and then pressed into charcoal to fill the case.

Small Shells. Small shells—armour-piercing 6 pounder steel—are in some cases forged under the steam hammer from a round bar; in other cases they are hollow forged and the base turned over in presses. They are then annealed and bored out. The interior inside the point is bored to a special shape, and is formed by a copying arrangement at the back of the shell. They are then rough turned on the parallel part and then the ogival, or conical head, is turned in a special lathe [**51**], which radiuses round the body. The shell is then reversed in the chuck and finished turned, and the groove for recess cut in to contain a driving band. There are several projections left standing up in this recess, and these are machined in the form of waves by the action of a cam acting upon the slide rest. These projections



51. SHELL-NOSE TURNING MACHINE

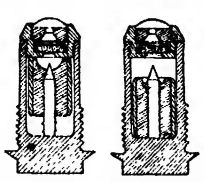
eat into the copper driving band, and the wavy contour prevents the band slipping round. The screw threads are cut into the base by a special tool.

The shells are hardened in water from the point for some distance up. The plugs are made from the bar in a hollow mandrel lathe, and are screwed tightly home into the base of the shell. The copper driving bands are compressed into the recess by a press having a relief valve, and the outsides are tapered to the front, and annular grooves are cut in them. The driving band takes the lands—or projections—and grooves of the rifling, so that the shell revolves when passing out of the gun; at the same time it obturates or makes a gas-tight joint, so that none of the powder gasses pass beyond this band. The nose is now bobbed up to the required shape by high speed emery wheels, controlled by a former saddle to give the cone shape and sharp point. They are now lacquered, inspected, and painted.

Armour-piercing Shell. This class of shell is a steel-tempered forging, with ogival-pointed head, with a small-size chamber inside for high explosive charge, and generally is fitted with a base fuse. Also many projectiles are fitted with a

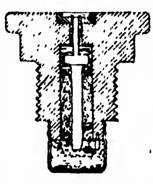
soft steel cap, which protects the front and generally eases the penetration of the shell by preventing its being broken up. The operations are somewhat similar to the smaller shell.

The shell is bored and counter-bored—or enlarged—inside, and the smaller diameter at the base has threads cut in it by internal milling, or by fixed cutters, to which the correct feed is given. This shell and others, after internally heating by steam, are coated with lacquer, to give a smooth internal surface to prevent premature explosions. The shell is then painted, and distinctive bands, showing the nature of the shell, are lined upon them. A semi-armour-piercing shell has thin walls, but is strong enough to withstand the shock of discharge. On striking or penetrating an object, the base percussion fuse ignites the burster and breaks the shell into fragments.



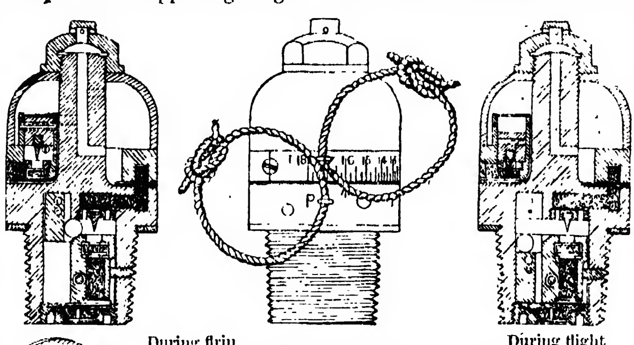
52, SMALL FUSES

Large cast steel common shell, suitable for 12-in. to 5-in. guns, are moulded with the head downwards. The mould is lined with a gannister composition, used by steelmakers to stand the high temperature. Suitable core prints are formed at each end. The hollow interior is formed by placing in a core, which is formed round a spindle. This is covered with asbestos, and over this again the "compo." To ensure sound casting, it is necessary for it to have a large superimposed head to compress the metal, and to ensure that it is fed to all parts of the shell. Moreover, the occluded gases and the poorer metal rise up into this head, which is afterwards cut off. The shells as cast are then annealed for twenty-four hours before passing on to the machine shop, where the processes that follow are somewhat similar to those for armour-piercing shell, except that they are tested by internal pressure.

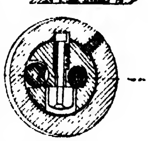


53, ELECTRIC PRIMER

Fuses. Several types of fuses are shown in 50, 52 and 54. The large percussion [50] consists of a stamped manganese bronze body. In firing the gun the piston pressure plate PP is blown in; this collapses the supporting ring—which is made of drawn pure tin tube—as shown in 50. This, by pushing up the bridle, releases one of the centrifugal pellets. These pellets fly outward. The detonating pellet with its cap is then free, and lies back at the base; but on striking it moves forward, the fixed needle above piercing the cap. The flash from this ignites the powder in the pellet and that around the needle plug, thus communicating with the burster inside the shell. This latter action is clearly shown during flight at C.



54, COMBINED TIME AND PERCUSSION FUSE



Small Percussion Fuses. These [52] are made of gunmetal for the small sizes, and steel for the larger. They contain the detonating composition in a recess in front. Below this is the lead guard pellet, supported by the roughened steel or brass needle that is embedded in it. On the shock of discharge the inertia of the lead guard causes it to set back, arming the needle—that is, causing its point to protrude. During flight the guard, with its projecting needle, lies backwards against the base of the fuse; but on impact it moves freely forward, the needle piercing the detonator and igniting the bursting charge in the shell. The smaller type of fuses are manufactured from rods in turret lathes with hollow mandrels and rod feed. In some later types of machines no less than four rods are manipulated at one time. It is impossible to describe the numerous types of fuses, such as delay action, also electric primers—for one type of which see 53—within the scope of this article. But the combined time and percussion fuse will be described briefly.

Combined Time and Percussion Fuse. This fuse [54] is used principally with shrapnel shell. The composition must burn in a regular manner, and is set to act by time at very short intervals. The principal parts of the time arrangements consist of the body, composition ring, and dome. In addition to this there is a percussion arrangement at its lower portion, to enable the shell to burst on impact in case of failure of the time fuse. This fuse is screwed on the exterior to fit into the shell, and bored out to take the percussion arrangement. The body extends upwards through the dome. The composition lies in the central belt of the body with a ring above it also containing the lighting composition and the hammer, with a steel needle suspended by a copper wire above the composition. There is a hole bored through the ring near the start of the composition channel to allow the gas to escape. The outsid of the ring is divided into eighteen half-seconds time of burning. The are further subdivided. The dome fits over the composition ring, and is held in place by the nut screwed on to the stem on top of the body. The action of this time part is such that, when the fuse is set, the shock of discharge causes the hammer to shear the wire, and fire the detonator and composition ring, which burns round the distance required, firing the charge in the horizontal channel, and the bursting charge in the lower chamber of the shell by passing down the primer tube, and thus explodes the shell. The percussion part is shown "before firing" and "during flight," to illustrate its action.

Either portion of this fuse can be used as desired, for time or percussion. The body is made out of bronze bar in a hollow mandrel lathe.

MUSICAL INSTRUMENT MAKING

The Making of Brass and Wood-wind Instruments, dealing with Processes Involved and Materials Employed

Following on page 6444

By J. P. LORD

IN actual practice, the trade of musical instrument making is divided and subdivided into innumerable classes, some makers confining themselves to one instrument only, while others make a variety; and again, in the manufacture of certain instruments, the entire work is distributed between a large number of operatives, while other instruments are practically made from start to finish by one man. For our own purposes of classification, we will divide the range of musical instruments as follows: (1) brass instruments; (2) wood-wind instruments; (3) stringed instruments; (4) pianos; (5) organs; (6) miscellaneous instruments, such as drums and cymbals.

BRASS INSTRUMENTS

The making of brass instruments is one of the branches of manufacture which are divided into two great sections, according as to whether the worker is a mechanic pure and simple, or a musician. That is to say, in theory at least, the actual construction can be accomplished by a man who has little or no knowledge of music, and then the instrument is passed on to an expert, gifted with a fine ear, by whom the final regulating touches are applied.

We will start with the brass—or silver, for that matter, if fancy instruments are to be made—in the sheet, just as it comes from the rolling mill. The metal sheets are of varying thicknesses, from $\frac{1}{24}$ in. upwards. The thinner sheets are used for the highest class of orchestral instruments, which have little wear and tear to withstand, while those instruments which are required for general band purposes are necessarily made of stouter metal.

In theory, every brass wind instrument, with the exception of the trombone, consists of a conical tube of brass, tapering gradually from the mouthpiece to the opening or bell. The fantastic twists and curves so familiar to us all are only theoretically contrivances to make handling practicable. Remember, however, that this strict theory is not borne out in practice, for undoubtedly the form of an instrument has some marked effect on the tone. It is true that a conical pipe of a certain length and of a certain bore will always give the same note; but the quality of that note will be greatly varied by the subsequent bending of the pipe, by the thickness of the metal, and by the sort of metal employed.

Making the Pipe. Now to make our pipe. In practice, it is not possible to make ordinary brass instruments out of one single piece of tubing, so the instrument is built up of a number of sections, preserving as nearly as possible the same taper from mouthpiece to bell. Each of these sections will, therefore, be a frustum of a cone.

The theoretical length of the pipe required being supplied by scientific musicians according to the taper employed by each instrument maker, the first thing to do is to fashion some templets. Disregarding the bell for the moment, imagine a tube of the dimensions you require cut open along the middle line, and flattened out. You will then have a frustum of a triangle, with the base the exact length of the circumference of the cone at its widest part, and the parallel line at the apex equal to the circumference at the mouthpiece. If about $\frac{1}{12}$ in. to $\frac{1}{8}$ in. be added to one side, to allow for overlapping, then such a plate would form a templet for the manufacture of a tube similar to that from which it was made.

In practice, such templets are made from stiff paper, and deal with sections of the tube only, a margin being allowed at the upper end of each for joining to the section above.

Cutting Out the Metal. The templet is laid on a suitable sheet of metal—good brass, we will assume, for the purposes of instruction—and its outline carefully traced out with a sharp-pointed graver, care being taken to avoid wastage as much as possible. With a strong pair of shears, the brass is then cut to the pattern, and laid on the bench in front of the workman. Next, both edges are filed on the slope till the metal has been reduced nearly one half in thickness. The object of this is to prevent the join being too bulky after joining.

Along one edge, then, the workman cuts a series of little nicks with his shears, each nick being between $\frac{5}{16}$ in. and $\frac{1}{4}$ in. in depth, according to the portion of the tube which is being made, those on small tubes being smaller than those on large ones. These nicks are placed in pairs, the component members of a pair being about $\frac{1}{4}$ in. apart, and separated from the next pair by a distance varying from $\frac{1}{2}$ in. to $1\frac{1}{2}$ in. The nicks must be perfectly parallel to one another, and parallel to the base line of the templet copy.

The Tube. Now the flat sheet has to be fashioned into a tube, which is done in this way. The workman places in his vice an iron—simply a piece of steel bar, tapered more or less to the cone which the tube is to assume. For straight tubes, the iron will, of course, have no taper.

Round this iron the workman proceeds to bend his plate of metal, hammering it, where necessary, with a boxwood mallet, but being very careful not to spread the metal at all by too vigorous hammering. With a little coaxing, the sheet soon bends round, and the filed edges are made to overlap to the extent allowed for in the pattern. The edge is lightly hammered down and adjusted, so that the two ends of the tube are even, and the join does not show a "step" at either top or bottom.

All being right, the tube is now opened again a little, the strength of the fingers being generally sufficient to do this, for the tube in its present stage forms a curved brass spring, and the small pieces of metal between the parallel nicks are prised up with a tool which resembles a small screwdriver with a slit in its edge. When the little slips of metal have been prised up the plain edge of the other side of the tube can be slipped under them. These little pieces of metal thus form a set of small dovetails, or "clems," as they are called.

When the plain edge has been adjusted under the clems in a straight line, the upstanding clems are hammered flat over the sound edge, and the whole joint is well beaten down. The object of first

thinning the edges of the metal sheet is now apparent.

After the joint has been tightly fixed by hammering, the tube has to be finally joined by brazing.

The Process of Brazing. Brazing, in this class of work is performed in this way. A little of the purest spelter is mixed with finely-powdered borax, well moistened with water. This mixture is laid along the parts to be brazed. The tube is then gradually brought up to the melting point of spelter, either in a forge or in a blowpipe flame. The instant the spelter runs the heat must be reduced.

There are certain precautions to be observed if success is to follow. First of all, the portion charged with the brazing mixture must be directed away from the flame till the whole tube is hot, otherwise the borax would bubble up and vanish, and brazing would be an impossibility. When the tube is nicely hot, then the mixture sets, and will no longer bubble. The heat is then applied to and around the proposed joint, and the brass becomes red-hot. Spelter melts some two or three degrees below the melting point of pure brass, and so the joint must be watched very carefully, for if the heat is not reduced the instant the smelter runs, a hole would certainly be burnt right through the tube, and the work either ruined or a difficult repair rendered necessary. Once the spelter has run, it is carried by the borax right along the joint, firmly uniting the metals. Should there be any danger of the joint springing open when heated in the brazing furnace, before the spelter runs, then the tube must be bound together with iron wire, to hold the joint in position.

When the tube is cool again, it will be seen that right along the joint there is a ridge of metal. This is now roughly taken off with a rasp, and the tube then put upon an iron of suitable size. The metal at the joint will be felt to present a ridge inside, if the finger be inserted, and this ridge must now be removed. The tube is held firmly on the iron, and the ridge and surrounding metal beaten with small, curved hammers till the surface is quite even, and till the inside is quite smooth. On examination, it will also be found that the metal along the joint has now been reduced to the thickness of the plain sheet from which the tube was fashioned.

This beating may have unduly hardened the brass at the joint, and so it is sometimes advisable to anneal the tube at this stage. Annealing is simply heating the tube till a dull red is produced, and then allowing it to cool slowly. It is a proceeding which must be resorted to whenever the metal has been consolidated by much hammering.

The rough tube must next be made perfectly cylindrical, and this is done by placing it on irons and beating it with hammers, while it is repeatedly turned round and round. The soft brass very rapidly follows the curvature of the iron, and a tube with a perfectly circular section is thus obtained.

Making the Bell. The bell is made from a very wide-mouthed cone. After it has been joined up into tube form, as in the foregoing directions, it is placed on a series of conical irons and beaten out to shape, frequent annealing being necessary. The final irons exactly correspond with the ultimate curvature of the bell.

All the various sections of the tube being thus prepared, the next task which faces the workman is the bending of all those which require to be bent. At first sight, this seems a very difficult operation, but in reality it is not so, a little care being all that is necessary.

Bending the Tubes. From experience we know that if we attempt to bend a straight piece of brass tube we can do so easily enough, but the tube will be flattened a good deal in the process, while ugly puckers will show on the inside of the curve. To prevent a good deal of the flattening, and to enable us to remedy the puckering, we must support the tube inside in some manner, and in practice this is done by filling up the tube with molten lead. If the lead is not over-heated, no harm whatever is done to the brass, and the gradual cooling of the mass makes the brass very soft and removes a good deal of its tendency to split.

The tubes being filled up with lead and cooled, the workman takes one and begins to bend it, having a pattern before him of the exact curve he wishes to impart. The bending is accomplished in various ways. Sometimes one end of the tube may be loosely gripped in the vice, and the end bent round, a little at a time, till the correct curve is arrived at; at other times a wooden pattern of the curve or a metal one is taken, and the lead-lined tube forcibly bent round it. The latter is the method employed, to give the beautiful circular form to French horns and instruments of that pattern.

But you must be very careful only to bend a very small section at a time, if bending without a fixed frame around which to bend. If not, you will find that instead of having a series of small, low ridges on the inside, there will be a lesser number of high ridges, with narrow bases, and the tube will be ruined when the next stage is reached.

Levelling the Inside of the Tube. When the bending is completed, and the curves exactly represent the models, if you examine the tube you will see that the outside is a little flattened, and could it be gauged you would find that the metal there was thinner than on the inside. The inside will be one mass of fine puckers, with broad bases, extending evenly all round the curve. These must now be removed. Laying the tube on a wooden block, the inside is hammered with wooden or metal hammers, each of the little mounds being beaten down smooth, the extra metal being thus distributed all over the interior surface of the curve. Had you been too hasty or violent in the bending, when you came to beat down the high, narrow-based ridges which would have been formed you would have found that instead of being easily reduced to the level, these ridges would have bent over, and the metal would have split right across the tube, which would have been utterly spoilt.

When the tube has been beaten and coaxed into shape after the bending, it is strongly heated till the lead melts sufficiently to be poured out. It is not necessary that the whole of the lead should be fluid; a very little melting will often suffice to enable the bulk of the metal to be shaken out of the tubes in a lump.

After slow cooling, the curves are now drawn through drawplates, and then placed on bent irons, and the final circular shape restored. If these operations have been carefully performed, the bend will look perfectly cylindrical, and the tube will show no trace of the puckering which it has undergone.

The surface of the tubes is now partially finished off, first of all by rough filing, followed by the use of a steel scraper, which in its turn is followed by polishing with strips of emery paper or cloth, till a fairly high polish is obtained, and all file-marks and scratches are removed. This is done to make the final polishing easy to accomplish when the instrument is put together.

The portions of the tube are then joined together, and it will be found that in the centre there is a vacancy. This is where the pistons and the piston work is to go. The joints are made with fine silver solder, run in very neatly. When the joint has set the excess of solder is carefully removed with a scraper, and the edges polished neatly, till it is difficult to detect the solder in the join.

The principle upon which the pistons act is simply the diversion of the column of air from one track to another. In ordinary instruments the pipes connected with the pistons are truly cylindrical, and this makes some of the high notes difficult to obtain. A firm of instrument makers have, however, recently invented a method of making the pistons and leads from one piston to the other conical, so that the taper is preserved throughout the entire instrument. The leads are the portions of curved tubing which the depression of the piston adds to the length of the total tube, and so lowers the pitch.

The pistons consist of a cylinder of metal, having inside it a metal plug, which is maintained at the top of the cylinder by a spring. On depressing the key the plug is pushed down. The plug is bored at various points to form channels for the air. The borings have to be lined with pieces of tube, neatly soldered in, and the openings must exactly fit the holes in the cylinder where the tubes of the instrument or of the leads are joined.

Tuning Slides. However accurately an instrument may be built, it is impossible to be quite certain that, when finished, it shall be exactly of one pitch, and so some means must be devised by which it can subsequently be regulated. Furthermore, as there are slight variations in pitch between even first-class orchestras, the player must be able to bring his instrument into complete accord with those playing with him. To make this possible, one of the loops, generally close to the mouthpiece end, so that the wind passes through it before reaching the pistons, is made to slide in and out of the two sections which it unites, instead of being firmly fixed at the joints, thus enabling the musician to lengthen or shorten the tube within certain limits. Thus the pitch can be raised or lowered a little. When the pitch is thus altered, the lengths of the tubes added by the pistons would be incorrect for the new pitch, and therefore a similar arrangement has to be made in the leads, so that they, too, can be made longer or shorter, and so brought into proper proportion to the entire tube length of the instrument. The simple sliding tube has been found the most efficient method of arranging the tuning of brass instruments, and is in general use, but it must be mentioned that various complications of it are to be found in strictly fancy instruments made by some manufacturers, who seem to rejoice in elaborate mechanism.

The Key Valve. One modification, however, must be mentioned, because of its general utility. While effecting the tuning of the instrument in the ordinary manner, by means of the common tuning slides, it is often advisable to be able to change the entire key of the instrument rapidly. This can be effected by means of a valve which adds sufficient length to the tube to lower the pitch a semitone or a tone, as may be desired. The leads of the piston work are then fitted with stops, which enable them to be drawn out the correct amount at once, without any tuning by ear. This extra mechanism is found to be of great assistance to French horn players and to cornet soloists.

Though the method of making curved tubes already given is that employed for the bulk of the bent work in brass instruments, yet certain curves are better constructed in another manner. Very small curved pipes, such as those between the first and second piston, and very large curved pipes, like those at the bottom bend of the huge brass bass instruments, are better built up than actually bent. This is because in the former case there is not sufficient material to work comfortably, and because the curve is so acute that puckering is unavoidable, and in the second case because of the great difficulty of properly bending a tube of, say, 3 in. diameter, filled with lead.

How a Curve is "Built." The method of building is simple enough. For very small curves, such as those in the valve work of a cornet, the tube is built in two pieces, each of which is beaten out of a curved piece of brass plate. The joins are down the outside and along the inside of the curved tube, so the sheet, before curving, will represent two U's. The curving, or hollowing, is accomplished by beating the metal on a piece of wood which has a groove cut in it of the proper curvature. Practical brass instrument makers have a number of apparently worthless pieces of wood, with rough, worn hollows in them. These are the wooden blocks on which their most reliable work is beaten, and to the workers are very valuable. The two U's, being beaten hollow with small hammers till the two halves fitted together make a perfect curved tube, have clems cut in them, and then are brazed in the same manner as the main tubing. The final rounding of the tube is effected on a curved iron.

Joining the two Tubes. Sometimes the bent tubes for the large brass bass instruments are built in the same fashion, but more often it is more economical to make them in two unequal-sized parts. The width of the two portions is the same, but one is much longer than the other. The reason for this is plain when we note that one piece forms the whole outer half of the curve, while the other makes the small inner portion of the same, the joins being along the sides. Both these portions are fashioned simply by hammering on blocks of wood, but while the longer piece must be bent with the curved hollow turned towards the inner portion of the U, the smaller piece has its hollowed side on the outside of the U. Both pieces are then brazed together, the joints cleaned up, and the large tube finally brought to a perfect round by hammering on irons. After cleaning and polishing, it is then ready to take its place in the instrument.

The Finishing Process. When the pistons have been fitted to the instrument the finisher takes it in hand and solders on the various supporting stays which help to keep the whole mass of tubes together. The outsides of the curves of large instruments are reinforced with strips of brass plate soldered on to protect the tubing from dents, and neat little collars are fastened round the ends of the tubes into which the slides go, and at the place where the crooks, or lengths of tube used for altering the pitch, are inserted between the mouthpiece and the main tube. Every visible scrap of solder is scraped and burnished away, and then the polish is finished off with a strip of rag sprinkled with a little Tripoli powder. Prior to the final polishing, however, a musical expert takes the instrument in hand, and tries it, to make sure that it is in tune and that there is ample play allowed for the tuning slides to permit of any reasonable differences in pitch being compensated for. If he finds that such is not the case, either fresh slides have to be fitted, or some portion

of the tubing replaced by a longer or shorter bit, as the case may be. Generally, it is desirable that the slide should be a little drawn when the instrument is tuned to give its normal pitch. This makes it possible both to sharpen and flatten the pitch, as occasion may require. The tone of the instrument and the facility with which the harmonic notes can be obtained will at once tell the expert if the tubing is absolutely faultless. His branch of the manufacture cannot be taught. Considerable natural talent, a marvellously accurate musical ear, and long experience are absolutely necessary.

Of the plating and engraving on musical instruments we shall not treat here, those being portions of the silversmith's craft [see page 5528, also METAL COATING].

Straight-tube Instruments. Instruments of the trombone and tuba class are not made with conical tubes, always excepting the short bell length. They can be made from tube constructed as indicated, or from hard drawn tube. The slide trombones and slide trumpets have no valves, but one of the U-tubes slides in and out of the limbs for a very long distance, and the lowering of the note in actual playing is thus effected, instead of by the addition of lengths of tube by means of the pistons. The movable portion in these instruments slides over the fixed portion, a point which must not be lost sight of.

Saxophones, sarrusophones, and ophicleides, which are conical brass instruments played by means of holes covered with keys, have their tubes made in the same way as ordinary brass instruments; but the holes are bored in the completed tube by means of an instrument similar to that which is used in making wooden instruments, which are there described.

WOOD-WIND INSTRUMENTS

The making of wood-wind instruments is a much more exacting branch of the instrument-maker's calling than the manufacture of brass ones. The reason is simple. You cannot add pieces to a wooden tube without injuring its resonance, so from the first you must accurately determine the length of each section. Again, if a hole is wrongly bored, it cannot be filled up and rebored, save for purposes of experiment. Added to this, there is the danger of splitting, inherent in all wood. Greater delicacy of workmanship is therefore necessary if first-class results are to be obtained.

The first players managed with a simple reed, crushed, and with a few rude holes pierced in it; to-day, the choicest woods of the world have to be sought if tone is required. Formerly, boxwood was employed in making wind instruments, but owing to its power of absorbing moisture, and so altering the tone of the flute or clarionet made of it, it is now regarded as unsuitable. Other woods, possessing the necessary degree of hardness, have an awkward knack of splitting without any apparent cause, and so have to be rejected, and for all practical purposes the choice of woods is now reduced to those we shall mention. Cocus, a very hard, brown wood, heavier than water, and imported from the West Indies, is the best all-round natural wood used. It is suitable for making flutes, clarionets, and piccolos, and is capable of giving a rich tone. It does not split readily, is very handsome, and not very treacherous to work. Rosewood is used for oboes, cor anglais, and bassoons. It is a little softer than cocus, and not quite so heavy. It is not a very easy wood to work, requiring a great deal of experience if the best results are to be obtained. Maple is sometimes used for bassoons on account of its lightness, but it is not nearly so reliable as rosewood, and is not much cheaper.

The Use of Ebonite. The most popular material at present for the making of wood-wind instruments which are likely to have to withstand rough usage, or great extremes of temperatures, is not a wood at all, but is a compound of indiarubber and sulphur, known in the musical trade as ebonite, and to the general public as vulcanite. The tone of ebonite instruments is not quite as perfect as those of the best quality wood, but as they are practically imperishable, never cracking, and not being affected by heat or cold, their advantages outweigh this slight loss of quality for all ordinary work.

The wood for instruments comes to England in logs, each of which weighs from ½ cwt. to 1 cwt. It is then stored away from the heat of the sun, protected against draughts and frost, for a number of years, till it is perfectly seasoned. When the time comes for it to be worked up it is split into billets suitable for the size of the instrument to be made. If it were sawn it would be much more liable to split in the subsequent operations, and many a defect, which splitting reveals, might not be discovered till the flute or bassoon was finished, when so much labour and time would have been wasted.

Turning the Wood. After being split into billets the wood again lies by for a short while, and is then roughly turned. This preliminary turning, simple as it sounds, is really a very important operation. The lathe used is one of the old-fashioned overhead pole lathes, the wood being revolved by a cord passed round it, and turning between dead centres. The object in using this pattern lathe is because it enables the turner to note any flaw in the wood, and by slightly shifting his centre to cut it out, still leaving sufficient sound wood to make a first-class instrument. The pole lathe also enables the turner to leave a raised boss on any part of the wooden cylinder he is working upon should he require to do so. In these days when metal pillars are used for all good keyed instruments, this is not a very important point, but in the making of low-grade instruments, with the keys working between bosses, it is a most useful factor in the lathe.

The wood having been roughed out, it is again examined, and if it passes muster, it is turned down to the extreme outside measurement of the instrument under construction, and again allowed to season for a short while to see if any cracks reveal themselves. The ends which are to fit into other joints are then turned to measurement and the instrument in embryo is ready for boring. It must be remembered that in working ebonite all this seasoning has not to be undergone, and so the manufacture is a more speedy business. Contrary to popular ideas, the ebonite is turned and worked exactly like wood; anything savouring of moulding would result in absolute failure.

Boring Wood Instruments. Much depends on the bore of a wooden instrument, and for a long time experts carried on active warfare over the respective merits of conical bores and cylindrical ones. The best flutes nowadays are made with a cylindrical body and a slightly conical head, the smallest portion of the cone being close to the cork which closes the upper end. This cone is said to be parabolic in section, but the parabola is so acute as to equal a cone to all but a mathematician. Oboes have a conical bore, while a great deal of the bore of the clarionet is cylindrical. The bassoon is a perfect cone, though the taper is very gradual indeed, as might be expected from its great length.

Both cylindrical and conical joints are bored in the same manner—namely, by a species of revolving gouge mounted on a mandrel of a lathe. This magnified drill is exactly of the diameter of the inside of the instrument under construction, and, of course, for instruments with conical bores, is cone-shaped. It has a cutting edge along its whole length. The billet of wood being fixed in position, the drill is started revolving, being entered exactly in the centre of the end of the wood, and allowed slowly to eat its way through the entire section, the wood being slowly fed up to it. Absolute accuracy is essential in this operation, and a variety of devices have been invented for keeping the wood in a dead straight line with the centre of the drill during the process, but the best manufacturers do not make use of these mechanical guides to any great extent.

The great danger in boring is the splitting of the wood, for it can be easily understood what a strain there must be on the fibres of the wood—say, of a bassoon joint some 2 ft. or more in length, with a conical drill, every fraction of whose edge during its whole length is actually cutting, revolving within it.

The "Butt." The butt, or foot joint of the bassoon requires two holes bored through its entire length, the smaller being bored from the bottom to the top, and the larger from the top to the bottom, for the first hole is wider at the bottom than at the top, while the larger hole is much wider at the top, the bottom being the same size as the largest diameter of the smaller hole. This is because in the foot the doubling of the bassoon pipe is effected, the bell of the bassoon, and consequently the widest part of its bore, being above the performer's head.

When the drilling is finished the inside of the tube is perfectly smooth; so finely do the drills cut that no sand-papering or other trimming is generally necessary. Here it may be mentioned that some manufacturers believe that the less sandpaper is used in the making of wood-wind instruments the better the resulting tone.

After the drilling, and sometimes before the wood is drilled, the outside is polished up on the lathe in the ordinary way. The wooden cylinders are then laid aside, standing in racks, for about three or four months, and kept at an even temperature. If the boring has caused any small cracks they will show themselves in this time, and further labour need not be wasted on the wood. This additional period of seasoning is also necessary to enable the internal portion of the wood to get thoroughly accustomed to the action of the air.

The Borings. Up to this point the cylinders, or conical tubes, have been made exactly to a fixed scale of measurements, these measurements differing according to the instruments under construction and the peculiarities of the individual maker. Consequently, as they all are of similar lengths, they would all give the same note, since the bores are the same. It follows, therefore, that if the holes are correctly placed on one of these pieces of wood, to give the proper notes, then if the holes on the others are placed in the same positions, all will give the same scale, with the same degree of accuracy, allowing for very minute alterations. Recognising this, first-class makers have adopted a machine which enables them to exactly copy any set of borings on any flute.

This piece of apparatus works in this way. Between two clutches the model is fixed, and, exactly parallel to it and about three inches below it, the cylinder to be bored is also secured by screw clamps. Travelling along a rod, parallel to the model and object is a small drilling lathe driven by a cord from some overhead source of power. The block carrying the drilling tool can be advanced in a straight line at right angles to the model, and towards it. The cutting drill, selected acording to the size of the hole, and revolving at a high speed, is on the face of this block exactly opposite the centre of the object wood. Above it, and of exactly the same length as the drill, is a plain, round steel rod. The size of this varies exactly as that of the drill. This steel rod acts as a guide and a check at the same time. The cutter beneath it can only advance just as much as this rod advances, and is bound to move strictly parallel to it. The model and the wooden tube beneath it are so mounted that if the model is revolved on its long axis through a certain number of degrees the wooden tube moves at exactly the same rate through exactly the same number of degrees; whatever is done to the model is copied faithfully by or on the object wood.

Cutting the Holes. The body tube of, say, a first-class flute which is perfectly tuned is selected as a model for flute bodies. All the keys are stripped off, leaving just the tube and holes, including even the small holes into which the key pillars fit. This is placed in the upper part of the machine, and in the lower is placed one of our seasoned cylinders of wood, which we propose to bore, and so transform into the body of a good flute.

A cutter and steel touch are selected of exactly the size of the large holes on the model. The touch is put into the upper part of the travelling lathe, and the cutter fixed to the lower spindle. The power is then turned on and the cutter, or drill, begins to revolve. The steel touch is now brought opposite to the first hole on the model, and introduced into it gently, the cutter beneath forcing its way into the wood of the copy to just the depth that the touch passes into the model. The hole is thus neatly and rapidly bored, and as far as position is concerned it is exactly the same as the first hole in the model, which is known to be correct. The other large holes are bored in the same manner. Then the power is turned off, and the cutter changed, as well as the touch, to suit the smaller key holes on the model. As the model is turned to bring these exactly opposite the touch, the copy follows it, and so the holes are again placed in their correct positions.

Preparing the Beds. Now, if you examine the holes of a good flute—that is, one with all holes covered, for uncovered holes do not require beds—you will notice that round the top of each hole the wood is sunk a little, and a still deeper groove, with a convex surface, leads from the extreme rim of the sunk portion up to the flat bed on which the pad of the key presses. To make these beds, a circular cutter with a concave surface is placed on the lower machine, and a touch corresponding to the entire surface of the bed put on the upper guide holder; or a plain large touch is placed on the upper machine holder, the depth of this particular groove being gauged by eye. The travelling lathe is then advanced, and the cutter follows, cutting a ring round the first holes, but the ring has a well-defined convex surface, since the cutter has a concave surface. When all these rings have been prepared, the flat beds are cut in much the same manner, only the cutter has a perfectly flat surface which just takes off the crest of the convex rim already cut. Thus neat, level beds are made, which will

enable the pads of the keys to "bite" nicely, and stop the holes accurately.

For other instruments the process is exactly the same. Wherever the touch goes, the cutter faithfully follows, only it cuts its own path in the copy. The slanting holes in the wing joint and the butt of a bassoon can be cut with this ingenious machine, for the travelling lathe can then be made to move in an oblique direction to the axis of the model, and consequently to cut oblique holes in the copy. It is obvious, too, that by replacing the revolving cutter by a fixed chisel, and permitting the copy to revolve, as well as the model, between centres, any inequality on the model could be reproduced on the copy, were it worth the trouble.

Tips, Rings, and Joints. According to the practice of the manufacturer the end rings, and joints of cork and linings are placed in the tubes either before the holes are drilled or afterwards. The wood is turned accurately to fit the rings, which are gently forced on, great care being exercised not to split the wood, or to strain it. There is nothing special in this branch of the trade, neat and accurate fitting being the sole essential. Where a flute head is lined, the metal tube is also inserted at this stage.

The pillars and rods and levers which go to make up the mechanism of the key action on wood-wind instruments are made either of silver or German silver. Their construction forms a neat branch of silversmith's work. The pans to hold the pads are stamped in a die press out of the metal sheet; the shanks and rods are fashioned out of silver or metal rods, or stout wire. The various component parts are joined together with fine silver solder, and polished and burnished up. The pads are of stuffing, covered with the finest skin. They are fixed in their pans either by a central screw, with a washer, or by means of cement.

Finishing. The bored tube of the instrument, with a supply of pads, levers and other mechanism is now handed over to a finisher, who proceeds to build up the instrument. Where the pillars are attached directly to the wood, the finisher has to tap a fine screw thread in each of the pillar holes in the tube, and screw in the pillars. When the bulk of the mechanism is on a long plate, this has to be screwed down on to the side of the tube. To the plate the pillars have been previously riveted. The finisher then puts in the keys and levers in regular order, depending upon the model of the instrument he is making. The little needle springs he inserts in the holes in the pillars with pliers, and tests them to see that they are not too strong, and yet sufficiently firm to close the holes tightly. This sounds as if it were a rapid job, but, as a matter of fact, it is very long and tedious, for no mechanical assistance can be given, and the whole of the adjusting has to be done by hand, with the greatest patience. It is one long task of filing and scraping, a little here and a little there, till each of the keys works perfectly by itself, and also works properly in conjunction with others if intended to do so. The finisher must be an instrumentalist, at least in as far as ability to play scales in every key on the instruments committed to his care is concerned; he should be gifted with a fine ear and a fine perception of tone.

When he has accurately fitted up the instrument, and tried it, being satisfied that the mechanical requirements are duly fulfilled, then the finished flute, or oboe, or bassoon, or whatever it may be, is passed to the expert, who decides whether the instrument is truly in tune throughout and perfect in every respect. If he finds one or two notes a little faulty, he gives instructions for their adjustment, either by removing a little wood from the bore of the tube at certain spots, or by altering the hole a fraction. If more than slight, but at the same time important, alterations are necessary, the best makers reject the instrument as unworthy to bear their name—and it would be well for the world of music if everybody did the same.

Fitting the Parts Together. Sometimes it may happen that while the individual joints of a wooden instrument are perfect, they do not work well together, and then the labour is not lost, as the parts can be built up in other instruments. The cause of this curious disagreement is not understood, for it has been known to occur when every part of a particular instrument has been built from the same log of wood, and from actually adjoining portions. To make a good examiner of wood-wind instruments, the artist must have a good theoretical and practical knowledge of the laws of sound, and must add to this a wide experience. It is a position only attained after years of close acquaintance with this class of instrument. The oboe, cor anglais, and bassoon are made in strict tune with the recognised concert pitch, and are incapable of alteration. The clarionet can be flattened a little by very slightly drawing out the head joint. The flute is best made so as to be up to concert pitch when the head is drawn out on the tuning slide about a couple of millimetres. In the opinion of some people, the flute can be flattened a good deal; but, as a matter of fact, it bears flattening very badly, for it stands to reason that if the holes are properly placed for one position of the slide, they must be wrong for all other positions.

Repairing Wind Instruments. The repairs to brass instruments are few in number and, in the majority of cases, of a very simple nature. The pistons may get out of order and their adjustment is only a matter of a few minutes for the man who made them—or the tube may get badly battered. Very often a battered tube can be restored to a playable condition without resulting loss of tone by removing the section from the instrument and shaping it again on the irons. Occasionally the job may be better and more economically done by fitting in an entirely new piece of tube of the proper calibre and thickness. Anything which savours of "soldering up a crack" is "botching" of the worst description, and cannot be called true repairing.

Wood-wind instruments suffer from one great ailment—namely, cracking, a fault which ebonite instruments are free from. Cracks, if not very bad, can often be stopped with composition very neatly, and no great loss of tone results. The famous flute player, Ciardi, played on an instrument with a terrible crack right down the head joint, yet his tone was as near perfection as has yet been attained, always excepting that produced by Nicholson. Defects in the mechanism of the keys are also frequently met with, being caused by a blow or a fall. These can either be rectified by the finisher, or may necessitate a new key being made for the instrument. Sometimes valuable instruments are accidentally damaged beyond repair.

SIDES AND ANGLES OF A TRIANGLE

Logarithms. Formulæ Connecting the Sides and Angles of a Triangle. Four Cases of Solution of Triangles

continued from page 6500

By HERBERT J. ALLPORT, M.A.

LOGARITHMS—continued

31. The decimal part of a logarithm is called the *mantissa*: the integral part is called the *characteristic.*

The logarithms of two numbers which have the same digits in the same order (i.e., they differ only in the position of the decimal point) have the same mantissa.

For example, let the numbers be 147·2 and ·01472. Then

$$147{\cdot}2 = {\cdot}01472 \times 10^4.$$
$$\therefore \log 147{\cdot}2 = \log {\cdot}01472 + 4 \log 10$$
$$= \log {\cdot}01472 + 4.$$

Hence, by keeping the mantissa always positive, the logarithms of numbers expressed by the same digits will only differ in the characteristic. Now, the characteristic of the logarithm of a given number can always be obtained by inspection. From Article **30** it is evident that

(i.) The characteristic of the logarithm of a number greater than 1 is *one less* than the number of *integral* figures in the number. Thus, characteristic of log 549·287 is 2, since there are *three* figures in the integral part, 549, of the number.

(ii.) The characteristic of the logarithm of a number less than 1 is negative, and is *one more* than the number of noughts between the decimal point and the first significant figure. The characteristic of log ·000582 is -4.

In order to denote that only the characteristic is negative, and the mantissa positive, the negative sign is written *over* the characteristic, and not *before* it. Thus, if the logarithm of a number is $-2 + {\cdot}8257143$, it is written $\bar{2}{\cdot}8257143$.

Since the characteristic is found by inspection, the mantissa only is printed in the book of logarithms. For example, opposite the number 59082 we find 7714552. This means that 7714552 is the decimal part of the logarithm of any number which consists of the digits 59082 in that order. Thus, log $5908{\cdot}2 = 3{\cdot}7714552$; or log $\cdot059082 = \bar{2}{\cdot}7714552$.

32. Books of logarithms vary in detail, but all of them contain instructions for using their contents. In *Chambers' Mathematical Tables*, mentioned in Part 44, the use of the tables is explained by many worked examples, which the student will find no difficulty in understanding. The only thing we need refer to here is the *Rule of Proportional Differences.* The tables give the logarithms of numbers from 1 to 100,000, *i.e.*, number of five figures. The above rule enables us to find, by means of the tables, the logarithms of numbers having six or seven figures.

The rule is that *when the differences between three numbers are small compared with the numbers these differences are proportional to the corresponding differences between the logarithms of the numbers.*

EXAMPLE. Find log 33651·4, having given that log 33651 = 4·5269980 and log 33652 = 4·5270109.

Let log $33651{\cdot}4 = 4{\cdot}5269980 + d$.

Then, we have three numbers: 33651, 33651·4, 33652. The differences between the first and second and between the second and third are ·4 and 1. Again, we have three logarithms corresponding to the numbers, viz.:

$$4{\cdot}5269980,\ 4{\cdot}5269980 + d,\ 4{\cdot}5270109.$$

The corresponding differences are d and ·0000129, and they are in proportion, so that

$$\frac{d}{{\cdot}0000129} = \frac{{\cdot}4}{1},$$

whence $d \doteq {\cdot}0000052$ (to seven places).

$$\therefore \log 33651{\cdot}4 = 4{\cdot}5269980 + {\cdot}0000052$$
$$= 4{\cdot}5270032.$$

33. The logarithms of the ratios of all angles from 0° to 90° have also been tabulated. Sines and cosines are less than 1, and so also are tangents of angles between 0° and 45°. The logarithms of these ratios will therefore have *negative* characteristics.

To avoid printing these negatives, the number 10 is added to each logarithm. The result is called the *tabular* logarithm of the sine, cosine, etc., and is indicated by the letter L. Thus, in the tables we find L tan 35° 4′ = 9·8463018, so that log tan 35° 4′ = 9·8463018 − 10 = $\bar{1}{\cdot}8463018$.

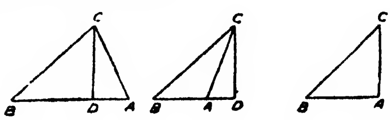
The rule of proportional differences is applied in the same way as in the case of numbers, so that from the logarithms of tan 35° 14′ and tan 35° 15′ we can find log tan 35° 14′ 25″, say.

Sides and Angles of a Triangle

34. In a triangle ABC, the letters A, B, C are used to denote the number of degrees in the angles at the points A, B, C respectively; so that "sin A" means "sine of the angle at A." The letters a, b, c, denote the lengths of the sides BC, CA, AB, *i.e.*, the sides opposite respectively to the points A, B, C.

35. *To prove that* $\cos A = \dfrac{b^2 + c^2 - a^2}{2bc}$.

Since a $\triangle$ has at least two acute angles, one of the angles B, C, must be acute. Let B be acute. Draw CD $\perp$ to BA or BA produced. In the three cases, where A is acute, obtuse, or a right angle, we have



(1) $BC^2 = CA^2 + AB^2 - 2\,BA \,.\, DA$ (*Prop.* 69);
or, $a^2 = b^2 + c^2 - 2c \,.\, DA$.

But $\dfrac{DA}{AC} = \cos A$, so that $DA = b \cos A$.

$\therefore\ a^2 = b^2 + c^2 - 2bc \cos A$.

(2) $BC^2 = CA^2 + AB^2 + 2BA \,.\, AD$ (*Prop.* 70);
or, $a^2 = b^2 + c^2 + 2bc \cos DAC$.

But $\cos DAC = \cos(180^\circ - A) = -\cos A$.

$\therefore\ a^2 = b^2 + c^2 - 2bc \cos A$.

(3) $BC^2 = CA^2 + AB^2$

$\therefore\ a^2 = b^2 + c^2 - 2bc \cos A$,
since $\cos A = \cos 90^\circ = 0$.

Hence, in all three cases we have

$$\cos A = \frac{b^2 + c^2 - a^2}{2bc}.$$

Similarly,

$$\cos B = \frac{c^2 + a^2 - b^2}{2ca},\quad \cos C = \frac{a^2 + b^2 - c^2}{2ab}.$$

36 Let $a + b + c = 2s$.
Then $b + c - a = b + c + a - 2a = 2s - 2a = 2(s - a)$.
Similarly, $c + a - b = 2(s - b)$,
and $a + b - c = 2(s - c)$.

37. *To prove that*

$$\sin\frac{A}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}},$$

and

$$\cos\frac{A}{2} = \sqrt{\frac{s(s-a)}{bc}}.$$

We have $2\sin^2\dfrac{A}{2} = 1 - \cos A$ [Art. 26]

$$= 1 - \frac{b^2 + c^2 - a^2}{2bc} = \frac{2bc - b^2 - c^2 + a^2}{2bc}$$

$$= \frac{a^2 - (b^2 + c^2 - 2bc)}{2bc} = \frac{a^2 - (b-c)^2}{2bc}$$

$$= \frac{(a + b - c)(a - b + c)}{2bc} = \frac{2(s-c) \cdot 2(s-b)}{2bc}.$$

$$\therefore\ \sin\frac{A}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}}$$

Also,

$$2\cos^2\frac{A}{2} = 1 + \cos A = 1 + \frac{b^2 + c^2 - a^2}{2bc}$$

$$= \frac{2bc + b^2 + c^2 - a^2}{2bc} = \frac{(b + c)^2 - a^2}{2bc}$$

$$= \frac{(b + c + a)(b + c - a)}{2bc} = \frac{2s \cdot 2(s-a)}{2bc}.$$

$$\therefore\ \cos\frac{A}{2} = \sqrt{\frac{s(s-a)}{bc}}.$$

Similarly,

$$\sin\frac{B}{2} = \sqrt{\frac{(s-c)(s-a)}{ca}},\quad \cos\frac{B}{2} = \sqrt{\frac{s(s-b)}{ca}},$$

$$\sin\frac{C}{2} = \sqrt{\frac{(s-a)(s-b)}{ab}},\quad \cos\frac{C}{2} = \sqrt{\frac{s(s-c)}{ab}}.$$

38. From the last article we have

$$\tan\frac{A}{2} = \frac{\sin\frac{A}{2}}{\cos\frac{A}{2}} = \frac{\sqrt{(s-b)(s-c)}}{\sqrt{s(s-a)}}.$$

Similarly for $\tan\dfrac{B}{2}$ and $\tan\dfrac{C}{2}$.

39. Since $\sin A = 2\sin\dfrac{A}{2} \,.\, \cos\dfrac{A}{2}$ [Art. 26].

$$\therefore\ \sin A = 2 \,.\, \sqrt{\frac{(s-b)(s-c)}{bc}} \,.\, \sqrt{\frac{s(s-a)}{bc}}$$

$$= \frac{2}{bc} \,.\, \sqrt{s(s-a)(s-b)(s-c)}.$$

The expression $\sqrt{s(s-a)(s-b)(s-c)}$ is usually denoted by S. Hence, $\dfrac{\sin A}{a} = \dfrac{2S}{abc}$. In the same way we get $\dfrac{\sin B}{b} = \dfrac{2S}{abc} = \dfrac{\sin C}{c}$.

Therefore, in any triangle

$$\frac{\sin A}{a} = \frac{\sin B}{b} = \frac{\sin C}{c}.$$

40 *To prove that* $\tan\dfrac{B-C}{2} = \dfrac{b-c}{b+c} \,.\, \cot\dfrac{A}{2}$.

Since $\dfrac{\sin B}{b} = \dfrac{\sin C}{c}$. $\quad\therefore\ \dfrac{b}{c} = \dfrac{\sin B}{\sin C}$.

$\therefore\ \dfrac{b-c}{b+c} = \dfrac{\sin B - \sin C}{\sin B + \sin C}$ [Algebra, Art. 139]

$$= \frac{2\sin\frac{B-C}{2} \,.\, \cos\frac{B+C}{2}}{2\sin\frac{B+C}{2} \,.\, \cos\frac{B-C}{2}} = \frac{\tan\frac{B-C}{2}}{\tan\frac{B+C}{2}}.$$

But $\qquad \dfrac{A + B + C}{2} = 90^\circ.$

$$\therefore\ \tan\frac{B+C}{2} = \tan\left(90^\circ - \frac{A}{2}\right) = \cot\frac{A}{2}.$$

$$\therefore\ \frac{b-c}{b+c} = \frac{\tan\frac{B-C}{2}}{\cot\frac{A}{2}};$$

or, $\qquad \tan\dfrac{B-C}{2} = \dfrac{b-c}{b+c}\cot\dfrac{A}{2}.$

Similar formulæ can be proved for $\tan\dfrac{C-A}{2}$, and $\tan\dfrac{A-B}{2}$.

41 By the aid of the formulæ in Articles **35** to **40** we can solve a triangle when we are given three of its parts, one of the given parts being a side. These formulæ are therefore very important.

Solution of Triangles

42 There are four cases.

(1) Given the three sides.
(2) Given one side and two angles
(3) Given two sides and the included angle
(4) Given two sides and the angle opposite one of them.

43 Given the three sides a, b, c.

From any of the formulæ of Articles **37** and **38**, we can calculate two angles, say **A** and B. The third angle is $180^\circ - A - B$.

For logarithmic computation these formulæ are adapted as follows

$$\tan\frac{A}{2} = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}}.$$

$$\therefore\ \log\tan\frac{A}{2} = L\tan\frac{A}{2} - 10$$

$$= \log\sqrt{\frac{(s-b)(s-c)}{s(s-a)}} = \log\left\{\frac{(s-b)(s-c)}{s(s-a)}\right\}^{\frac{1}{2}}$$

$$= \tfrac{1}{2}\{\log(s-b) + \log(s-c) - \log s - \log(s-a)\}.$$

CIVIL ENGINEERING ABROAD

The Profession and Practice of the Civil Engineer in Greater Britain. The Labour Supply for Engineering Works

Continued from page 6498

By C. O. BURGE

ENGINEERING is more important abroad, for, apart from the question that the area of construction in Europe is largely closed, the magnitude of operations at home have never been, as a rule, on anything like the scale of those abroad, either completed, in progress, or projected, for examples of which we have only to think of such works as the Suez Canal, the Hawkesbury Bridge in Australia, with its foundations 160 ft. below water, the deepest ever reached; the Zambesi bridge, with its bold span of 500 ft. thrown over a chasm of nearly the same depth; and the Coolgardie water supply scheme in West Australia, in which the water is pumped about 1,700 ft. high through pipes extending from the source, near the sea at Perth, to the goldfields 351 miles far inland.

Climate. One of the most potent causes of difference in the engineering conditions at home and abroad is that due to climate. In moist, hot countries, like those near the coasts of West Africa, Natal, India, North Queensland, and other tropical and even sub-tropical regions, the decay of materials, especially ordinary timber, is rapid, and must be provided against by the use of special classes of timber, or by the substitution of stone or metal in works where wood, otherwise, would be better adapted. Heat also saps the energies of the workman—European or native. In India, during the prevalence of the monsoon rains, work and surveys have often to be suspended for lengthened periods, and the same happens in Canada during the extreme frosts and cold of winter.

Even as regards daily hours of work, climate is a factor. Near the Equator it is always unpleasant, and sometimes dangerous, for a European to be out of doors in the middle of the day, and even natives, at certain seasons, start work earlier and leave off later, to allow of a prolonged mid-day *siesta*, and work is often done by moonlight in such cases.

Heat and Design. Heat also affects design: for instance, hesitation to employ underground railways in Australian cities, or long tunnels through its hills, or those of similar regions, is due to the fact that engine-drivers and guards run considerable risks from the heat, accompanied by noxious gases, while going through; while obviously in sewerage schemes, the temperature has to be taken into consideration. On the other hand, snow sheds have to be provided at certain points in Canada to protect railways and other communications from obstruction in winter.

In some districts, more especially inland in Australia, parts of the Cape, and in the Argentine, want of water occasionally occurs for prolonged periods, and the engineer and his helpers sometimes have to go through great personal suffering. There are numerous districts where the water supplies are as much as 50 to 60 miles apart, and great cost is incurred in keeping even a small party supplied. Works and surveys in some cases have had to be temporarily stopped for this reason.

Health. Again, climate has much to do with the health of the engineer abroad, exposed as he is to its vicissitudes more than are most followers of other associations, but in nearly all the warmer climates with which we are dealing, there are highlands with exquisite climates, easy of access, where temporary refuge from the heat and lassitude of the lower levels can be had. In New Zealand, Tasmania, and many parts of Australia, South America, and South Africa, ideal climates exist, superior in many respects to our own, and, in most parts of the world, with youth, a good constitution and temperate habits, and the open-air life, the engineer can reckon on a fairly healthy life.

Labour. In the outlying lands, labour, one of the great means of engineering construction in any country, varies in character, not only from that of the British Isles, but from that of any other. Variety of labour is to a great extent due to climatic conditions. And first as to quantity. In India we have thousands of available hands, almost in every district, not only amply furnishing the unskilled labour, but all the artisans and clerks, and even the foremen and assistant engineers required, and in the case of the first-named, there is double the corresponding force in other lands, for women, as well as men, are found doing navvy as well as other work. On the other hand, in Australasia and Canada, there is a comparatively limited supply of white labour, and in these, as contrasted with India, we find the extremes of high and low wages.

Intermediate to these two extremes of India and Australia are the cases of South Africa, the West Indies, and numerous other places where coloured labour is used chiefly or only for unskilled work, the higher classes, at all events, of artisans' work being done by the whites, while in those parts which are largely dependent on Chinese labour, such as in the Straits Settlements and British Columbia, good skilled labour can be found among its ranks.

Quality of Labour. But we have to deal with quality as well as quantity of labour, and by quality it must not be understood that mere individual effectiveness in strength or skill is meant. If so, the Englishman by birth or descent would generally take a top place. It is the all-round value to the engineer for his purpose which is in question, taking not only physical strength and skill into consideration, but wages paid, trustworthiness, intelligence, manageability, endurance and sobriety, in many of which respects it must be allowed that other races stand higher. In the last-named quality the Indian coolie is pre-eminent, and not only actually, but in proportion to amount of work done, accepts perhaps the lowest reward of all mankind for manual labour. Economists state that the rate of wages for unskilled labour may be divided into two classes—namely, first, the *market* rate, which is that which prevails in the more wealthy communities, and is mainly influenced by the law of supply and demand; and secondly, the *natural* rate, where these laws find their limit, and which represents—having regard to the prices of commodities—the lowest means of sustenance for the workman and his dependants. It is obvious that no supply of labour, however great, can

bring wages below this point, as, should they be lower, the labourer would starve, and the work would end. The labouring classes of India and some other populous tropical countries are, to a great extent, living on natural wages, hence the economical advantage, leaving other considerations aside, of their employment. Thus there is, in India especially, the disinclination of the native to leave his village, and follow the demand for labour, and the absence of any desire to be richer than his forefathers or neighbours. Moreover, his domestic requirements are so few that the women are, as already stated, as numerously employed as the men, and this again tends to lower rates, the latter being direct producers

Oriental Labour. As a rule, the coloured man is nervous about taking risks, the competitive spirit in the face of them being absent, so that, though small contracts are not infrequently taken by them, fortunes are seldom made. Whether it be by day work or piece work, the rates are so low that methods of work, and even designs, differ largely from European standards, as we shall see later. Indian native masons, bricklayers, carpenters, blacksmiths, etc., do quite half as much work as Europeans, for a fourth or fifth of their wages; while an ordinary labourer at earthwork will do a quarter of the work of an English navvy at a seventh or an eighth of his wage. There are exceptions to this, however, in such heavy work as railway platelaying and the like, when it is inconvenient to crowd a sufficient number of hands so as to make up for want of individual strength in each of them. On the construction of the Canadian Pacific Railway, for instance, by white labour, as compared with that of an Indian line, about the same time, the same rate of progress was made in laying and lining up the rails, in the one case, by one-eighth of the number of workmen employed in the other, their wages bearing, inversely, about the same proportion.

Generally speaking, the men on whom the civil engineer in India, Ceylon, and Burmah has to rely are steady, easily controllable, law-abiding, and, to the limits of their strength, which is not great, hardworking.

Similar, in many respects, but more powerful in physique, and readier to take up the risks of contract work, are the Chinamen, who are numerous in the Straits Settlements; in Canada, west of the Rocky Mountains, and in Chili and Peru. They make excellent artisans, and working long hours at low wages, and being orderly and trustworthy, they form about the best material for his purpose that the engineer abroad can find. As to contracts and piece work, the Chinaman knows better than most men how to make a hard bargain; but once made, he can be trusted to carry it out loyally to the end, be it ever so bitter.

African and American Labour. The coloured races of South Africa, and those of the central and western parts, and the descendants of the latter in the West Indies, are physically much more vigorous than those of India generally, but they are impatient of continuous exertion, lazier, and frequently less manageable. Kaffirs save a few pounds on works, and are off generally without notice, sacrificing all pay due, with a few mats and pots, constituting their entire belongings; then, after having arranged for the purchase of a few cows, and perhaps sold a daughter or two, will turn up again for another short period of work. While the comparatively feeble Hindoo works steadily to the limits of his strength, and is easily controlled by his native maistry or ganger, the able-bodied Kaffir of South Africa, and the negro of the West Indies, require more or less forcible persuasion of the white foreman to utilise to the full their robust strength. Owing to this, Natal is obliged, in order to develop her resources, to import Indian coolies, though it is fully peopled by Kaffirs and Zulus, the latter especially being physically one of the finest of the coloured races. Coolies are also imported into Mauritius and Tasmania. The negroes of the West Coast and in the West Indies can be taught trades and do fairly well for skilled labour, but the South African native, as a rule, is good only for ordinary labour; the Malays, however, of which there are many in the Cape, make fair artisans, though they do not generally go inland, fish being their favourite diet. In Mexico and Central and South America, the full or half-blooded Indian races supply an able-bodied and generally satisfactory class of workmen, skilled and unskilled, when led by white foremen and inspectors.

The Italian workmen are found largely in the Argentine and other South American States, and, especially those from North Italy, are splendid workers, sober, thrifty, and intelligent. They are specially good at quarry and mason work. The workmen of Northern European race in Australasia, South Africa, or Canada, are much the same as those at home, except as affected by their generally much higher wages, which sometimes induce improvidence and gambling.

Speaking generally, the black and yellow races are very temperate in their habits, comparing favourably in this respect with the white man, some of whom drink heavily when the monthly pay day enables them to do so.

In this general summary of the description of labour with which the expatriated British engineer may possibly have to deal it may be noticed that the Japanese are omitted. Until very recently, this could not have been properly done, as English engineers were frequently employed in public works there of all kinds. But not the least wonderful of the many strides forward recently made by this remarkable race is the acquisition by many of them of the peaceful art of the civil engineer, so that, practically, the European practitioner has been shut out.

Cost of Labour. Obviously, wages are dependent on the varying data of demand and supply, cost and standard of living, and quality, so that no more than a general idea of the rates prevailing can be given. To begin with the lowest. In most parts of India, the men work for 6d., and the women for 3d. a day; while in Ceylon rates are somewhat higher. The West African natives work for 7d. to 9d.; Kaffirs in South Africa for 1s. to 1s. 6d., and the half-breeds called Cape boys, whose work, language, clothes, and general standard of living approach that of the European, can earn more than double as much. The wages of Mexican and South American natives range from 1s. 6d. to 3s., while Chinamen's wages vary much according to the country in which they are working. Workmen of European birth or descent can usually earn from 4s. up to 8s. in countries abroad cool enough for the exercise of their labour. The foregoing rates are for unskilled work. The wages of artisans range from 50 per cent. to 100 per cent. more.

The economical result of work done, taking into consideration the mere constituent of manual labour, is, as a rule, much in favour of that done for the lower wage—that is to say, though less work is done for this lower wage, it is not less in the same proportion, for, as has been previously shown, the

wages are less wasted in their spending, more of the results being returned in work.

Political Systems and Trade Unionism. The privileges and restrictions resulting from these among white workers abroad are powerful influences on the conduct of engineering construction. They are practically unknown, as affecting work, among the coloured races, though Chinamen are beginning to use strikes occasionally as a means of raising wages. In Australasia these influences are perhaps more powerful than elsewhere. Arbitration courts are established in many states of the Commonwealth, the intention of which is entirely well meant, as endeavouring to prevent strikes and lock-outs, to the benefit of the employers and men, and, to some extent, this has been achieved. But, generally, the existence of these courts is not favourable to the economical construction of work.

Animal Labour. As regards the use of domestic animals in engineering construction, the only one used in the United Kingdom is the horse. Abroad, not only is the horse employed in a greater degree, but a variety of other quadrupeds are used, and as the engineer has constantly to deal with them it is necessary that their habits and uses should be fully explained. In India, the horse is used only for riding and driving, generally the former on inspection work.

The bullock, and less frequently the tamed buffalo, do all the heavy work in the south of India, while in the north, this is shared by the elephant and the camel. The great intelligence of the elephant is generally utilised in engineering practice: for instance, after a few lessons, he can be trusted, without further guidance, to carry water pipes in his trunk, and lay them end for end, the spigot of one next to the faucet of its neighbour, ready for joining, alongside of the trench for which they are intended. Elephants will also roll over large stones, and lift them into tiers, ready for setting by the masons. They are intelligent enough to understand the rights of labour, and nothing will persuade one to work after the signal is given for the dinner hour, or for knocking-off time. These animals are also used for draught, specially built large waggons being constructed for the purpose. Not only are their brain and muscular powers thus exercised, but the weight of their bodies is taken advantage of, for walking over newly-made earthwork, and consolidating it, as efficiently as by a steam roller.

Camels are also much used as beasts of burden, and it is almost incredible the amount of loading they can carry slung over the back. For instance, in the transport of merchandise, it is not unusual to load two pianos in their cases, one on each flank of one of those much-enduring animals. In Australia, horses and oxen are used for team work, and the former for riding and driving. Light four-wheeled vehicles, called buggies, are employed, sometimes with one, generally with a pair, and occasionally with four horses. Practically, there are no ponies, mules, or donkeys, to be found in Australia. A few camels, with their Afghan drivers, have been imported for service in the dry inland country.

In South Africa we find teams of horses, of mules, but more frequently of oxen, sometimes twenty-four of the latter in one waggon. The mules are mostly imported from Monte Video, and, though not so powerful as horses, are much hardier, eating fodder which a horse would refuse, and standing drought much better. They are also free from horse sickness, which is endemic at the Cape. Mules are inferior to oxen in one respect, that, when struggling with a load, they easily lose heart, where oxen, through sheer stupidity, go on putting their whole strength into their task, never thinking of any possibility of failure.

Natural Productions. These stand prominently forward when we consider the facilities or otherwise in any country for engineering construction. We find that in most of the countries with which we are dealing these are quite as plentiful as at home, and in some cases, especially as regards timber, much more so. Every description of building stone, and material for bricks and tiles, abound, and are largely made use of. A peculiar kind of stone, called *laterite*, which is unknown at home, is much used in India and Ceylon. When first extricated, it is a flaky ferruginous sandy clay, of a red colour, rather friable and soft, so that it can be easily cut into brick form, but it hardens on exposure. The extensive employment of stone and brick is more usual in the cheap labour countries, as the use of these imply considerable skilled manual work. Timber, as a substitute for these, for the contrary reason, is preferred where skilled labour is expensive, and more especially where, as in Australia, the hard woods are exceptionally strong and durable. In India, few timbers are immune from the effects of the climate and white ants, but deodar or cedar, blackwood, sâl, ironwood, satinwood, and teak, are used, and even, hard as they are, in joinery work, the cheap labour allowing much time to be spent on it. The Australian hard woods are all very close grained and heavy, weighing up to 80 lb. per cubic foot, nearly twice as much as most English species. There are hundreds of varieties, but the most known and used are ironbark, box, tallow-wood, blackbutt, red and blue gum, mahogany, and turpentine, and in Western Australia, jarrah and karri. Turpentine is proof against the Teredo Navalis, or seaworm. These are often used without seasoning of any kind, and as railway sleepers and in bridgework, have been found perfectly sound after thirty to forty years' use. Very little labour is expended on these timbers, as they are only roughly hewn to the dimensions required, for most classes of engineering construction, and, the forests being very widely distributed all over the continent, the supply is never very far from the seat of demand.

Native Timber. Australian timber is largely exported. South Africa is differently circumstanced, for the forests there are more or less isolated and, from the want of railway communication, a want which is decreasing yearly, it often pays better to import timber from the Baltic and Australia than to use the home produce. Where accessible, however, good timber is plentiful, such as yellow wood, ironwood, assegai, milkwood, sneezewood, and stinkwood. The latter, it may be said, derives its name from its pleasing odour, the prefix in Dutch not having lost, as in our allied tongue, its original agreeable sense. In West Africa the timbers are generally inferior. The Canadian timbers approximate generally to those of the northern parts of the United States, and may be said, as a rule, to be inferior in strength and durability to those of the Southern latitudes. There are great quantities of the softer woods in British Columbia, the gigantic Douglas fir being largely exported to Australia, under the name of Oregon pine, for purposes for which, from their excessive hardness, the native woods are unfit. In Mexico, and many parts of South and Central America, though there are valuable timbers, difficulty of access often leads to importation.

In hot countries, the ravages of white ants, even in very hard woods, cause great difficulty. These

insects work in large bodies, excavating galleries inside the wood, so that often their depredations are unknown till utter collapse discloses them. Creosote, corrosive sublimate, and petroleum have been used as preventives with more or less effect, but with the harder kinds of wood it is difficult, even when compressed air is used, to force the liquid into the close-grained fibres of the timber: for instance, sâl and ironwood will not absorb more than 1 lb per cubic foot. In the Australian bush wooden houses are general, and in the northern warmer parts it is common to see an inverted tin basin on the top of each of the supporting posts, above which the superstructure of the building is erected. This is to insulate the house from its supports in the earth, where the white ant originates. The posts, of course, require occasional renewing.

Stone and Iron. Gravel and broken stone for concrete and ballast are generally fairly distributed, but there are notable exceptions, such as in the coast belt of West Africa, and in alluvial deltas, where sound deposits of considerable depth occur. The absence in such places of this much required engineering material gives rise to great expense in transport from more favoured localities. Iron ore of good quality, with its neighbour, coal, to smelt it, is found extensively in India, Australia, South Africa, and Canada, but labour conditions, and often its geographical position, have presented difficulties, so that importation of manufactured steel from Europe and the United States largely predominates. Canada, however, has some important steel works. Limes and materials for cement making are much in evidence also, but isolation, the question of carriage as in the case of timber, as well as in some cases inferior quality, leads to considerable importations of Portland cement from England. This is specially the case in Australia. In Canada, however, the local manufacturer of cement has already reached a larger figure than the imports.

In many countries, more especially on the coasts, very good lime is produced from sea-shells. With regard to material generally, the immediate products of the earth, such as stone, metals, sand, etc., have their exact counterparts more or less plentifully distributed, all over the earth; but the timbers are, to a great extent, distinct in character in nearly every country.

Remoteness of Operations. Perhaps the circumstances which differentiate the duties of the civil engineer abroad from those of his co-worker at home in the greatest degree are the effects of the distances from civilised and manufacturing centres at which he has to carry on his operations. There are, of course, numerous exceptions, and many of the difficulties to which we shall have to refer will not be found if his work should lie in, or near to, the large and populous cities which now rival those at home in the provision of his wants.

In remote parts few or none of the advantages of civilisation are available. Temporary houses or tents for the engineer, his staff, and sometimes for his labourers, have to be erected and shifted as required. Provisions have to be brought, at suitable intervals, from considerable distances, according to facilities for transport: and even, not infrequently, large numbers of men have to be rationed, the business of supply being similar to that of an army in the field, while there have been instances in which clothing has had to be furnished. A doctor has probably to be specially engaged to look after the health of the camps, and if the nature of the work requires a large number of men to be stationary in one place for any considerable time special sanitary works have to be provided. Then the law has to be enforced. It is very usual in these cases to constitute the engineer a magistrate, and to give him the necessary powers and the use of constables to carry them out, as well as a temporary gaol in which delinquents can be locked up. The men have to be paid periodically, and for this a travelling pay vehicle, with an armed escort, is required to bring the necessary cash from headquarters for the monthly pay, as it would not be safe to keep a large amount of money in the camp. Frequently a special mail service has to be instituted between headquarters and the construction camp. Sometimes a temporary telegraph wire is found to be useful. Owing to the different races often employed, periodical religious services for the men are not often practical, but these are sometimes arranged for. The local engineer in charge is head of all these organisations, hence he requires more qualifications than usually suffice for the ordinary work of his profession.

Public Works Abroad. In the self-governing Colonies, such as Canada, Australasia, Cape Colony and Natal, the procedure is the same in principle, though differing considerably in detail, as that obtaining in the United Kingdom; that is to say, approval of Parliament and the Governor's assent to all considerable works is required, whether the promoters be the Government itself, or private companies, or individuals. A Bill embodying the nature of the project is presented, and if passed this becomes an Act. In India, and what are called the Crown Colonies, there being no parliament, the works, if not initiated by the Government itself, as is frequently the case, must be recommended by the Governor-General or Governor, assisted by his council, and approved by the Home Government, on the advice of the Secretary of State for India, or for the Colonies, as the case may be. The smaller provinces in India have, however, a limited power of undertaking lesser works, but the larger ones must go before the Governor-General in council.

In countries abroad not under the British flag works not undertaken directly by the State must be sanctioned by the Government, this sanction being called a concession, and generally containing stipulations as to conditions, privileges, subsidies, etc., to which we shall presently refer.

Subsidies and Land Grants. With regard to State assistance in grants of land or money. In Canada, in unsettled districts, the Government has given to the promoters of railways alternate blocks of 160 acres each, adjoining the route on either side, which the latter are able to sell, to considerable advantage, in smaller lots, after the railway is open for traffic. In the case of the Canadian Pacific Railway, the Government assistance amounted to over £5,000,000 in money and 25,000,000 acres of land. It is very evident that, important as this line has become subsequently to the world, no private company unassisted could have undertaken it, as, passing chiefly through a then uninhabited desert across a continent, no profits could have been counted on for many years after completion. Jamaica, West Australia, and other countries, have followed the same plan to some extent.

Local Assistance. Cases have occurred in the Colonies where the State, generally providing funds for public works, has hesitated in proceeding in particular cases owing to doubts as to success, and where the inhabitants of the district are so interested and confident that, without disturbing the general policy of Government construction, they have assisted the State by some of the methods

referred to, or by submitting to a local tax; but unless the assistance is by ready cash or leviable tax, security for fulfilment is very necessary.

Contract and Departmental Work. In connection with the construction of works abroad, one important variation from home practice should be mentioned. Generally in the United Kingdom, in Europe and America—Canada in this respect, as in many others, following the lead of the United States—the promoters of works, whether governments, municipalities, or companies, employ contractors. This method has in many cases abroad been abandoned, and the promoters have carried out their operations directly themselves, both by day work and small contracts, or departmentally, as it has come to be called. The relative merits of these systems we have not space to discuss, but it is necessary to state that the engineer, under the latter one, has to combine his ordinary duties with those of a contractor's agent.

Small Contracts. Whether the system be by contract or departmental, the introduction into it of small contracts, as against day work, has special advantages abroad, where superintendence is often difficult to obtain, and always costly, more of this being required when the incentive to personal exertion of piece work is absent. Though there are cases in which day work cannot be avoided, such as those involving risks which a small contractor would not take, the fact that it is the best method is well demonstrated by the knowledge that it is that usually employed by the large contractor himself. Small contracts, for labour only, have sometimes been let to workmen on the principle of what is known as a Dutch auction. In the case of the earlier South African railways, in which the workers were a medley of English navvies, Italians, Greeks, half-breeds, Kaffirs, Malays, and other nationalities, excavation of earthwork, for instance, was put up at a starting price per cubic yard, and bids offered at lower and lower rates, by different competitors, until knocked down to the lowest bidder. He would then form his gang, generally of his own race, to do the work.

A variety of the small contract method, often in practice abroad, where the intelligence of the workmen is equal to it, is that of the *butty gang*. By this a gang of men contract to do a certain work, and when finished, the engineer, or overseer, divides equally among them the money due on the measurement.

The Profession Abroad. Not many years ago, the countries to which this course more particularly refers had to rely on the United Kingdom for the civil engineers they required; but gradually, and indeed properly, the Colonies and other places have become, comparatively speaking, well supplied, not only by such men who have, after the expiration of their agreements, decided to remain in the country, but by others who have gone out voluntarily to try their chances. These, with their Colonial pupils and others trained at local universities, since established, have rendered many lands self-contained in this respect. Moreover, there is actually a tendency, in a few states, to frame regulations for the practice of the profession, which throw difficulties in the way of strangers engaging in it at all.

In India, Australasia, South and West Africa—and, to a small extent, in North and South America—so many of the public works are carried out by the Government that a large proportion of the engineers are practically, and in some cases actually, members of the Civil Service, entering on their employment by regulated tests or examinations, acquiring pension rights, etc. In such countries, of course, the field for the engineer in what is there called private practice is very limited. For example, in one of the principal states of the Australian Commonwealth over 75 per cent. of the civil engineers are in Government employment, and in such cases the remainder have often to eke out a sufficient livelihood by combining their calling with that of architect, or land surveyor, or both. Contractors, in all countries, are frequent employers of engineers. The system of apprenticeship is not so general as it used to be, the more usual plan of entry into the profession abroad being through local university training; but not infrequently, irregular methods of becoming a professional civil engineer are tolerated, such, for instance, as promotion from the position of a draughtsman or inspector, to the higher status, with or without an examination.

In India there are universities, with affiliated engineering colleges at Calcutta, Madras, Bombay, Allahabad, and Lahore, on the model of the London University, besides two colleges for civil engineers. These, however, are primarily meant for the natives of the country, among whom there are already a considerable number of trained and capable men, many being corporate members of the Institution of Civil Engineers. In the capitals of all the greater Colonies there are also efficient universities, with engineering schools and laboratories, and there are usually in such cities also engineering societies, composed of the practising members of the profession, where papers are read and discussed.

Qualifications of an Engineer Abroad. Abroad, it is more than ever necessary for the engineer to remember the old adage, that an ounce of practice is worth a ton of theory. Certainly, a different set of qualifications, both physical and moral, is required from that which is sufficient for home work. As hardships are more likely and, in a few cases, worse climates may be encountered, a better physique and sounder health are necessary. Greater resourcefulness also is wanted in the engineer, as he has not the same means to his hand for his requirements, and he has probably, owing to distance, not equal opportunities of consultation in difficulties with his superior officer. Should survey work be engaged upon, the following acquirements, which, for the most part, will be gained locally, are a great help: First, a sense of locality—a great gift in far-away lands, what is called in Australia being a good bushman—that is, being a close but almost unconscious observer of physical features, such as the position of the sun and stars, the growth of moss on the weather side of trees, and countless indications which may guide him who has lost his way, far from help, in the trackless forest. Then, a knowledge of horses with their points and ailments, of riding, shooting, fishing, rowing, cooking, use of tools, tent-mending, and rough surgery—all these help the surveyor in camp. If the engineer's lot should be cast in countries outside the English-speaking Colonies, the acquisition of native languages may be necessary, and is always desirable, but this may well be left till his arrival on the spot.

In the United Kingdom there exists an elaborate ordnance survey in considerable detail. Therefore, the operations necessary to make it serve for a map or plan, on which the proposed work may be drawn, and from which it may be marked out, are not considerable in extent [see CIVIL ENGINEERING, page 1145]. In many cases, little more is

required than to measure up fences, houses, etc., which have been added since the date of the ordnance survey, or to enlarge at points where special works require more detail. There are, of course, in India, and some of the Colonies, small scale Government surveys, but these are generally insufficient, except for what is called preliminary or trial work.

Primeval Conditions. But there may be regions to be dealt with which do not possess maps even of any kind, however small, and of which the geography has to be virtually discovered by the surveyor. Explorations, followed by rough reconnaissance surveys, totally unnecessary and unknown in home operations, are indispensable preliminaries, and, owing to dense forests, he may have to adopt as his base line some trade route, possibly only a bridle path, which, though wanting in directness, may be the only feasible one without the great delay of cutting his way through in a more direct line.

Surveying by Photography. Reconnaissance surveys by means of photography are common in both North and South America. This is a system which it would require a textbook to explain, and therefore it cannot be more than referred to here. "Photographic Surveying," by E. Deville, published in Ottawa in 1895, is a good work on the subject. Sufficient it is for us to say that the system consists in the determination of the position of any objects as to their distance, elevation, and direction, in relation to the observer, by means of the calculated proportions which exist between the apparent perspective distances, etc., as either traced on a vertical glass, through which the observer sees them, or as received on a photographic plate, and the true dimensions [see page 595]. The system is sometimes preferred to the use of the plane table [see page 710], as the field work consists of observing only, the plotting being done in the office, thus saving some of the wages of the chainmen. It is often called "Photogrammetry," and by other similar names, but Deville prefers "Iconometry," as though photography affords the most convenient means of doing the work, it is not the essence of it.

Location. Coming to the second part of the engineering surveyor's work, that of location or designing, and marking on the ground the position of the proposed work, the latter merely a mechanical operation, differs only in minor respects from that required under home conditions [see page 801], but the circumstances governing the choice of location, or design, are very different in each case. For example, in laying out a road, railway, canal, or pipe line, the home engineer is almost as much concerned with minimum interference with private property as he is with topographical features, and his best result is obtained when a judicious mean is attained, varying towards the one object or the other, according to the value of the property and the extent of the physical difficulty before him. Abroad, except close to large cities, the property consideration is as nothing, and, practically, the whole attention is concentrated in avoiding or dealing with natural obstructions.

Location of Townships. In new countries it not infrequently happens that an engineering work, more especially a railway or a road, precedes settlement, unlike such undertakings in the older lands, which are never projected except between places already settled and populated to some extent, though, of course, an increase may be looked for due to the improved communication.

Not so always in the Colonies. In some cases, therefore, of a projected road or railway, towns and villages will not have come into being, even on paper, in a district be it ever so fertile. In these cases it often falls to the lot of the engineer to fix sites for future towns which will not only be suitable, as regards water supply, drainage, foundations, etc., but also conformable to the project with which he is more immediately concerned.

Resources of the Country. Then in the newer lands the facilities for the construction of any proposed work are often little known beforehand, and the surveyor is consequently called upon in that case to furnish a report on the resources of the district as to stone, timber, gravel, material for bricks and lime, water supply, etc., and even sometimes as to the fertility of the soil and mineral productiveness, with the view of informing those who have to decide as to the desirability of the proposal. So it will be seen that in order to judge rightly in these matters, quite an additional number of qualifications to that necessary for the home practitioner is required.

Surveying Instruments. As to instruments, the surveyor will find abroad a tendency, unless when special accuracy is required, to the use of light ones, more especially where labour is dear—in fact, he will probably often have to carry some of them himself. It is not uncommon, for instance, to meet in Australia the surveyor riding at a rapid pace through the bush with a theodolite set upon its legs and carried on the rider's shoulders. For the same reason there is a tendency to do, if possible, by a theodolite the work ordinarily performed by means of a spirit level, so as to combine two different operations with the one instrument. Various forms of tacheometers have been devised, partly with the same end in view, though the weight of this instrument is an objection [see page 710]. The plane table [see page 710] is much used for the preliminary survey which is such a prominent feature of our course, and the ordinary miner's dial has been found very useful in the dense tropical forest of West Africa, and is preferred there to the prismatic compass [see page 267]. The instruments used in iconometry are various, both for use in the field and for plotting, such as the photo theodolite, the photometer, the diagraph, the perspectograph, the centro-linead, and the perspectometer.

As regards the later and more detailed surveys, the instruments used abroad are generally similar to those at home, but steel bands, instead of the ordinary link chain, are almost universally employed, as less likely to catch in undergrowth, etc. In countries where the metrical system prevails, the chain is 20 metres long, which is about 4¾ in. shorter than the English 66-ft. chain. The levelling staff is also divided into metres and centimetres. A feature in the marking of the position of proposed works in new countries is the necessity of making marks for this purpose very substantial and permanent, and to number them, for, owing to the absence of artificial features, such as fences, etc., it would be otherwise difficult to find them again when the construction engineer comes on the ground.

CIVIL ENGINEERING *concluded*

PRINTING FROM STONE

The Craft and Trade of Lithography. The Cumbrous Stone and its Metal Substitutes. Lithographic Inks. Colour Printing. Rotary Printing

LITHOGRAPHY
Continued from page 6486

By CHARLES HARRAP

LITHOGRAPHY as a business or craft is but young compared with the majority of trades, as its discovery by Alois Senefelder dates back only to 1798. It still appears but a new art to many of the older workers and to those who have intimately investigated its early stages and its early specimens.

As a craft it is one attended with so many difficulties and so many "discoveries" that it is rendered at once pleasant, as well as intricate, to all who may be engaged therein. Not only do these trying circumstances surround the man who has learnt the trade, but they come upon the amateur or novice in the way of surprises which, for some years, are very trying, not to say disheartening. The toils of the trade are not rendered any easier by the traditions which have been handed down through three or four generations of workers who learnt originally only how to work by inspection and under special guidance, without ever attempting to learn why particular methods were adopted. This has proved not only a barrier to progress, but has been the cause of preserving the use of methods and materials which ought to have been discarded at an early date—yet it is these very antiquated notions which are held in such respect by the old-fashioned craftsman.

The Trade of Lithography. From its inception as a business in London about 1818, the trade has been gradually on the increase, and at the present time no less than 10,000 craftsmen are directly employed in the production of lithographic prints in Great Britain alone. But although the trade is a small one, it has probably given greater pleasure to a larger number of persons than any other craft, large or small. It has been the means of preserving the works of excellent artists in a beautiful and lasting form, and this has been accomplished at a minimum of cost.

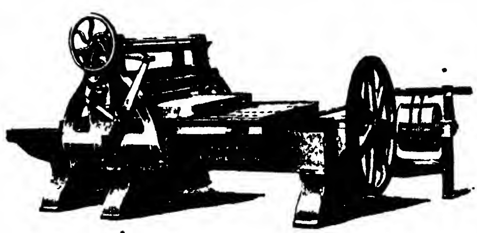
Lithography is responsible for the production of many pictures, as posters and showcards, which have given great pleasure to the whole people, and have assisted in illuminating the dark corners of our streets and otherwise unsightly hoardings. The many ways in which lithography has been brought to bear upon other printing crafts has done much to increase the production and lessen the cost of such arts as engraving and photography. As an illustrative art it has been so often and so successfully called into requisition as to make it practically indispensable to all good publications. Of course, it has had its trials, and it was many years before it ousted such processes as aquatint and mezzotint, as well as much copper and steel plate engraving, from their premier positions.

In the early days of the art it attracted some of the best artists or sketchers as a means of actually producing their own work directly upon the stone; and one artist, R. J. Lane, became an Associate of the Royal Academy through his superb productions from sketches and original productions directly upon stone.

What Lithography is. Lithography is, as its derivation implies, writing or drawing upon stone. But it has the further meaning of producing copies or prints from a stone. More recently the trade of lithography has been construed to include both printing from zinc (*zincography*) and from aluminium (*aluminography*). If a generic term can be applied, the whole of the different methods should be termed planography, as they are all, virtually, methods of printing from a flat surface or plane. The expression flat surface must be further defined as polished surface, or a grained surface, in contradistinction to a surface etched in high relief. The use of zinc as a printing surface was very little posterior to stone, but aluminium cannot be placed prior to 1890.

All three methods are generally practised by the lithographic printer; and not a few printers are also able to work the various photographic processes akin to, and including, photo-lithography and collotype. So numerous are the methods employed that a lithographic printer has at his command the means of producing any print from the roughest draft plan or specification of the architect to the finest form of imitation photograph, in black or colour. The photographic processes now applicable to lithography are so far advanced that three-colour work is practically within its available bounds.

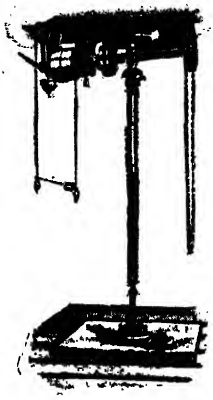
Lithographic Stones. The stone used in lithography is an exceedingly fine, close-grained chalk or marble, geologically known as a "slate," the latter term having been applied because of the form in which it exists in quarries. These quarries are largely developed around Solenhofen, and extend many miles. But a formation of similar stone runs from Bavaria northwards into Norway and Sweden, and southwards through Switzerland, France, Italy, Spain, across by Corsica and Sardinia, into North Africa.



1. STONE-PLANING MACHINE

Formations of the same rock are known in Turkey (around Salonica), Greece, Asia Minor, and the Caucasus mountains, and stones from all these districts have been actually used. A firm in Greece has printed largely from Greek stones; another firm in Berlin has used Caucasian stone; samples from Turkey and Asia Minor have been used in England; and Spanish stone is largely used in Barcelona. French stones have had considerable patronage, but German stones are, without doubt, the finest products, and are used throughout the world; and it is estimated that in a not far distant future the supply will be exhausted. It is this fact, coupled with the cost and weight of stones, which has caused the

introduction of metal plate substitutes, and a strong attempt to compound a stone of similar qualities. The efforts in this direction have been many during the last fifty years; but the want of knowledge of the actual composition of the stone, and the inability to apply the forces which originally compressed this fine chalky mud into a durable rock, have so far been a barrier to its accomplishment.



2. STONE GRINDING AND POLISHING MACHINE

Artificial Stones. At present, many forms of stone are successfully copied artificially, and it seems more than probable that if artificial production should be successful in the lithographic trade, it will prove doubly beneficial, for at the Bavarian quarries the appearance of the country is disfigured by the enormous mounds—even hills—of stone-quarrying debris, which could be used, and a cheaper article put upon the market. At the present time (1907) a firm successfully manufacturing marble (exhibited at the Building Trades' Exhibition, 1907) is progressing with the manufacture of lithographic stone.

3. ADVANCE LITHO PRINTING MACHINE

The statement that failure in making artificial stone may be due to a want of knowledge of the constituents of lithographic slate is perhaps open to criticism. The composition is broadly that of marble, with a little something else which makes the difference—a small difference, but an important one. The original geological formation was probably in progress some hundreds of thousands of years, and the gradual consolidation of the rock was attended by such circumstances in watery surroundings, the juxtaposition of various chemicals and a heavy pressure, that the result is a stone varying in its character just so much—yet very little—from marble, that while the latter is quite useless, the lithographic slate is the only article that can be used. Like marble and chalk, it undoubtedly owes its origin to immeasurable quantities of fine shells—shells pulverised to an imponderable dust—and ultimately deposited in marine waters as a mud, to be converted finally into stone.

The Chemistry of Lithography. The actual processes of lithography, zincography, and aluminography, are dependent upon chemical actions. In pursuing these methods, the chemistry of each must always be the actuator of the printer, for the same chemicals may not be used to attain the same object in each case.

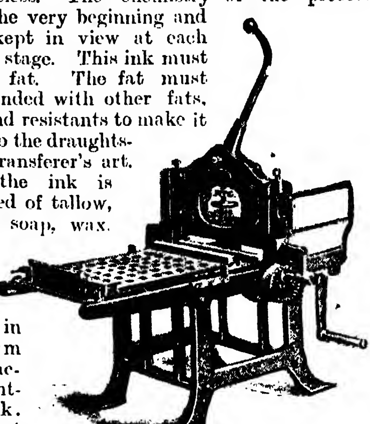
The objects of the chemicals used may be set forth as (1) rendering the surface non-sensitive to grease; (2) rendering the surface sensitive to grease; (3) rendering the work invulnerable to decomposition by acid; (4) rendering the work easily removable by acid; (5) attacking the constituents of the ink used in drawing to make them combine with the printing surface; (6) compounding the original drawing and transferring inks; and (7) compounding the printing inks.

The foregoing brief survey naturally leads directly to a closer description of lithography in detail. In dealing with the subject, little will be said of zincography and aluminography, except by briefly mentioning some of the variations of treatment.

Preparation of the Stone. To obtain an original upon a stone, the stone must be ground down to a slab of equal thickness, so that both surfaces are parallel; then one surface must be ground perfectly level to receive the work. This is accomplished by grinding with sand, by the more remote hand methods, the more recent mechanical appliances [2], or by the latest device of planing the surface in a machine constructed with a long steel planing blade [1]. This machine may be said to be the most perfect appliance yet introduced for the purpose, as it can be gauged to plane off an extremely thin layer of stone, leaving a perfectly level surface all over.

After grinding or planing, the surface is burnished with a close-grained slate, until it presents a distinct semi-glassy polish, without scratches. Upon this surface, when dry, original work may be drawn or transferred, providing the subject is executed in a line or dot. If the work is of a "grained" character, the polished stone must be suitably grained by sprinkling with fine sifted sand, and rubbing the sand evenly into the stone all over, until the surface is broken up into a fine grain. The sand is then washed off, and the work drawn upon the dry stone with specially prepared ink, called crayons.

The Inks of Lithography. By whatever method the original work is put upon a stone the ink used must contain certain standard articles or it is useless. The chemistry of the process starts at the very beginning and must be kept in view at each succeeding stage. This ink must contain a fat. The fat must be compounded with other fats, solvents, and resistants to make it amenable to the draughtsman's or transferer's art. Generally the ink is compounded of tallow, palm oil, soap, wax, stearin, shellac, bitumen, and a diluent in the form of manufactured printing ink. These are not all used in one ink.



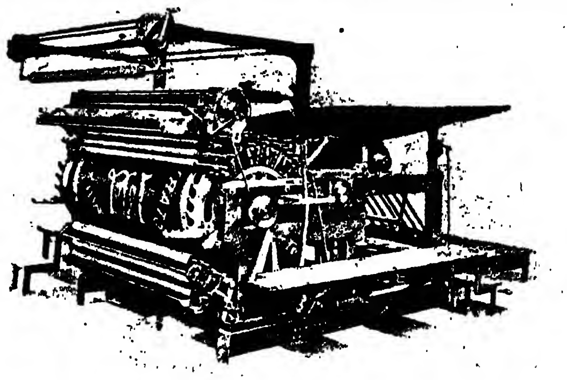
4. MODERN GERMAN HAND-PRESS

Thus, the draughtsman's ink may contain tallow, wax, soap, shellac and printing ink; the stone transferring ink, tallow, stearin, palm oil, soap, and printing ink; and the copperplate transferrer's

ink may be somewhat similar to the last with bitumen or asphalt. Crayons may contain only tallow, soap, wax, and shellac. Photo-lithographic transfer ink may be similar to plate transferrer's ink without soap. The variety of the lacs is subject to variation to meet the needs of greater or less hardness, or necessity for etching. The object to be attained is to bring into contact with the stone some form of free fatty acid. It is common knowledge that chalk—lithographic stone—when treated with an acid suffers decomposition and some compound is the result. This is especially the case when a fatty acid attacks the stone, as the resulting compound is an insoluble salt of the calcium of the stone with the fatty acid of the ink. This compound is the real printing "surface" procured upon the stone. Similarly, fatty acids (as well as many other acids) attack zinc and aluminium, and in these cases produce an insoluble compound which gives the printing "surface."

Etching the Stone. The work having been drawn or transferred upon the stone, the printer proceeds to obtain impressions. If the work consist of heavy masses of thick ink it must be "etched" or treated with an acid that will decompose the surplus soap in the ink and convert it into an insoluble compound with the stone. This is especially necessary with work drawn in crayon upon grained stone. The etch may be a watery solution of nitric acid, or tannic acid, or weak tea; or a mixture of gum arabic solution and nitric acid.

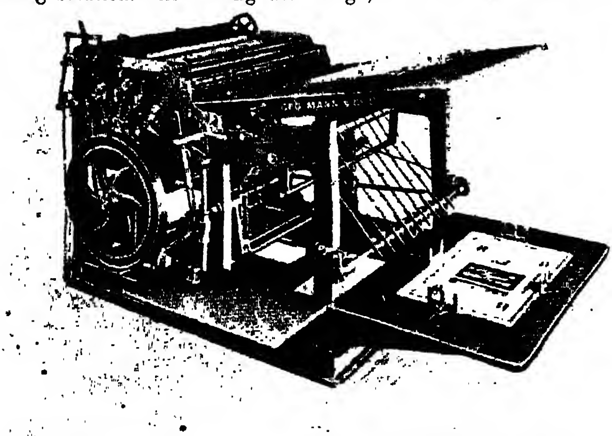
The older method of etching grained stones was with a very dilute solution of nitric acid in water, and it was applied in two ways. The first was to pour over, or deluge the stone with a large jug full of the etch, the whole of it running off the stone into a jug and being used again. The second was to place the stone in a rocking-trough, and fill the trough to the top edge of the stone with the etching solution. In rocking the trough, a wave of etch passed evenly over the stone and left it clear. Both these methods have the pre-eminent advantage of leaving the stone free after immersion, thus allowing the heavy bubbles of gas to escape from the surface before a second etch is commenced. In either case, the applications of the etch are numerous before it is completed, and its completion is so much a matter of experience that no rules can be given. This phase of the subject is dealt with apparently in greater detail than it warrants; but it is so important in its bearings that both the principle and methods involved might be applied usefully to some present-day practices.



5. LINOTYPE LITHO ROTARY PRESS

This treatment having been performed, the actual work on the stone is in a more or less insoluble condition in hot or cold water, and is strengthened by the etch. The work may then be carefully inked, either by dabbing or rubbing printing ink on it with a fine soft rag, or by rolling up with ink on a leather roller; in any case gummy water must be kept on the stone to preserve uniform dampness and to prevent the particles of the original ink from catching upon the surface of the stone and forming a scum upon its surface. Having charged the work with ink the stone may be washed clean.

Preparing for Printing. If the work be not drawn, or transferred, in heavy thick masses, the first etching may be dispensed with. Such treatment also applies to work put on the stone in a hard or bituminous ink which has not had time, or does not contain sufficient active agents, to cause its ready combination with the stone, and does not require an etch. After charging with ink and washing clean, the work cannot be considered in quite such a strong condition as necessary, and it should be covered with a fine resisting powder, such as resin, talc, or silica, when it may be lightly "etched" with dilute nitric acid. The acid actually decomposes any remaining soap in the ink, as well as the actual stone, thereby carrying away many loose particles of grease which have been carried accidentally on to the surface of the stone. The stone is again washed, and well covered with gum arabic. This gum is of a complex composition, and there is little doubt that it forms a surface on the stone



6. METAL-PLATE ROTARY LITHO PRINTING MACHINE

impenetrable to grease. Finally, after the gum has dried, it may be washed off; the work is then "cleaned" or washed out with turpentine prior to final rolling up. It is then thoroughly cleaned up by using a scraper of steel, a wooden stump with acid, or a fine stick of polishing stone prior to printing the copies from the stone.

Printing Machinery. The printing is usually done in a machine which is fitted with damping rollers and leather inking rollers to imitate the hand press method of damping a stone well [4]. Printing is seldom done from the original drawings. Transfers are taken from the originals and put upon new stones, so as to preserve the originals for further use. The originals themselves may be transferred to zinc or aluminium plates and stored away, thus liberating the expensive stone. Wherever possible, the originals should be drawn on the plates. The impression is procured upon paper which is carried on to the surface of the stone upon a cylinder—the cylinder being forced down upon a stone by powerful springs or weights. The action of the machine is to take the stone under damping rollers, which moisten the surface of the stone to prevent greasy ink catching; thence under the series of inking rollers. The stone returns under the inking rollers, getting fed a second time, and in completing its backward journey the printing paper is brought down upon its surface. The contact of the paper with the stone is reduced to the fine line made by a perfect cylinder coming in contact with the flat surface of the stone, the whole pressure of the powerful weights or springs being brought to bear upon this rapidly moving line of contact [3].

The latest idea in lithographic (planographic) printing machinery embodies the possible culmination in the art of printing from a flat surface. In the past it has been the common practice to print upon paper by direct contact of the hard surfaces of the cylinder and the stone or metal plate. This practice has had its variations in the Orloff method as applied to printing on paper, printing on tin, and collotype printing, where the printing surface is soft. But this principle has been applied to lithographic printing upon paper in the well-known lithographic machine of the rotary type [5]. The success of such method has been proved upon hard and rough paper by printing from an intermediate soft transfer appliance, as introduced in 1907 by G. Mann & Co., of Leeds, under their patent of 1903 [6].

Lithographs in Colour. The feature of lithography which, perhaps, to the general public is the most interesting, is the production of coloured prints—chromolithographs—upon paper, card, earthenware, silk, satin, etc. The process is difficult owing to the great care which is necessary in every detail. An oil painting is reproduced in the following way. A tracing is taken from the picture. This tracing is generally made upon a thin sheet of gelatin, the actual tracing being done by "cutting" in the gelatin with a fine steel point. This copy takes not only the general outline of the subject but includes the boundaries and contours of all the various colours and mixtures of colours. This *engraving* on the gelatin is then filled in with transfer ink, carefully cleaned, damped (in a special damping book), and laid down upon a perfectly clean stone. It is run through the press and transferred to the stone, to be gummed up and rolled up as ordinary work. It then constitutes the *key* or guide. From it a number of impressions are taken upon a hard-faced paper or paper mounted on zinc, so that there will be one impression for each colour that the artist intends to use. These impressions are dusted with an offset powder, of common red chalk, or aniline, magnesia, and carbolic acid. The latter is the best as when put upon the stone it penetrates, and the stone may be washed and polished lightly without removing it.

These dusted impressions are run down upon separate clean stones, and then constitute the offsets, to which the artist draws all the colours in the proper lithographic ink. When complete they are all rolled up in the ordinary way, and the impressions in each colour are pulled, one by one, on top of each other until the whole picture is finished. The process requires great care in getting each colour to print in its correct place—*registering*; and in the use of colours which, by overlapping one another, give the correct colour scheme of the original.

Transfer Processes. In the preparation of originals, the stone, zinc, or aluminium is not employed for drawing directly upon entirely. Many originals are executed upon transfer paper. The paper is prepared with a gelatinous surface compounded with an inert dust. Transfers may be taken from copper plates, steel plates, stones, or type, and patched up into the necessary design, when they are transferred to stone.

A branch of the transfer process prepares originals direct from photographic negatives in line, dot, or stipple. It is applicable to producing certain kinds of originals direct upon aluminium, zinc and even stone. It is applied to producing work by the colloytpe, photo-stone and photo-lithographic processes, little used prior to the past ten years [see pages 6483 and 6486].

Transfers are used in all cases where a large number of prints are produced at the same time.

Substitutes for the Cumbersome Stone. Both zinc and aluminium have been adopted, more extensively in recent years, chiefly owing to their adaptability to be "mounted" upon cylinders, in rotary machines, which have been much improved in the past ten years.

The same reagents will not suit all surfaces. Nitric acid is the acid par excellence for the general treatment of stone; it is positively inert upon aluminium for similar purposes, and on zinc its effect is not beneficial. Oxalic acid has particular uses upon stone, which are opposed to its effect on aluminium. Caustic soda, little used upon stone, is a solvent of aluminium, and on zinc is distinctly useful. Phosphoric acid is scarcely used upon stone, whilst with zinc it is of prime importance. Much more could be written on the differences between the treatment of these surfaces.

The applications of planographic printing are both beautiful and numerous. The well-known oleographs, the ever delightful Christmas cards, the illustrated toy books, and the host of atlases, natural history books, and artistic publications, owe their value and their charm to this business—a business which is not an amateur one, which is not of an ephemeral character, but one in which success can be attained only by many years of steady application.

Three good books on the subject are "Practical Lithography," by A. Seymour (1903, Scott, Greenwood & Co.), "Handbook of Lithography," by David Cumming (1904, A. & C. Black), and the "Grammar of Lithography," by V. D. Richmond (E. Menken).

SYSTEM IN THE FACTORY

Factory Organisation. Records of Cost and Labour.
Time Recorders and Other Labour-saving Appliances

Continued from page 6522

By D. N. DUNLOP

THE revolution in business methods which is silently taking place is nowhere more apparent than in the factory. New processes, the invention of new tools, new methods of gearing them and increasing their efficiency, the use of new combinations of cutting steel, have not only caused radical changes in factory practice, but also in the character and skill of the labour employed.

Industrial organisation has become a new science. The authorities and executive required by a factory organised on up-to-date lines are shown in the table below.

The Complete Factory System. A complete factory system comprises three main divisions:

(*a*) The system of cost accounting and record keeping.

(*b*) A system controlling the procedure by which raw material is converted into a finished product, including records of all kinds of labour and of machinery.

(*c*) A system for keeping accurate records of raw material and finished product received or produced, requisitioned and on hand.

To be effectual the cost system must at least perform the following functions:

1. It must furnish records of the work and relative efficiency of workmen and foremen, as well as of machines and departments.

2. It must act as a diagram for the organisation of the whole factory which it holds together.

DEPARTMENTS.		DEPARTMENTS.	
MECHANICAL ENGINEERING ..	*Mechanical Engineer:* power, plumbing, testing, equipment.	BUSINESS MANAGER AND ASSISTANT	Sales, advertisements, collections, purchases, costs, estimates, audits.
STORES AND STOCK	*Chief Storekeeper:* production orders, all material, requisitions, perpetual inventory, shipping requisitions, finished product, tools.	ACCOUNTING	Bookkeeping, pay-rolls, sales, collections, billing, costs, cash, disbursements.
RECEIVING ROOM	*Receiving Clerk* unpacking, checking receipts, purchase and requisition.	CORRESPONDENCE	Letter writing, mailing, postage, telegraph and telephone, contract writing, filing of office documents.
DRAWING ROOM	*Chief Draughtsman:* drafting for products, outside contracts, equipment.	SALES DEPARTMENT	Salesmen, agents, dealers, regular products, parts and repairs, outside work.
PATTERN ROOM	*Foreman:* pattern making, carpenter work, pattern stores, requisitions.	PUBLICITY	*Manager:* advertisement writers, translators, researchers, photographers, engravers, artists, catalogues, circulars, pamphlets, press work, printing.
TOOL ROOM	*Foreman:* all tools made for own use, and outside work.	PURCHASE	Material, supplies, office stores, tools, machinery.
SHIPPING ROOM	*Shipping Clerk, Warehouse Clerk* packing, shipping, transport, checking invoices, shipping documents.	ORDERS	*Order Clerk:* regular product, repairs, parts, outside work.
SUPERINTENDENT'S OFFICE ..	*Superintendent:* manufacturing inspection, tracking orders, all requisitions, auditing, maintenance, outside expense, shipping.		

N.B.—The chief authorities are given in italics.

3. It must enable the superintendent to follow the work through each department of the factory, to detect defects and provide remedies.

4. By means of a system of receipts and requisitions, it ensures that everything used or produced in the factory shall be accounted for, and responsibility for all defects and losses located.

5. It keeps watch on the output per man, per machine, per department, and for the whole factory, giving danger signals when the ratio of costs to output oversteps safe limits.

6. It furnishes the means of securing comparisons on all manufactured products as well as data for a close analysis of the comparative costs of jobs at different periods; and of estimated costs, tenders, and contracts.

Systems of Cost Keeping. The cost department of a factory under a chief accountant or cost-keeper takes cognizance of the important factors of *material*, *labour*, *factory burden* (*manufacturing expense*), *general expense*, including depreciation, and *special items of cost*. It deals with them in harmony with the other systems of organisation.

It is necessary to keep three sets of costs for every product manufactured.

1. The *flat cost* or *prime cost*, including the price of raw material or stock parts, and the cost of the productive labour.

2. The *factory cost*, comprising the prime cost, plus the *factory burden*—that is, factory non-productive labour, manufacturing supplies, and any other expenses incurred by the factory directly.

3. The *total* or *selling cost*, consisting of the factory cost, plus the proper percentage of the general expenses chargeable to the order, for items such as interest on capital, insurance, depreciation, salaries, rent, taxes, maintenance, etc.

The organisation of a cost department necessitates only a small addition to the staff—namely, the cost-keeper or factory accountant, and perhaps one or more clerks, according to the magnitude of the business, and a few for the card-filing cabinets.

Routine of the System. The prime functions of this system have already been discussed. The system ensures that none but written orders, duly signed, take effect in any department, and that clerical work is eliminated as much as possible from the shops. Work is set going in the cost department by the issuing of a production order signed by the general manager, which concerns the whole establishment. The general manager's clerk then makes out the factory order in duplicate, giving it a number which must be recorded on every card, loose-leaf, or voucher concerning it, and accompanies the work on its progress through the shops; the order bears particulars as to estimate, tender, correspondence, and customer, which enable the whole history of its genesis to be kept on record.

The factory order passes on to the superintendent, who files it after making out a separate production order for each department concerned. If the order be for a new type of machine, the superintendent sends written instructions to the drawing office, where the necessary drawings are put together.

Working lists are then drawn up for the foremen, giving them detailed instructions concerning every operation, even the most trivial, which is to be performed in their shops; the duplicates of the working lists are filed in manilla folders for reference; they contain an additional column for the cost of each item to be added on completion of the order.

In the Stockroom. Each foreman on receipt of the production order and working lists sends a requisition card, prepared for him in the cost department, after duly signing it, to the storekeeper for the raw material or stock parts necessary for the operations in his shop.

The stock-keeper, on issuing the material, returns the card to the foreman and registers the disbursement in the card index of his perpetual inventory, fills in a material disbursement card, which he forwards to the cost department. The cost of the material may be filled in by the stock-keeper, but the better plan is to keep all records of costs in the cost and record departments, and to leave that item to the cost-keeper to fill in.

The amount is charged to the shop in question, and the card remains on file with other disbursement cards for the same order, until the labour cards come in from the departments concerned and furnish the data necessary for compiling the three sets of costs mentioned above. The disbursement cards act as signals to the stock-tracer, who may be one of the inspectors, and whose duty it is to follow the progress of each order, step by step, through the shops, deriving his clues from the various cards which come in to the cost department. The stock tracer's records take the form of transfer cards, recording the factory order number, the date, the departments between which the transfer takes place, the number of pieces, the number passed, the cause of rejection, the name of the part and symbol or number, the machine on which it is used, the storage record (section, bin, shelf, or rack), the requisition order number, remarks, and the signature of foreman.

Progress Through the Shops. Meanwhile, the production order proceeds through the shops. The foreman is furnished with job cards, one for each job, ruled and filled in as far as possible, in the cost department, leaving him the date, name of workman, and signature to add. The cards are prepared in advance so that no time is lost between jobs. The workman registers the time at which he starts a job on a mechanical recorder, and when the work has been examined by the foreman he registers the time in the "finished" column of his card, receiving at the same time the card for the next job, which he at once registers in start column. The foreman signs the card for the finished job, and forwards it to the cost department; but he keeps the production order and material requisition card until the order is completed. As the cards come in daily—one might say hourly—from the various departments, including painting, assembling, testing, packing, shipping, the cards belonging to the same order are filed together, and the detailed total-cost card is made out from them, a duplicate being sent to the commercial office for the use of the bookkeeper, who charges the amounts to their proper accounts in the loose-leaf ledgers.

Orders for repairs are treated in exactly the same manner; the number assigned is, however, in that case preceded by R for outside work, and by MR (maintenance repairs) for repairs to the plant.

The Record Office. The functions of the record office, which may at first sight appear to be unnecessary, are really of the greatest importance in modern industry. At first these may be undertaken by the cost department, but as the utility of the records becomes appreciated, and fresh series of records suggest themselves, then the need for a separate department asserts itself. The cost department furnishes the data; the record office makes use of them to compile deductions, statements of efficiency and of progress. An efficient record office has the power to secure the reduction of the cost of production to the lowest minimum,

and, by a thorough system of supervision and control, to eliminate waste.

The Distribution of Manufacturing and General Expense. Manufacturing expense, or the factory burden and general expense, affect respectively the factory and the selling cost. It is evident that, to be profitable, manufacturing must include selling the output at a definite profit on the entire cost; the difference between the selling or total cost and the selling price must, in fact, be pure profit. We have seen how a modern department arrives at the prime cost by means of a simple and direct system. The computation of factory and selling costs, which are no less important, is generally considered to be a matter of great complexity and difficulty. This is undeniably the case in a factory deficient in organisation and without an up-to-date cost system. The result is that the task is often shirked, and a percentage is estimated to represent expenses, which is often wide of the mark, and entails heavy losses.

The Factory Burden. The chief items of factory expense are interest on capital, rent, taxes, insurance on buildings and machines, depreciation and maintenance of equipment, power, lighting, heating per area of floor-space, supervision, salaries, general unproductive labour, supplies, etc.

Approximate expenses should on no account be charged equally to all jobs passing through the shops, excepting those expenses which, from their very nature, cannot be connected with any operation. It is obvious that in large machine shops, for instance, each machine or group of machines involves a certain running expenditure per hour, such as power, attendance, depreciation, maintenance, supplies. *These expenses are all proportional to the time the machine is running,* and cease when it is at rest. The other items of expense are fixed, and never vary.

The Machine Rate. All the expenses which should be borne by each individual machine must be carefully computed and charged by means of an hourly rate to the job for which the machine has been used. In order to accomplish this, it is necessary to take the following steps:

1. The items composing the machine rate must be figured out.
2. A schedule of classification for all machines used must be made, as explained in the section on the applications of the card system.
3. The workman's job card should be ruled to include columns for the hours during which the machine has been operated, for its number, and for the hourly rate.

In order to deal fairly with the two different classes of charges, the fixed expenses, which are constant for the year, divided by the number of hours the machine has worked, form the *machine rate.* Those expenses which vary with the conditions of commercial and shop efficiency are thrown into a *supplemental* or *variable* rate, computed weekly and charged equally to all jobs passing through the shops. A card-index is used for the schedule of classification for the machines, a separate card being allotted to each individual machine, showing its number, cost, interest, insurance, depreciation, rent, taxes, floor-space, and the machine rate as soon as it has been figured out.

Example of Machine Rate. The following is an example of the application of the system: The rate for a machine, No. 312, costing £600, might be approximately as in the following table.

	£	s.	d.
Interest on capital at 5 per cent.	30	0	0
Depreciation	60	0	0
Insurance	50	0	0
Floor Burden (rent and taxes per square foot of floor space)	140	0	0
Power	60	0	0
Share of general supervision	10	0	0
Waste-oil and belting, etc.	30	0	0
	£380	0	0

On account of machine No. 312, £380÷2,400 hours worked during the year=3s. 2d. hourly machine rate for the year.

The supplemental or variable rate is computed thus: The same items given above per machine *are debited in the aggregate per shop* for the week, each shop being credited with the total machine rate charge for all machines for the week, collected from the weekly summaries of job cards. The balance is divided by the total hours worked during the week by all machines in that shop, which gives the supplemental rate per hour, to be charged to each job over and above the hourly rate, according to the number of hours' work put into the job.

Supplemental Rate. This system is easily put into practice, as in the following example:

Labour costs of order No. 617, Dept. IV.:

CASE A.

	£	s.	d.
10 hours of machine No 24 at 3d. per hour	0	2	6
12 ,, No 112 at 5d. ,,	0	5	0
8 ,, No. 425 at 1s. 6d. ,,	0	12	0
3 ,, No. 312 at 3s. 2d. ,,	0	9	6
15 ,, No. 390 at 9d. ,,	0	11	3
48 hours' machine work total cost.. ..	2	0	3
Add variable rate at 4·5d. per hour for 48 hrs.	0	18	0

	£	s.	d.
Wages 10 hours at 10d per hour	0	8	4
,, 12 ,, 8d. ,,	0	8	0
,, 8 ,, 8d ,,	0	5	4
,, 3 ,, 18d ,,	0	4	6
,, 15 ,, 9d. ,,	0	11	3
,, 48 ,, Total wages	1	17	5

	£	s.	d.
	1	17	5
Percentage for general unproductive labour (labourers, oilers, etc.), 5 per cent. of productive	0	1	10¼
	£4	17	6¼

The value of this method of distributing manufacturing expense is fully demonstrated by the next example, showing the costs for Dept. IV. of a similar order performed in another month:

CASE B.

	£	s	d.
48 hours' machine time as before	2	0	3
Variable rate 48 hours at 10d.	2	0	0
Wages as before	1	17	5
Percentage for general unproductive labour, as before, 5 per cent. of productive ..	0	1	10¼
	5	19	6¼

The same order, performed in the same Dept. IV., but by different workmen, in another month, gives the result shown in next example:

CASE C.

	£	s.	d.
6 hours of machine No. 24 at 3d. per hour	0	1	6
12 ,, No. 112 at 5d. ,,	0	5	0
4 ,, No. 425 at 1s. 6d. ,,	0	6	0
3 ,, No 312 at 3s 2d. ,,	0	9	6
10 ,, No. 390 at 9d. ,,	0	7	6
35	1	0	8
Add variable rate at 4·5d. per hour for 35 hrs.	0	13	1½
	2	2	9½

	£	s.	d.
Wages 6 hours at 1s per hour	0	6	0
,, 12 ,, 8d. ,,	0	8	0
,, 4 ,, 1s. ,,	0	4	0
,, 3 ,, 1s. 6d. ,,	0	4	6
,, 10 ,, 1s. ,,	0	10	0
	1	12	6

	£	s.	d.
	1	12	6
Percentage for unproductive labour, 5 per cent. as before	0	1	7½
	£3	16	11

Lessons from these Examples. The conditions revealed by these figures are highly interesting, and would have remained unsuspected under the old methods of expense distribution. In Case A the variable rate was 4.5d., showing that trade was good and the machines in nearly full work. In Case B the same job cost 22s. more, the same workmen being employed at the same wages, the increased cost being due to the heavy variable rate of 10d., which betrays the fact that many machines stood idle that month. This shows the bearing of trade conditions on the cost of production. In Case C the factors of cost have varied. In some cases skilled and high-priced labour has been introduced, showing the bearing of the efficiency of the workman on production cost.

Machine No. 24 takes 6 hours of labour at 1s. instead of 10 hours at 10d.; machine No. 425 takes 4 hours of labour at 1s. instead of 8 hours at 8d.; and machine No. 390 takes 10 hours at 1s. instead of 15 hours at 9d. The variable rate is the same as in Case A, but as the machines do the work in less time the machine rate for Case C works out at £1 0s. 8d. instead of £2 0s. 3d. for Cases A and B. The variable rate in Case C is reduced from 18s. to 13s. 11d. *as a result of higher efficiency of the workman*. The wages, which were increased in three cases respectively from 10d. to 1s. per hour, from 8d. to 1s., and from 9d. to 1s., nevertheless figure at £1 12s. 6d. for Case C as against £1 17s. 5d. for Case A, the percentage for unproductive labour falling likewise from 1s. 10½d. to 1s. 7½d. In Case C the total job cost £3 16s. 11d. for labour and factory burden as against £4 17s. 6½d. in Case A, trade conditions being the same. Had the factory in question distributed the factory burden by means of an even percentage for both classes of expense, the same for every month of the year, the loss would have been there all the same, but it would have remained undetected, and the greater the sales at the bad times of the year the greater the losses made.

Unproductive Labour. The percentage of unproductive labour chargeable for each shop is obtained weekly from the pay roll, and is pro-rated over the cost of productive labour for the same period; the indirect charge is thus absorbed in the final cost of production as nearly as possible in accordance with facts. By this system of computation the factory cost of a product is composed of:

(*a*) The cost of productive labour.

(*b*) The cost of productive material.

(*c*) The machine rate for all machines used in the processes of manufacture, charged for the exact time during which they were running.

(*d*) The supplementary rate for the same number of hours as (*c*), covering the undistributed factory expense relating to machines.

(*e*) The percentage covering the cost of all unproductive labour unconnected with the machines.

(*f*) The percentage covering the cost of all unproductive material or supplies, such as brooms, buckets, stationery, soap, etc., unconnected with the machines, computed weekly from the storekeeper's disbursement cards.

The selling cost is found by adding to the factory cost the percentage of general establishment and commercial expense for office salaries, rent, insurance, interest, depreciation on all departments outside the factory itself.

Systems for the Stores and Stock Department. The stores and stock department which cares for all material is one of the first to be systematised. Each of the two terms used for material has a definite meaning. *Stores* denotes raw material and partly or wholly finished articles *purchased from outside*, whereas *stock* consists of finished articles or parts *manufactured by the factory itself*.

Stores are productive when they consist of material or parts used directly to produce stock; non-productive when they consist of supplies for factory or office necessary for the routine work or for the maintenance of the plant, such as emery wheels, grindstones, stationery, files, knives, buckets, twine, brooms, etc.

The Equipment. The store or stock department consists of a room or series of rooms in a central position under the control of a stock keeper, who alone is authorised to make disbursements, and then only on written and signed requisition.

The shelves, bins, and racks should be easy of access, well built, and provided with some mechanical device for registering disbursements, so that the stock keeper may know at a glance what his reserve is. Counting scales and all devices which assist in weighing and counting out disbursements rapidly and with unfailing accuracy should be provided. On the slip-in cards are spaces for inserting the number of the box, the date received and returned empty, the name of stores, number of pieces or quantity, the factory order and requisition numbers, and lines for the signatures of foremen and stock-keeper. The stock keeper needs a cabinet for his perpetual inventory and drawers for a supply of disbursement and other cards. The staff consists of the stock keeper and of one or two assistants without authority to authorise disbursements. The former is responsible for every ounce of material and every unit of stock committed to his charge which must be accounted for. If there be a record office, no clerk will be needed. A number of trucks must be provided for the transport and delivery of material, and the collection of empty boxes, [illegible] to fetch and carry stores on requisitions under any circumstances; the latter are conveyed from the shops to the store department through pneumatic tubes.

Routine of the System. We will suppose that the stock keeper discovers by means of finger signals in the slip of red tabs on the cards of his perpetual inventory that fresh stores are required. If there be a record office he makes out a purchase order after consultation with the record keeper, and sends this order to the general manager for signature; it is then passed on to the correspondence department, where it is duly registered and signed, the duplicate order being sent to the record office. If there be no record office the stockkeeper merely notifies the manager of the purchase department by means of a requisition card, giving the particulars of the purchase.

As soon as he receives the stores, the stock keeper makes out a material received card, giving the number of the requisition order, date, the quantity and condition of the goods; he sends this card to the cost keeper, the freight and lading charges having been sent direct to the cost department from the receiving room. The stock keeper then duly registers the material received and the balance on hand on his perpetual inventory card, as well as on the dial or indicator as he stores the goods in bin, shelf, or rack. In the record office, the requisition cards received by the stock keeper are filed in a week's file as they come in from the stores department, until the weekly stock room disbursement and inventory reports are made out. These show the total disbursements charged to each order,

and to each department, classified as productive and non-productive, or as charge or factory burden. From these disbursement cards, the cost department compiles the factory burden and general expense summaries and computes the weekly machine rate and supplementary rate, the percentage for non-productive factory labour, which are then pro-rated on the output for the week. The cost clerk uses these to determine the factory cost and selling cost for each article on order.

System of Timekeeping. Labour is the most important factor in all business undertakings, and figures as the largest item in the cost of production. We have already considered, in a foregoing section, the advantages of a labour department, and the most satisfactory methods of treating employees. A practical, up-to-date system of timekeeping is required, however, for the working of the cost department. For want of accurate records of the distribution of the labour charged in the pay-roll among the production orders, managers are reduced to guessing or estimating, as it is called. Experience has shown the danger of such an expedient; the workman must furnish two kinds of records, but as the workman is a bad hand at writing, machines are used as substitutes.

The Mechanical Recorder. The Rochester mechanical recorder consists of a clock working in connection with ingenious printing mechanism. A card ruled for every working day of the week, and further divided for morning and afternoon, both *in* and *out*, is taken by the workman on entering from the "out" rack at the side of the recorder. He drops the card into a slot under the dial, presses a lever, and the exact time shown by the clock is printed in the proper space on the card, which then drops into a receptacle. The workman takes it out, checks the entry, thus preventing the possibility of argument on pay-day, and places the card in the "in" rack. Every night after the workmen have passed out, the time-clerk collects the time-cards from the rack and leaves the intermediate set to take their place; one set of buff cards being for Monday, Wednesday, and Friday, the other, blue, for Tuesday, Thursday, and Saturday, the object of this being to enable the cost department to use the cards day by day, for the purpose of checking the job-cards. Timekeeping at the gate is entirely unnecessary and is being abandoned.

The Job-card. Instead of the old-time board, on which the men were expected to enter from memory at the end of the day the time they had spent on each job, the mechanical recorders are used, and the workmen is relieved of all clerical work. The recorder registers the time occupied by each operation, a separate job-card being used for each. The card is prepared before the work is handed to the workman, and bears his name, the date, order number, department number, name and particulars of operation to be performed, the schedule number of the machine or tool used, its hourly rate, the rate of pay of the workman, whether by hour or piece, with a column for extension; spaces are besides provided, under "start" and "finish," for the recorder to register the time expended. The workman having registered "start" pins the card up in front of him until the job is completed, when he takes it to the foreman, who examines it and punches or signs it. The workman goes through the same performance with the recorder to register "finish" on that card, and again "start" on the new card which the foreman held in readiness for him with his next job. If the foreman be alert, not a minute need be lost between jobs, in fact, the latter is held responsible for all such intermediate loss of time.

The foreman forwards the job-completed cards as he receives them from the men by pneumatic tube to the cost department, where they are filed temporarily for the day with other job-cards under the man's name or number. After being balanced with the day time-cards, the job-cards are used by the record office to compile various records such as the comparative cost-card. From the records the manager can see at a glance the workmen who have distinguished themselves and proved most efficient.

Three different labour summaries are compiled by the record office from these two sets of time-cards.

1. The weekly labour summary of productive and non-productive labour for each department which is charged to that department.
2. The total labour summary for the factory (this may be issued by the cost department if preferred).
3. The total labour card for each order, indexed numerically, which is issued as soon as the order is complete, and furnishes data for the detailed complete costs sheet.

Day-rate and Piece-work. Day-rate of pay by the hour is the oldest and simplest method of remunerating labour; it has the disadvantage of placing the employer at the mercy of the workman by making the labour cost of a product entirely dependent on the honesty and skill of the workman. Piece-work carries with it advantages and penalties; it tends to place the workman at the mercy of the employer, in the matter of cutting the rate, but it gives the workman the entire benefit of the increased output per hour. The evils of this system are its failure to safeguard the interests of the workman and the demoralising effects of the penalties it carries; the workman loses, if he be unskilful or slack in making an effort, and fails to make a day's wage at his hourly rate; but, on the other hand, if he be over-zealous, he is certain to find the rate cut, the result being a partial or total relaxation of effort.

The Premium Plan. The premium plan is the fairest of all methods in principle, and is already the most widely practised; its central idea is an equitable division between employer and workman of any profit due to increased output of the latter. It presupposes the payment of the time-rate of wages as a basis, so that to the slow workman a fair wage is assured without fear of penalty, a fixed premium being offered per hour saved on the standard time agreed upon for each job. The premium consists generally of 33⅓ per cent. or 50 per cent. (in the Halsey system), which works out thus:

Supposing the standard time for a job be fixed at ten hours, the tables on next page show the working of the premium plan on the basis of both 33⅓ per cent. and of 50 per cent. premium.

A modification of Halsey's premium plan introduced by Mr. Jas. Rowan, of Glasgow, and known as the Rowan premium plan, is preferred by many. This system gives the workman a premium proportionate to the time saved on the time limit. If a man reduces the ten hour limit by two hours, *i.e.*, 20 per cent., he gets a 20 per cent. increase in wages; if by three hours, a 30 per cent. increase and so on. Here the workman's advantage is greater on the first saving of time, but decreases on the subsequent savings, compared to the other methods, as the saving increases.

WITH A PREMIUM OF 33⅓ PER CENT										
Time expended	Wages [illegible]		Premium		[illegible]		[illegible]		Workman's [illegible]	[illegible] of
Hours	s	d	s	d	s	d	s	d	Pence	[illegible]
10	10	0			10	0	—		12	—
9	[illegible]	0	0	4	[illegible]	4		[illegible]	1[illegible] 44	[illegible]
8	8	0	0	8	8	8	1	4	13	[illegible]
7	7	0	1	0	8	0	2	0	13 1	14 [illegible]
6	6	0	1	4	7	4	[illegible]	8	14 [illegible]	[illegible]2[illegible]
5	5	0	1	8	6	8	3	4	16	33⅓
WITH PREMIUM ON SCALE OF [illegible] PER CENT										
10	10	0			10	0			12	
9	9	0	0	[illegible]	[illegible]	6		[illegible]	1[illegible]	
8	8	0	1	0	[illegible]	0	1	0	13	1[illegible]
7	7	0	1	[illegible]	8	[illegible]	1	[illegible]	14	[illegible]1 4
6	6	0	[illegible]	0	8	0		0	16	33⅓
5	5	0	2	[illegible]	7	[illegible]	[illegible]	6	18	0

Profit sharing schemes for the remuneration of labour are open to many objections, one being that until the custom of frequent balances—say monthly—has become universal the benefit to be derived by the workman is too long deferred. Secondly, the profits or losses of an industrial enterprise depend on many factors with which the workman is not in the least concerned. It is not fair that he should share in either profit or loss except on the item of cost of labour alone in the costs of production, a plan which has indeed been suggested, but which is too complicated in the working to find much favour with master or man.

Labour-Saving Machinery. A false idea obtains credence among the employees in many British factories that labour saving machinery is a menace to the working man. This is mere ignorant prejudice.

There is more scope for skill and sharp wits in working most machines than in accomplishing one manual process indefinitely.

Labour saving machines are not only used in the workshops for manufacturing, but also in cost keeping for the factory, such as the tabulator, to which reference has been made elsewhere in this series. It is a machine which we owe to the genius of America. It has proved of the greatest use not only in industry but to statisticians and others engaged in census work, agricultural and parliamentary returns, in which the rapidity and accuracy with which this electric machine makes computations is of the greatest value. In the factory all the various totals from the time and labour cards or any other, can be added by means of this machine with absolute accuracy in a few seconds. It adds up several columns of figures from the cards as they are fed to it and registers the totals on a dial, adding simultaneously, for instance, the number of hours and quarter hours, and the cost of the labour in £ s d. One clerk calls out the totals or results to the puncher, who transcribes the figures into holes, checking them over with the check, and the cards are then fed into the machines, unless they are to be sorted first into groups.

The Calculagraph. The most prolific source of error in factory cost keeping is undoubtedly the method of recording time, time being the most important element in computing the cost of labour. Experience has shown that the average clerk frequently makes mistakes in recording elapsed time by means of a pencil and clock dial, nor does he always subtract the time of day correctly when furnished with mechanical recorder time cards. There is the additional danger that when looking over a card containing times of beginning and times of stopping, he will mix the records and subtract from the wrong finishing time. The calculagraph saves 50 per cent or more of the time clerk's work by registering the time at which the job began (much as other mechanical recorders), subtracting this from the time of finishing and printing the difference or time elapsed in hours and minutes on the card dropped into the slot. All the workman has to do is to push the card into the slot and pull a lever. The number of calculations this clever machine can make is only limited by the number of cards it is possible to push consecutively into the slot during a given time.

The Addressograph. Another labour saver is the *addressograph*, a useful machine originally intended, as its name indicates, for addressing envelopes or wrappers of regular correspondents or subscribers. It is also adapted for preparing the list of names of the weekly pay roll of workmen. The numbers and names of the men, with the rate of pay, number of department, whether productive or non-productive, are set up in rubber type in small metal frames linked together in an endless chain. The chain when set up is passed over a drum which is made to revolve by pressing a lever with the foot, printing the names etc. in succession on a sheet ruled and printed for the purpose. You may have as many chains of 40 links each as you require to use with the same machine. The pay rolls can thus be made out with great saving of time. The idea can be extended and the machine used for a variety of purposes.

Thexton's Envelope Sealer and Stamp Affixer. This ingenious device automatically seals envelopes fed to it at a rapid rate, weighs and stamps them, registering on an indicator strip the number of letters of each denomination of stamp affixed. This machine is not only a labour saver of the greatest value, but its register also forms a check on the accuracy of the postal account.

Finally, there are date stamps innumerable and other devices well known to all business men. The *[illegible]* is a useful contrivance, not for supplying brains to those who are deficient, but for treasuring up ideas, criticisms, items of new [illegible] data, in fact, which the busy man knows he may find useful some day and yet cannot entrust entirely to a memory overcharged already with detail. Instead of jotting down the ideas in a note book they are jotted down on a leaf from the desk pad. A spare drawer in the desk acts as a brain box. The only accessory which has to be purchased is a set of coloured guide cards with tabs on which may be written a letter of the alphabet or a subject. The *memos* are numbered and then dropped in front of the guide card bearing the initial of the keyword. A sheet of blue paper is kept directly in front of each guide card, on which are written the keywords of the memos, being numbered consecutively, beginning at 1 for each letter of the alphabet, so that you have a complete list of the subjects filed for reference. It is quicker to run your eye down the list than to search through the papers, and the number gives a clue to the location of the particular item wanted in the batch in front of the guide card.

STEAM TURBINES

The Advent of the Turbine. The Parsons and other Turbines. Details of Turbine Construction

By JOSEPH G. HORNER

BEFORE the advent of the little "Turbinia," in 1894, neither engineers nor the general public had ever dreamed of the possibilities that lay in the steam turbine. Rotary engines in large numbers had been patented and made, but they were mostly unsuccessful. The advantages of the rotary engine are that there are no reciprocating parts to be brought to rest, and to have the direction of their motion changed twice during every revolution of the engine shaft. Hence, the turning effort at the latter is regular, apart from the equalising effect of a flywheel. In fact, so regular is the movement of a steam turbine at the highest speeds that it will run steadily without being bolted down to a bed-plate. Standing with the back to the turbine, it is often difficult to say whether it is running or not. Besides these advantages, there are the absence of slide valves with their friction, and of rubbing parts, such as crossheads and their guides, no crank shaft or crank pins with their bearings, and no reciprocating piston, requiring oil. And especially valuable in marine engineering is the smaller space occupied by the turbine, both in area and in height, in comparison with the reciprocating engines of equal power, the relationship being about as one cubic foot to four.

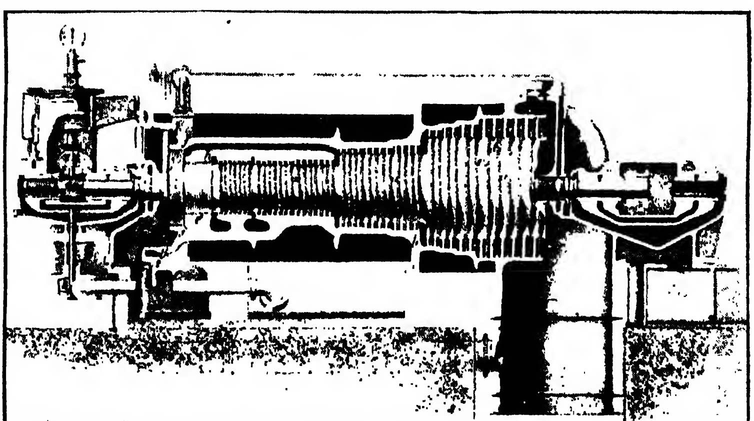
Water and Steam Turbines. Though the water turbine had come into general use, displacing water-wheels in large numbers of cases, it was reserved for the Hon. C. A. Parsons to show how the same essential design could be utilised for steam operation. But steam is highly elastic and water is not, which fact renders several modifications in design and speed necessary; but essentially the steam and the water turbine resemble each other. Each is designed in either reaction, or impulse types of wheels. The idea underlying the two classes of turbines is therefore alike, whether water or steam be used. In each case, instead of static pressure there is dynamic action, the action of a liquid in rapid motion operating either by impact, or through the influence of inertia.

The differences in the two are these: water has a much greater density than steam, and therefore water turbines can be operated correspondingly slower than steam turbines. The latter must have a high velocity: even a moderate velocity is possible only by placing many turbine wheels in series. The high degree of elasticity of steam results in expansions, to utilise which diverging conical jets are essential in simple turbine engines, but are not required with water motors. And when turbines are placed in series they must be of increasing capacities to utilise the successive expansions. Also the result of expansion is to produce condensation of the particles of water mixed with the steam, to increase the friction, and cut away the leading edges of the blades and shorten the life of the engines. Turbines thus differ, it will be seen, from reciprocating engines in the fact that the rotary motion is due to differences in steam pressure, either by reaction or impulse, instead of static pressure between piston and cylinder ends.

Classification. Steam turbines may be classed as compound or multi-expansion; as single expansion, and under a third group, which comprises features of both kinds, with other variations. The Parsons, Rateau, and Zoelly belong to the first, the De Laval to the second, and the Curtis, the Reidler-Stumpf, and some others to the third.

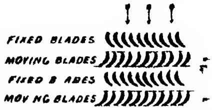
Compound Turbines. The first compound steam turbine, built by Parsons, in 1884, is now in the South Kensington Museum. Without compounding, the moderate speeds required in commercial engines would not be possible. It is easy to expand the steam down to 125 stages by passing it through one high-pressure, and two low-pressure turbines. In 1892 the turbine was first adapted to work in conjunction with a condenser.

The Parsons Turbine. In this [81] the steam is expanded many times, passing through a succession of turbine rings proportioned for small successive drops in pressure. The great advantage of this arrangement is that the steam travels at a very moderate velocity, and the rate of rotation is sufficiently slow - from 100 ft. to 300 ft. surface speed per second—to permit the turbine to be coupled directly to dynamos, screw propellers, fans, etc., without the necessity for gearing down. Moreover, though the expansion at each



81. SECTION OF PARSONS TURBINE

stage is minute in amount, the total expansion over the whole range is large. Actually from 70 per cent to 80 per cent of the total energy in the steam can be delivered to a shaft coupled to the turbine. In view of the fact of great expansion, the value of vacuum is great, more so than in reciprocating engines; hence a good condensing plant is an essential part of the equipment of a steam turbine. An increase of 1 in. of vacuum above 26 in. diminishes steam consumption by from 4 per cent to 7 per cent. In the other direction superheating the steam has a similar effect, and it is therefore practised. Every 10° F of superheat reduces steam consumption by about 1 per cent.

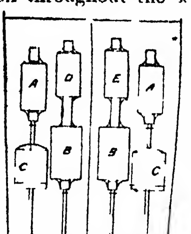


82. BLADES OF PARSONS TURBINE

The design of the Parsons turbine is shown in longitudinal section in 81. Essentially this comprises a revolving drum or shaft, *a*, the "rotor," of large diameter, within a cylinder, *b*, leaving an annular space between the two, which space is occupied by two distinct and numerous sets of rings of blades. The rings *c* which project radially from the spindle are the moving blades or vanes, those, *d*, which project inwards from the casing are the fixed or guide blades, and these alternate with spaces between. By this arrangement the friction of the steam is reduced to a minimum, and the clearances are slight.

Action of Turbine.

The action of the mechanism is as follows. Steam enters at one end, at the left hand of the figure, and travels through the annular space between the shaft and its casing. Coming first in contact with a ring of fixed blades it strikes the first ring of movable blades [see the detail 82], causing them and the spindle to which they are attached to revolve, the relative dispositions of the blades ensuring this movement as in water turbines. The steam thence passes into the next ring of fixed blades and is diverted thereby into the succeeding ring of movable blades [see the detail diagram 82]. And thus this action goes on throughout the series.



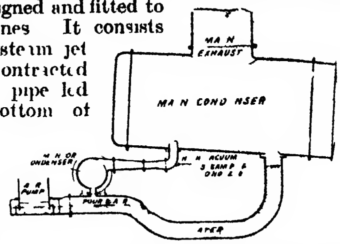
85. SHAFT ARRANGEMENT OF TURBINE MACHINERY (Suitable for warships)

A. High-power turbine. *B.* Low-power turbine. *C.* Condenser. *D.* High-power cruising turbine. *E.* Low-power cruising turbine

It will, however, be noted that the spindle [*a* 81] is made with three diameters. These correspond with three main stages of expansion, because, as the steam continually expands and loses pressure, the blades have to be larger at the low-pressure stages. The blades themselves also increase in diameter along each main stage.

As the pressure of the steam would impart an end-long thrust to the turbine, this is resisted by three pistons, *e*, *f*, *g*, one corresponding with each of the stages of expansion. Communication is made between the steam at each stage and its piston through the three passages seen, *h*, *j*, and *k*.

In order to help in maintaining a high vacuum a new apparatus, the "vacuum augmentor" [83], has been designed and fitted to several turbines. It consists of a small steam jet placed in a contracted portion of a pipe led from the bottom of the condenser. The jet draws water from the latter and delivers it to the air pump through a small auxiliary cooler, so reducing the air to a very small amount.



83. PARSONS VACUUM AUGMENTOR

Governing in the Parsons turbines for electric lighting stations is generally effected by a centrifugal governor, which moves a small relay plunger that regulates the steam admitted to a relay which in turn acts on the main steam admission valve, which is usually of the double-beat or balanced type.

Marine Turbines.

It is a far cry from the little Turbinia of 1894 with her engines of 2,000 h.p. to the vast Lusitania. Step by step the suitability of the turbine has been demonstrated for torpedo boats, destroyers, Clyde pleasure steamers, yachts, cross-Channel steamers, the Atlantic liners, and big cruisers. The advantages over reciprocating engines are numerous, the drawbacks few. The saving of weight of machinery is considerable, the centre of gravity is low down, the steam consumption is less. The drawbacks are those due to the high speed of turbines and the relatively slow speed of propellers, and to the non-reversibility of turbine engines. In warships another difficulty lies in the slow rates for cruising and the high speeds that would be required in time of action. These difficulties are got over by using various sets of turbines, high and low pressure, and for going ahead and astern, each turbine set having its own propeller and shaft. Figures 84 and 85 show arrangements for a Channel steamer and a cruiser. The invention of a reversible turbine would be a source of fortune. In the "Carmania," one high-pressure turbine is

A. Foundation rings. *B.* Caulking strips. *C.* Channel strips

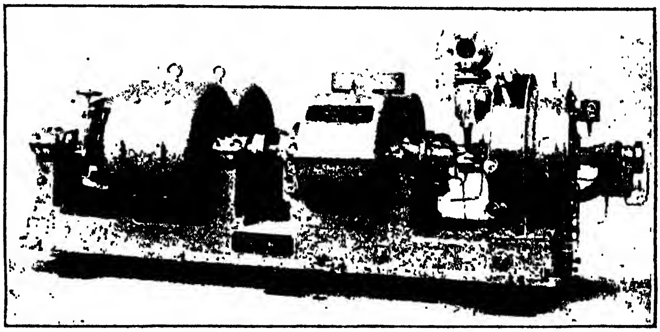
placed in the centre line of the vessel, and two combined low-pressure ahead and astern turbines in the two wings respectively. The turbines make about 185 revolutions per minute. The low-pressure turbine casings are 14 ft. outside diameter, by 36 ft. long. In the "Lusitania" there are four shafts, each driving an independent propeller. On the two wing shafts there are the high-pressure turbines, taking steam direct from the boilers. Thence it passes to the low-pressure turbines on the inner shafts, and thence to the condensers. There are two turbines on the inner shafts for going astern, making six turbine sets in all. The surface speed of the rotor blades is from 100 ft. to nearly 150 ft. per second. At each row of blades there is a drop in steam pressure of about 1 lb. per square inch.

The Parsons turbines have been now applied to vessels of every class, the most notable being the cruiser "Dreadnought," and the liners "Lusitania" and "Mauretania." The total power of marine turbines only, of the Parsons type, made up to the present is 385,000 h.p., distributed as follows: pleasure steamers, 18,200; cross-Channel steamers, 149,900; yachts, 18,100; ocean-going steamers, 91,900; war vessels, 106,900. The total power of marine turbines of other types is about 16,000 h.p. The principal application of the steam turbines as yet has been to marine work and the driving of dynamos in power stations. Their practicability has also been demonstrated in the driving of fans, of centrifugal pumps, of air compressers, and as blowing engines. The total horse-power of turbines of the Parsons type is nearly 2,000,000 h.p.

Fixing the Blades. The difficulties in building up the blades of turbines are immense, since there must be no risk of their working loose and falling out, but these difficulties can be fully appreciated only by those who have seen the operations of building up. In the turbines of the "Carmania" the total number of blades is about 1,115,000. They vary in length, being longer in the low than in the high pressure engines. They have, therefore, to be bound together with circumferential strips, and soldered. Each individual blade has to be fitted in place, caulked, set, and individually inspected. Afterwards there are difficulties in balancing, and in erection of the rotor within its casing.

Messrs. Willans & Robinson, Ltd., manufacture the Parsons turbine, with modifications of their own. One of these relates to the method of fixing the blades, shown in **86**. The blades are built up into segments, usually half rings, both for the shaft or rotor, and the casing. Each blade is stamped so as to form a dovetailed root or tang at the end which is fixed into the segment. The free ends of the blades are riveted into, and protected by, a ring or shrouding of channel section. The blades for a half ring are assembled by lightly riveting the tongue of each blade into the channel shrouding, and thrusting the dovetailed tangs into the slots in the foundation ring. The half ring is then placed in the groove provided for it in shaft, or casing, and there fixed by means of a caulking strip. Afterwards the riveting to the channel shrouding is completed. The dovetailed fitting at the root, with the pressure of the caulking strap, prevents the blades and rings from risk of flying out by centrifugal force.

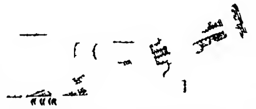
The De Laval Turbine. This [**87**] is a high-pressure or non-compound turbine. The issuing steam expands in the nozzle [**88**] and strikes the bucket of the moving wheel with a velocity of from 3,000 ft. to 4,000 ft. per second, which wheel rotates at a surface speed of about 1,380 ft. per second. The velocities of the wheels are so high that reduction has to be made for driving purposes by means of toothed gears. This turbine resembles in principle the Pelton wheel, and it has but one circle of buckets. These turbines are very remarkable on account of the extremely high speed at which they run, making from 10,000 to 30,000 revolutions per minute, according to size. Steam of any pressure may be used, but the higher the pressure the greater the power developed. A remarkable feature is that whatever the initial pressure the expansion takes place adiabatically down to the pressure which exists in the chamber in which the turbine wheel revolves. The steam is expanded in the conical nozzles [**88**], and this gives a very high velocity of outflow. Professor Zeuner has shown that if the steam is expanded adiabatically in a suitable nozzle all the potential energy of the steam is transformed into kinetic energy, and that the latter corresponds with the amount of work which the same steam would have performed if expanded in the same proportion in the cylinder of an ordinary engine. At 200 lb. initial pressure, steam expanded in a nozzle down to the pressure of the atmosphere has a velocity of outflow of 3,115 ft. per second; or down to 28 in. vacuum, of 4,127 ft. per second. Steam expanded in a nozzle from 280 lb. pressure above the atmosphere down to 28 in. vacuum leaves the nozzle with a velocity of 4,229 ft. per second, or over 48 miles per minute! With such a velocity the jet would pass round the earth in 8 hours 37 minutes. A 300-h.p. turbine wheel which runs at a peripheral velocity of 1,450 ft. per second, and is 31½ in. in diameter, would travel round the earth at the equator in 25 hours.



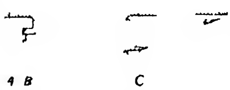
87. 225-H.P. TURBINE DYNAMO

The Nozzles. Much depends on the designs and arrangements of nozzles. A nozzle of a given dimension can pass only a certain quantity of steam at a certain pressure. Thus [**89**], one proportioned for steam of 200 lb. pressure will pass 479 lb. of dry saturated steam per hour, which fact is taken account of to ascertain the steam consumption of turbines. The nozzles are placed at a definite angle with the plane of rotation of the wheel—namely, 20°. The linear velocity of the buckets should be 47 per cent. of the velocity of the steam. The absolute velocity of the steam leaving the buckets

should be 34 per cent of the initial velocity The energy absorbed by the turbine wheel is then 88 per cent of the kinetic energy of the steam The nozzles are only about one sixteenth of an inch away from the buckets, so that there is no loss of velocity The nozzles are proportioned to the pressure of steam Figure 89 illustrates one for 200 lb steam pressure, and 28 in vacuum At the section A where the steam enters the pressure is 200 lb above the atmosphere It is dry and free from moisture In the nozzle B its pressure becomes 110 lb and it holds 4 per cent of moisture its velocity is 1 500 ft per second At C the largest section with 28 in of vacuum the percentage of moisture becomes 24 per cent and the velocity 4,127 ft per second The proportion between the areas of the large and small sections should be 27 2345 The steam nozzles are arranged at intervals round the wheel receiving the steam from a chest in the turbine case Each nozzle has its shutting off valve [88] so that it can be opened or closed at will which permits of working the turbines at reduced load



88 DE LAVAL NOZZLE AND SHUTTING OFF VALVE

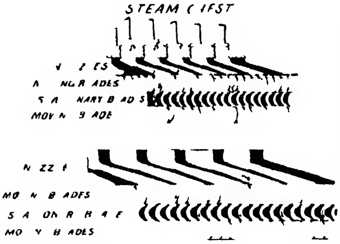


89 DE LAVAL NOZZLE

Flexible Shaft Each bucket has to be fitted separately into the solid wheel the fitting being by dovetails The flexible shaft is an essential detail of these wheels without which no amount of balancing would prevent vibration at the high speeds of revolution A rigid shaft would soon cause ruin to the bearings Using a flexible shaft the vibrations disappear at a certain stage This is not readily capable of explanation but the fact is clear from tests At the early stages of running the shaft vibrates but at what is termed the critical speed the vibration ceases and the shaft runs steadily this stage being termed the settling of the wheel The shafts are small on account of the high speed that for a 300 h p wheel being only 1½ in diameter

The very high speed of revolution has its utilities and its drawbacks It is valuable for the direct driving of dynamos of centrifugal pumps and of fans But reduction gear is necessary for ordinary machinery Double helical gears are used The pinion is cut in one piece with the shaft, and is of hard steel and the teeth of the gearing wheels are cut in a softer steel the linear velocity of the teeth is about 1 000 ft per second The regulation of the speed is by means of a centrifugal governor, fixed on one of the gear wheel shafts which controls a double seated throttle valve

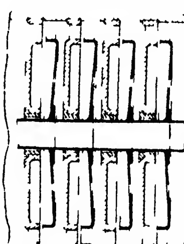
The Curtis Turbine. This is of the impulse type Groups of expanding nozzles are used to convert potential energy into kinetic energy But expansion is also carried out in two or more stages, thus combining the principles of the two main types of turbines already described The number of stages is governed by the degrees of expansion, and by the velocity which is desirable Each stage is separated from the one adjacent by a diaphragm, steam tight, except where nozzles are inserted for the steam to pass into the next stage Figure 90 is a diagram of the relative positions of admission valves, nozzles, and buckets in a two stage turbine The steam coming from the steam chest passes through a series of expanding nozzles thence through two or more rings of moving blades, or buckets on the rotor or shaft Stationary blades on the casing redirect the steam received from the rotating buckets into the next set of rotating buckets, and so on A high steam velocity thus made to impart a moderate speed to the turbine This turbine is of vertical type The steam issues from the nozzles at a rate of about 2 000 ft per second and the surface velocity of the buckets is about 100 ft per second The revolving buckets are cut out of a solid ring by machinery, and so are those in the stationary blades which avoids risk of accidental loosening of these important elements



90 DIAGRAM OF CURTIS STEAM TURBINE

The Zoelly Turbine. This is a multi stage impulse motor It comprises a high and low pressure casing each containing about five elements Steam is introduced into the first set of guides and so passing through the series expands and loses pressure, doing work until exhaustion takes place The high and low pressure casings are distinct but on the same bed plate The number of elements is few in comparison with most turbines and the efficiencies are high

The Rateau Turbine This comprises a series of moving rings alternating with discs fitted to the inside of the casing But it differs from the Parsons in being of what is termed multi cellular type [91] That is the moving vanes are fixed to the peripheries of flat wheels separated from each other by diaphragms which divide the interior of the turbine into cells Each element in a single cell comprises one distributor and one moving wheel It is claimed that very considerable play can be left between moving parts in this design which facilitates construction and lessens risk as wear takes place Also the pressure is uniform there is no longitudinal thrust on the moving parts Vanes of cylindrical form are riveted on the peripheries of the discs and a steel band riveted to the vanes These moving wheels turn between circular diaphragms provided with distributing vanes which enter circumferentially into grooves formed in the interior of the turbine casing



91 DIAGRAM OF RATEAU TURBINE BLADES

The mathematics of turbine engineering must be studied in works devoted to the subject The real difficulties are those due to construction, consequent on the large number of buckets, the high rates of rotation, and the evils of wear There are other turbines besides those named, but up to the present time these have been the most successful There are types in America and Germany little known here, many engineers are also now working at the problem of a gas-driven turbine.

NON-TEXTILE DYEING

Broad Principles of Dyeing. The Methods Employed in Colouring Leather, Paper, Straw, Grass, Wood, Chip, and Feathers

Continued from page 6594

By HERBERT ROBSON

THIS course cannot pretend to be exhaustive, for the subject itself is almost inexhaustible. It is obvious that there must be many omissions in view of the vast number of articles that are coloured artificially for one purpose or another. The aim, therefore, has been to describe the methods of dyeing of as long a list as possible of the principal commercial commodities.

It is very evident also that the scope of the course does not allow anything approaching a full account of all the processes used in dyeing such goods as leather, for instance. Volumes have been devoted to this subject alone, and the aim of this course must be to indicate the broad principles upon which the dyer works in treating each material. This, however elementary, should be of service. In all branches of dyeing the first thing the craftsman must master is the broad principles of his art. This knowledge acquired, the rest is a matter of experiment and practice.

In this article we shall consider briefly the dyeing of leather, paper, straw, grass, wood, chip, and feathers; in the concluding articles we shall study briefly the processes of dyeing marble and stone, sand, horn, ivory, vegetable ivory, bone, mother-of-pearl, celluloid, glue, gelatin and soap.

Leather. Leather dyeing proper, carried out with dyes in solution, must be distinguished from leather painting. It is a very common practice to colour leather with pigments, but in this case it is simply a question of mechanical adhesion of the colour to the surface, and the methods do not come properly under the head of dyeing.

In leather dyeing proper, the effect produced depends upon three perfectly distinct causes. One of these is the mechanical inclusion of dyestuff in the pores of the material—that is, its imprisonment in interstices which nothing can reach except a liquid. In these spaces the dye is deposited in the solid form by the evaporation of the solvent, and is protected from external agencies by the surrounding walls of leather.

The second cause is the chemical combination of the dye with the leather material itself. Like wool and other animal substances, leather has a strong affinity for certain dyes.

The third is the production of a lake by combining the action of the dye solution on the leather with that of a mordant. When tannin or chrome is used in preparing the leather from the raw hide, it may be made to play a double part by acting as a mordant as well.

As regards the dyes used, their number is very large, and if proper care is taken, almost any dye on the market may be used for leather. Some of them require an acid, some an alkaline, some a neutral bath. The choice of dyes and methods depends also upon the manner in which the hide has been tanned. There are three principal methods. One is with inorganic salts, especially with those of chromium and iron; a second is with tannin from oak bark, or very commonly from sumach, while the third is chamoising, or preparing the skin with an animal fat, such as fish or horse oil. It is easy to see that if these methods are combined, as is often the case at present in the preparation of the same lot of leather, the difficulties of the dyer, who has to regulate his procedure by the chemical nature of the leather, are much increased. The following table of analyses will show this forcibly.

—	Oak bark tanned leather	Mineral tanned leather	Chamois leather
	Per cent	Per cent	Per cent
Water	18 0	25 0	22 0
Leather	72 9	59 0	66 0
Uncombined tannin	4 7		—
Ash	0 8	15 65	2 0
Fat	0 8	0 3	10 0
Unaccounted for	2 8	0 05	—
	100 0	100 0	100 0

Of the 10 per cent of fat in the chamois leather, 6 per cent are in combination with the hide substance and 4 per cent in excess.

These figures clearly show that the procedure must be very different for the three sorts, although the dyes used are practically the same in all cases, and depend solely upon the colour to be produced. It is often stated that the form of tannin used has an influence on the dye—that sumach tanned leather, for example, cannot be dyed in the same way as oak bark tanned leather. This is quite a mistake. The active ingredient in the tan, if not identical in all cases from the chemical point of view, is so from the standpoint of practical results.

Dyeing Varieties of Leather. The main principles underlying the dyeing of the three sorts of leather may be stated briefly. With oak bark leather, or other leather tanned by natural tans, attention must be paid to two points, namely, the natural affinity for dyes of the leather itself, and the utilisation as a mordant of the free tannin present in excess, so as to save in the use of other mordants. With chrome leather, or other minerally tanned leather, regard must be had to the lake-forming properties of the metallic oxides present. They must be utilised as mordants as far as possible.

In the case of chamois leather we have to rely either upon the chemical affinity of the dye for leather, or upon mordanting, or to take advantage of both. In the first two cases, of course, the absorption of the dye into the pores, already noticed, takes place, and is by no means a negligible factor in the result. As regards chamois leather, however, it is in many cases necessary to remove the superfluous grease before dyeing, as its presence not only hinders the absorption into the pores, but by forming, as it were, an insulating layer, it prevents due contact between the fibre and the chemicals used for the purpose in hand.

The dyeing of bark-tanned leather is dependent entirely upon the previous treatment. It is quite impossible to dye properly a badly tanned leather. The flesh side must be perfect, or no care will prevent

the formation of streaks and spots. The tan must also be uniformly distributed through the entire mass of the leather, or the same results will ensue. When a leather has been dyed which is nearly but not quite faultless in these respects, it may seem unexceptionable on leaving the dyer's hands, but it will be sure to develop unlevelness of shade after exposure to atmospheric influences. If the dyer finds that a sample of the leather does not dye uniformly after careful washing, he should retan it with sumach. This does a good deal towards securing uniformity.

Dyes for Leather. Tan leather is dyed with coal-tar dyes, with colour lakes, and also with direct vegetable and mineral colouring matters. Nine-tenths of the leather dyed is dyed with coal-tar dyes. The number of dyes used is very great, and several different processes are therefore in vogue. Genuine russia leather is dyed black with logwood on a mordant of alum and copperas, and red with sanders wood on an alum mordant. Other colours are dyed with anilines. Most dyers use logwood for black, and for ordinary leathers a tannin mordant is used, the full black being secured with a little fustic. Many, however, use nigrosine. For brown shoes, Azoflavine RS and Fast Brown are largely used.

In dyeing with coal-tar colours which require a mordant, lactic acid, bichromate, tartar-emetic, yellow prussiate, and the sulphates of alumina, iron and copper, are those chiefly employed. Most of the coal-tar colours used are, however, substantive dyes, and the shade is regulated by the strength of the bath—that is, by the amount of dyestuff absorbed by a given amount of leather. Tannin-dyed leathers take neutral or basic dyes without a mordant, and acid dyes, if mordanted with the appropriate mordant. Alum-tanned and chrome-tanned leather take acid dyes substantively.

The great object to be gained on tanned leather used for bootmaking and in upholstery is fastness to light. In the case of boots, the dye is, or ought to be, protected from weather by the usual dressings. Hence the dyer picks such dyes as are fast to light, and when possible, those which require no mordanting. It has been found that if bark-tanned leather is painted over with an ammonical solution of an alizarine, and then mordanted with alum or iron, a good colour can be got without much heating, which would tender the leather. It is found that the use of iron or aluminium salts as basic as possible is desirable, as the neutral salts do not easily form lakes with alizarines, so that a good deal of the dyestuff is wasted. Basic nitrate of iron appears to answer every requirement in this connection, and is effectual at a temperature which does not exceed what is bearable by the hand.

Dyeing Chrome Leather. Chrome leather dyes directly with great ease with any acid coal-tar dye, the only precaution necessary being that the leather should be thoroughly wetted before entering into the dye-bath. For neutral or basic aniline dyes a previous mordanting with sumach is necessary for light shades. For darker shades the sumach is replaced with fustic, and for the darkest with a mixture of fustic and logwood. Alizarine dyes answer very well for chrome leather because the material stands the high temperature reqnired, which bark-tanned leather will not do, except by the special treatment ab ve mentioned. They are also particularly good on chrome leather because chrome is the best mordant for alizarines generally. Lactic acid is a very useful assistant mordant for chrome leather if specially fast shades are required. It should be pure, however, as impurities are extremely apt to produce unlevel shades, especially with dyewoods or sumach.

Chamois leather can be mechanically coloured by rubbing in any desired pigment. If, however, it is to be dyed with a substantive or adjective coal-tar dye, it is freed from fat by washing and then dyed exactly in the same way as tanned leather. For light shades a preliminary bleaching is usually necessary, and this is usually done with sulphurous acid and permanganate of potash. When the leather has become a full brown by impregnation in the permanganate solution it is rinsed, and put into sulphurous acid solution just sufficiently long to remove the precipitated oxide of manganese. It is then rinsed and dried. Sulphurous acid alone cannot be used as it tenders the leather and does not bleach it thoroughly.

Dyeing Paper. Although the mineral colours are largely used in dyeing paper, the artificial dyestuffs are destined to take the first place in paper dyeing as in wool and cotton dyeing. While the earliest procedure was to amalgamate the dye with the size and thus to apply it to the paper after manufacture, it has now been found much better to dye the pulp, thereby securing the colouring of the paper through its whole thickness. This operation is by no means so difficult as cotton or wool dyeing, inasmuch as it is only necessary that the colour should not rub off, should be fast to light, and should not injure the cohesion of the paper. Hence, the paper-maker has a very large choice of dyes, and as the mineral dyes are especially cheap and fast to light, his preference for them is easy to understand, although they act prejudicially upon the durability.

The most usually employed of these mineral dyes are ochre, chrome-yellow and chrome-red, Prussian blue, ultramarine, graphite, and lamp-black. These must be added to the pulp (after having been ground as finely as possible), either in a pulp mill or in a vat provided with a stirrer. The stirrer is necessary with heavy substances such as red-lead, litharge, chrome-yellow, manganese, etc., on account of their great tendency to settle to the bottom of the vat.

Some few mineral dyes can be actually made in the pulp, as, for example, Prussian blue, by adding to the pulp ferric chloride and potassic ferrocyanide, ochre by adding ferric chloride or ferrous sulphate and milk of lime. The two reagents are added in succession, and it is most important to mix the first thoroughly with the pulp before adding the second, and yet not to allow it time to penetrate into the interior of the fibres. Neglect of these precautions will produce want of uniformity in results as well as waste of colouring matter, for more of the latter will be required to produce the required depth of shade. By generating the dye in the pulp itself it is got in a finer state of division than is attainable by grinding, so that the colours are brighter and more uniform.

Mineral Dyes for Paper. It is, perhaps, unnecessary to say that the fineness of the tints depends also upon the constitution of the pulp, and for pure lively colours the latter must be carefully chosen or previously bleached. When the pulp contains coloured rag, it can only be brought to a different colour by concealing the first, and for this the coal-tar colours are most suitable.

The following is a brief account of the mineral dyes most commonly used:

Reds—Red-lead and cinnabar. Almost disused now on account of their high specific gravity and of the greater cheapness of aniline reds.

Yellows and Oranges. Chrome-yellow, which is absolutely fast to light, is the best yellow. By adding reds to this, any desired orange hue can be obtained. Ochre is best generated in the pulp, as directed above, on account of the labour required to grind and levigate it properly. If levigated chalk is used instead of quicklime to form the ochre, the froth produced by the escape of carbonic acid can be easily got rid of by pouring in a little petroleum. Ferric chloride is better than ferrous sulphate, as when the latter is used the proper colour is reached only when the ferrous salt has become oxidised by the air, and for this time and stirring are necessary.

Blues. Turnbull's and Prussian blues are readily generated in the pulp, and are even to this day unsurpassed by any coal-tar colours. In using ultramarine, any excess of acid or of sulphate of alumina must be absent from the pulp as both destroy the colour.

Greens. Brunswick and many other poisonous greens have now been entirely displaced by a mixture of Prussian blue and chrome-yellow, or by coal-tar colours. Seventeen parts of the chrome-yellow and one of Prussian blue gives an almost pure green. Different shades are, of course, procured by altering these proportions.

Blacks. Of special importance for grey shades of black are lampblack and graphite.

Vegetable Dyes for Paper. As regards vegetable dyes, logwood, fustic, and cutch are chiefly used on account of their cheapness and comparative fastness to light. Saffron, madder, annotto, and indigo have been driven from paper-dyeing by better or cheaper products. Logwood is used either for darkening other dyes or for making a lake of a dirty violet hue by boiling the logwood extract with tin salt. This lake is used with iron salts for grey and black papers.

A splendid black is secured by the following process: A clear solution of cutch in hot water is added to the pulp. After an hour a weight of bichromate of potash equal to one-fifth of that of the cutch is added, and after another hour one-fourth of the same weight of alum. After yet another interval, logwood extract and nitrate of iron are added till the black is deep enough. Any desired blue shade can now be imparted by judicious additions of ferrocyanide of potash.

Coal-tar Dyes for Paper. The coal-tar colours are mostly soluble in water. If they were used for paper in the same way as for fabrics most of the dye would run off in the waste water from the machine wires. It is, therefore, necessary to precipitate the dye in an insoluble state upon the fibres of the paper—that is, to use mordants, except in the case of one class of dyes, to be mentioned later. The size, however, constitutes a very suitable fixing medium for coal-tar dyes, whether it be made from resin or wax.

Solution of resin soap, when mixed with sulphate of alumina, gives a gelatinous precipitate of the aluminium salt of abietic acid. This precipitate has a great advantage over that obtained with ordinary soap in that it does not clot together, but remains in a perfectly uniform and purely divided state. This is a most important property, because the alumina-soap precipitates act as mordants, and do not give a uniform tint unless they remain in a state of minute subdivision. Not without importance, too, is the bulk of the precipitate, for the spreading of the dye over a large surface gives more brilliant hues. But resin size has yet another advantage as a mordant, for it answers equally well both for acid and for basic dyes, whereas tannate of antimony in cotton-dyeing can be used only for basic dyes. From the possession of this valuable property by the resin soap it follows that different proportions must be used according to the nature of the dye.

Fixing Dyes on Paper. In order to test the fixing power of the size for a particular colour an experiment must be made, adding in each case 5 per cent. resin soap to the pulp, then the proper amount of sulphate of alumina, and lastly the dye. The waste water from the machine wires should be colourless, or nearly so, and this test made with a large number of dyes has shown that the basic coal-tar colours answer best.

But even they will not do for a paper containing less size than the above unless 2·4 per cent. of tannin and as much acetate of soda is also added to the pulp. This addition is desirable, even with strongly sized pulp, if dark shades are required. Bismarck Brown and Saffranine have, however, so much affinity for cellulose that the tannin and acetate of soda are rarely required for them. Too quick drying and too hot calendering have a more or less bad effect upon most of the aniline colours and prevent the production of really lively tints.

The direct cotton dyes answer splendidly for paper, whether sized or not, but their high price has hitherto caused them to be little in demand among paper manufacturers, except for *papier de luxe.* In the first rank of them for pulp dyeing stand Erica, Brilliant Yellow, Chrysamine, Oxyphenine, Congo Brown, and Diamine Black. The process of using these substantive dyes is to size first, then to neutralise any excess of acid with the smallest possible quantity of soda, and then to add the dye. If the waste water is not properly clear, a little Glauber's salt may be added.

Dyeing Straw. Straw consists of the stalks of grasses, more particularly the cereal grasses, and of leguminous plants, such as beans and peas. The value of straw depends upon its length and toughness, as regards the dyer's point of view, and in both these respects rye straw probably holds the first place.

The farmer and the dyer are not at one with regard to straw. With the former its chief function is necessarily that of being a support for the grain, which is thus exposed to the ripening action of the air and of the sun. Straw from the threshing floor is, however, not exactly what the dyer wants. From his standpoint it has been allowed to grow too long. It has acquired with age a closeness of texture and a marked colour of its own which make it very unamenable to his processes. It is also generally somewhat damaged during the threshing. The strong colour it acquires prevents any but very dark shades being dyed on it without previous bleaching and is very difficult to discharge, while the closeness and resistant nature of the siliceous external skin of the straw is very unfavourable to both bleaching and dyeing.

Straw Suitable for Dyeing. Hence, straw intended for hats is obtained from grasses (usually wheat, which is largely cultivated for this purpose in Tuscany) grown solely from the point of view of straw production, and the plants are cut down before they are thoroughly ripe. The straw is then bleached in the sun on grass, exactly as linen is, with occasional sprinkling with water.

If chemical bleaching is resorted to, chlorine is the most reliable agent, although peroxide of hydrogen or sodium answers nearly as well. Chlorine is apt to tender the straw, especially if its action is

unduly prolonged or if the straw is not well rinsed afterwards. Sulphur bleaching is usually only temporary, the straw gradually returns to its original colour on exposure to air and light. Permanganate has been used with success, but it is troublesome to work with, and requires very careful watching. All chemical bleaching weakens the straw more or less.

Preparing Straw for Dyeing. The preliminary treatment before dyeing consists in softening the fibre as far as possible in order that the dye may penetrate. At the same time the process removes all grease and other foreign bodies which would cause unlevel dyeing, as well as any sap which may still remain in the straw. This softening is usually effected by soaking first in a weak lye of carbonate of soda, and then in water, which may be used cold, warm, or boiling according to circumstances. No rules can be given except to try cold water first, and warm before boiling water. A little experience will soon enable the dyer to tell by the feel when the straw has been made permeable enough. Steaming is sometimes resorted to instead.

Dyewoods were formerly largely used, and in point of fact almost exclusively, and they are still in current use for the purpose, especially Brazil wood and logwood, but nine-tenths of all the straw dyeing nowadays is done with coal-tar dyes, with or without a preliminary bleaching, according to whether the colour is to be light or dark.

Dyes for Straw. Coal-tar dyes should be chosen which are soluble both in alcohol and in water, as strong tinctures of such dyes can be kept in stock and diluted with water as required for use. Substantive dyes are those chiefly used, and the only requirements which have to be fulfilled are good colour and fair fastness to light. As examples of favourite dyes for straw dyeing we may mention Eosine, Rose Bengal, Naphthalene Yellow, Safranine, Phosphine, Malachite Green, Acid Green, Bismarck Brown and Methyl Violet.

As a general rule, mordanting, when necessary, has to be done at the boil and the dyeing also. Although substantive dyeing of straw can, as a rule, be done without boiling, it is advisable to boil even with substantive dyes, if great fastness is desired. The time of boiling varies with the mordant and the dye, and the mordanting and the dyeing may each take from half an hour to two hours, according to circumstances.

Dyeing Grass. Most grasses, like plant fibre in general, can be easily dyed in fairly durable tints, and all dyes which can be employed for wood or straw are suitable for grasses. Practically, nowadays, coal-tar colours are almost exclusively used and most of them require no mordant. The extracts of cutch, curcuma, the redwoods and logwood are, however, sometimes employed. For light shades the grass must, of course, undergo a preliminary bleaching, which is done exactly as with textiles, and in all cases the grass must be thoroughly soaked in lukewarm water before being placed in the dye-bath. If this precaution is neglected the inequalities always existing in the texture will cause unlevel dyeing.

Aniline dyes are kept by the grass dyer in concentrated solutions in water or spirit, which are diluted for use as required. The bath must be made of a material which has no action on the liquor. There is nothing better than stone-glazed earthenware or enamelled iron. The vessels used must be deep enough to give the grass full play and to prevent any chance of damage to the stems. After dyeing it is usually advisable to give a gloss to the material. It is better to do this as late as possible, as there is a danger of impairing the lustre if operations are carried out after the dressing. The glossing agents employed are gum, preferably gum arabic, but for cheap articles, dextrin, oil, and gelatin will do. Gum or oil can be added to the dyebath or can be rubbed in after dyeing by means of a rag dipped in mucilage or oil. The goods must be made quite dry afterwards by rubbing with clean cloths. If gelatin is used it should be dissolved in lukewarm water with a little alum and soap. The solution is applied with a sponge. In all cases brushing and ironing the dry material enhances the gloss considerably.

Dyeing Wood. Woodworkers rarely call their tinting processes dyeing, but rather staining. This distinction has arisen from the fact that in earlier times wood was always coloured by the use, not of dyes, but of colourless liquids which produced various colours on coming into contact with the woody fibre. For instance, lead salts by reacting with the cell contents of the wood produce colour compounds. This method of dyeing wood was confined to the production of dark shades and is now entirely neglected, although it gives the fastest colours. The reason of this is that the effect of the stain depends upon the age and upon the degree of seasoning of the wood.

It is, therefore, very difficult to obtain any given colour if we depend upon the chemical reactions above indicated, and nowadays, when rapid work is essential, the coal tar colours are chiefly relied upon with two important exceptions—permanganate of potash and the dyewoods. As is the case with bone and ivory, the colour is largely dependent, as regards fastness, upon penetration. Hence, for dyeing proper, every facility must be afforded for this penetration.

Another point is that the penetration must be as uniform as possible, and this can be ensured only by cleaning the surface and making it as level as possible by planing and sandpapering. The durability of the colour can in any case be greatly increased by varnishing the dyed wood with a colourless varnish. It is true that these varnishes are rather expensive, but for ornamental work in wood the extra expense is in many cases justifiable. The best varnishes are solutions of bleached shellac in spirit or the best copal varnishes.

Bleaching Wood for Dyeing. A good bleach bath for wood is made by dissolving 8 lb. of pure oxalic acid, or 4 lb. of concentrated sulphuric acid and 3 lb. of oxalic acid, in 50 gallons of cold, soft water, and then slowly stirring in 5 lb. of sodium peroxide. The bath is then made alkaline, if it is not already so, with more peroxide, or with waterglass. The wood is soaked in this at from 70° F. to 100° F. until bleached. It is then rinsed, soured in very weak acid, again rinsed and dried. The time required for the bleaching varies, of course, with the thickness of the wood. A few days will bleach wood a fifth of an inch thick. Another bath is made from peroxide of hydrogen and ammonia. Neither peroxide nor ammonia injures the wood nor the health of the worker.

Wood is dyed by brushing over it a solution of the dyestuff, or by immersion in the dyebath. The method may be preceded or followed, as the case may be, by the application of a mordant also in solution. The solutions may be applied hot or cold,

and the selection of the temperature depends both upon the nature of the wood and upon the nature of the solutions applied. When they can be used cold, the results are generally more durable, but with many close-grained woods, such as ash, walnut, oak, etc., it is impossible to get sufficient penetration except with hot solutions. The general rules to be regarded for particular colours will now be briefly described.

Dyeing Wood Black. Black is dyed substantively by soaking the wood in, or by painting it with, a substantive coal-tar black. Any substantive cotton dye will answer the purpose well. Another method is to paint the wood alternately with bichromate of potash and with solution of extract of logwood. It is usual here to make the first coat with logwood. It is essential to use the logwood first, and to allow the wood to dry before any subsequent painting with logwood. Want of uniformity is sure to result if these rules are not observed. Sulphate of copper or nitrate of iron can be substituted for the bichromate. The iron salt, however, gives a black free from the shade of green which is very apt to accompany a copper black. An excellent black is also got by alternate applications, whether by painting or by soaking, of pyrogallic acid and protosulphate—or, better, pyroligneate of iron.

Dyeing Wood Brown. Brown is always dyed with a basic aniline dye, such as Bismarck Brown, or with permanganate of potash. This salt gives a fast brown, due to the deposition of oxide of manganese in the fibre, and is much used for staining floors and furniture made of deal and other pale woods. It must, however, be remembered that the colour is the result of a reduction of the potash salt, and therefore of an oxidation of certain constituents of the wood. This consideration shows that there is some risk of impairing the strength of the wood. Permanganate is therefore more suitable for unseasoned than for seasoned wood. In the former the sap-constituents still existing in the wood are those which undergo most of the oxidising action. In this way the wood is not only seasoned to some extent, but the cellulose, its essential ingredient, is left unaffected. The sap-constituents, too, are not without their effect in binding the colour by forming lakes. Permanganate solution must never be used too hot, especially on unseasoned wood, as the differences in affinity will then certainly cause unlevel dyeing. It is also much better, for the same reason, to apply a weak solution of permanganate several times than a strong solution once or twice.

Cutch is sometimes used for dyeing wood brown with a bichromate mordant, applied either before or after the dye. All other colours are dyed almost exclusively with coal-tar dyes, and it may be generally said that all direct cotton dyes will serve for wood if used with the proper precautions. The selection depends greatly upon price.

Fuming Oak. Two exceptional methods remain for notice. One is the darkening of oak by exposure to ammonia gas. The wood is exposed to the fumes arising from dishes full of concentrated ammonia solution in a closed chamber. Old oak is very effectively imitated in this way. The other is the production of a mercury red, which not only gives a very brilliant colour, but acts as a perfect preservative if the wood is not exposed to outdoor influences. The wood is soaked first in a solution of iodide of potassium, and then in one of corrosive sublimate. Full time must be given for the penetration of the first solution before the second is used. A convenient strength for the iodide of potassium is 1 oz. in 1 lb. of water. The sublimate solution must be weaker, say one-third of the strength. When the desired colour has been obtained the wood is thoroughly dried and then oiled and polished.

Dyeing Chip. Wood chip and plaited straw, largely used for hats, are dyed very simply after the fashion of wood and straw respectively. Since artificial silk was introduced, however, "satin chip" is often used, and the unwary garment dyer who treats this like wood or straw, with which it is sometimes mixed, is aghast at the result. Satin chip is natural, or more usually artificial, silk threads pasted together side by side with gelatin into a flat ribbon. For cheaper tapes, cotton, jute, or hemp are used instead of silk.

Dyeing Feathers. Before feathers can be dyed or bleached they must be cleansed from dirt and grease. This is done with warm soap-and-water. Rinse afterwards, first in warm and then in cold water. If preferred, the feathers can be cleaned with petroleum ether. The best bleaching agent, and one which does not injure the feather, is peroxide of hydrogen. The bleaching liquid consists of peroxide of hydrogen of 30 per cent. made neutral with ammonia, so that it does not redden blue litmus paper. The bath is used undiluted for obstinate colours, but should be diluted with water whenever possible. It must not be stronger than necessary, and it can always be strengthened by adding more of the strong bath, some of which should be reserved when the rest is diluted. The feathers are totally immersed, and the bath is covered up to keep out dust and light. It is best to put it in a dark place. The bleaching usually takes about twelve hours. The feathers are then rinsed in soft water, and dried without artificial heat. If kept well covered and shielded from light, the bleach bath can be used several times without renewal.

Dyes for Feathers. The subjoined three dyeing methods have been found to be the best.

A. Dye at the boil in a neutral bath with one of the following dyes: Chrysoidine AC crystals, Vesuvine 4 BC, Phosphine extra, Leather Yellow OG, Leather Red OGR, Leather Brown O, Safranine Red O, Azophosphine GO, BRO, Fuchsine, Cerise GR, Grenadine O, Safranine O, Methylene Violet, Methylene Green, Methylene Grey, Malachite Green crystals, Brilliant Green, Coral Black H.

B. Dye at the boil in a bath acid with sulphuric acid with one of the following dyes: Acid Fuchsine, Orseilline RB, Bleu de Lyon RR, Cotton Blue No. 2, China Blue No. 2, Patent Blue VA, Fast Blue OR, Bordeaux GBR, Deep Black G, Fast Blue Black C, Naphthalene Green V, Azo Yellow conc, Victoria Yellow, Orange II, Fast Brown O, Ponceau GR, RR, Fast Red O.

C. Dye in a bath acid with acetic acid with one of the following dyes: Rose Bengal GB, Phloxine GO, Rosaline OB, OT, Rhodamine O, 4 G, Eosine AG, Erythrosine. Any mode shade can be got by combining these.

The feathers are finally rinsed and dried. They are curled over a small charcoal fire, into which a little sulphur is thrown when white feathers are being curled, and a little sugar when coloured feathers are under treatment.

Very beautiful effects can be got by spraying the feathers with very minute drops from a sprayer. In this way different parts of a feather can be dyed different colours, and the various hues may be made to pass gradually into one another.

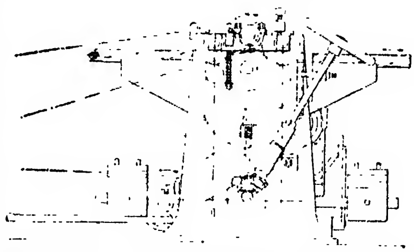
PLANING & MOULDING MACHINES

Trying-up Machines. Panel Planers. Four-cutter Planing and Moulding Machines. Vertical Spindle Moulders. General Joiners

By FRED HORNER

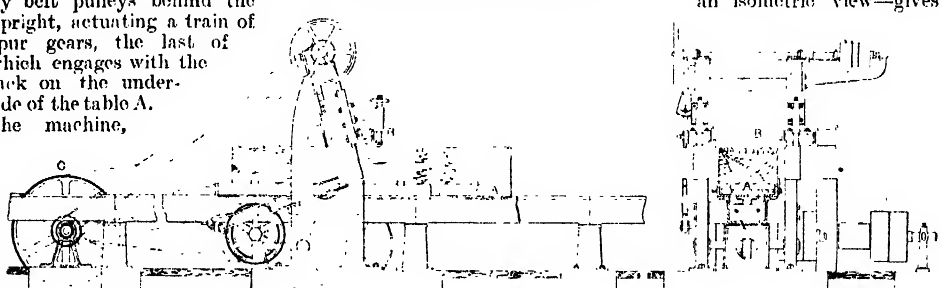
Trying-up Machines. Before describing other classes of planers which bear resemblances to those illustrated in the previous article, we have to notice a particular type of planer—the *trying-up* machine—which is adapted for truing up heavy pieces of timber. Such timber is often too irregular and hard to pass through a roller feed with true results, so they are clamped to a travelling table and fed under the revolving cutters, leaving the planed face quite flat. The general form of the machine is represented in **56**—Messrs. A. Ransome & Co., Ltd., Newark-on-Trent—which shows the timber gripped on the travelling table, A, passing under the adze block at B (covered with a guard). The height of the adze block spindle is adjustable, by sliding it up or down the sloping housings, through hand, or belt, operating vertical screws. The driving of the spindle is by belt from the countershaft C at the rear. The traverse of the table, from 15 ft. to 30 ft. per minute, with a quick return of 80 ft., is effected by belt pulleys behind the upright, actuating a train of spur gears, the last of which engages with the rack on the underside of the table A. The machine, which takes wood up to 20 in. by 20 in., is adapted not only for plain, large work, but can be used for truing and planing a large number of moderate sized pieces, such as the parts of doors, packed together on the table. Moulding and grooving can also be done by replacing the plain adze block with suitable cutters; and in machines provided with additional vertical side spindles, carrying cutter blocks, the edges of timber can be planed. Some trying-up or squaring-up machines have a large disc holding a set of cutters, and mounted on a vertical spindle. The results turned out on these machines are very accurate, but they are rather slower in output than the types with horizontal adze block. A roller feed is fitted when necessary to the tables of trying-up machines for the continuous feeding of thin boards, which do not require to be clamped by the table dogs.

Panel Planers. The surface planing and thicknessing machines, or *panel* planers, which are used for all classes of boards and panels of moderate size, are constructed to pass the timber over a table, above which the cutter cylinder is revolving. The thickness is varied by altering the height of this table. In **55**, a machine by Messrs. John McDowall & Sons, it will be noticed that there is a considerable resemblance in outline to the combined planer shown in the previous article [**54**, page 6452]. The *over-hand* table is omitted, but the other arrangements are much the same. The raising of the table is effected by the inclined shaft and hand wheel, communicating by bevel gears to the vertical elevating screw.



55. 24 IN. × 7½ IN. SURFACE PLANING AND THICKNESSING MACHINE

Another variety of these machines is the *two-side* or *double* surfacer, which has two cutter cylinders, one above and one below, so that a board or panel is finished at one operation. In **58** we illustrate the Whitney planer, one of the most successful types—Baxter D. Whitney & Son, Winchendon, Mass., U.S.A. The photograph shows the external appearance and the arrangement of the countershafts. The drawing [**60**]—an isometric view—gives a section taken longitudinally, and is lettered for comparison with the list of names of parts beneath, which are mostly self-explanatory. It may be mentioned, however, that the lower rolls are supported, and raised or lowered, upon inclined planes, instead of with screws, thus forming a solid bedding and a perfect resistance to the effects of the rapidly revolving cutters, which may be likened to a series of blows, as they strike the wood. Another important feature is the *pressure bars*, necessary on such planing machines. They are placed in front and behind the cutter cylinders, and hold the timber down firmly, affording support to the fibre close to the knives, so that it cannot splinter or tear out. The front bar acts as a *chip breaker*, a small steel spring being placed beneath it, so that there is no risk of tearing out the wood at cross-grained places. The feeding rolls are made sectionally, each being built up of a number of rings which are fitted with spring devices, so

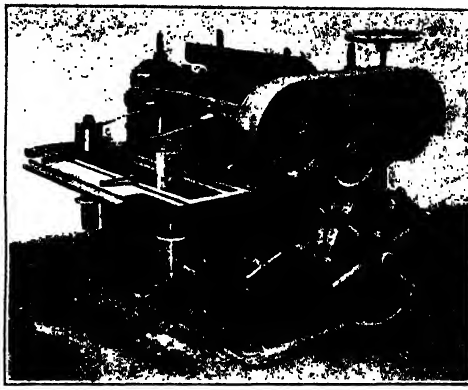


56. 20-IN. TRYING-UP MACHINE

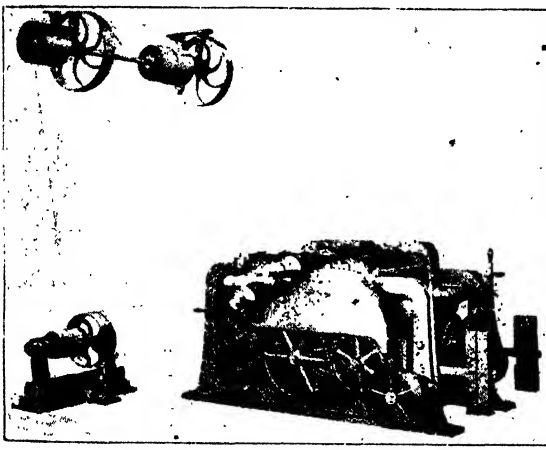
that they give a little, and so accommodate uneven timber. The upper cylinder comes into operation first, so that the top face of the board presents a true surface to the subsequent rolls which keep it in contact with the lower cutter cylinder.

The capabilities of the panel planer are greatly increased by fitting side spindles [59]—Ransome—set vertically, and carrying cutter blocks at the top to work the edges of boards, etc., at the same time the surfaces are planed. By putting on suitable cutters, tonguing and grooving and moulding can be done. The side spindles are adjusted vertically and laterally.

Four-cutter Planers. The most complete types of machines are those which work all four faces of the wood simultaneously—the *four-cutter* machines. These have the highest output, and a very good finish is imparted provided proper care is taken in working the machine. They embody a *fixed* knife in addition to revolving cutters, this knife giving a very smooth surface to the work. But as good results can be obtained only by feeding the stuff past the knife at a high rate, and as this demands great power, it is more convenient to use a fixed knife on one side of the wood only—the under side—working the other side and the edges with rotating cutters. In 61, which gives side



57. PANEL PLANER WITH SIDE SPINDLES



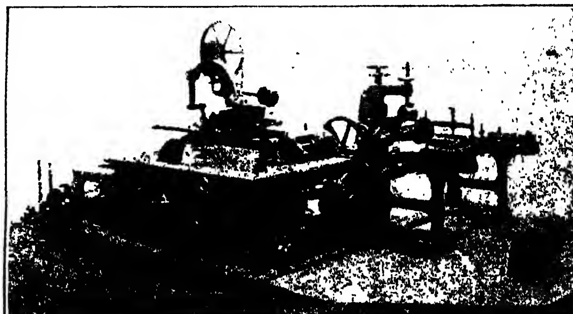
58. WHITNEY DOUBLE SURFACER

elevation and end view of a 16 in. by 6 in. four-cutter machine for heavy work—A. Ransome & Co., Ltd.—the respective positions of the cutters are indicated at A, B, C and D, these letters being put on the timber for clearness. The timber is fed in at the right-hand end, first by two pairs of large serrated rollers, driven by gearing, and weighted through balanced levers. On arriving at A, the wood is attacked by the bottom cutter block there, which trues the under side. Passing on to B, the fixed knife is encountered, this finishing the under side. A series of pressure rollers are placed above A and B, each roller being provided with an independent weight, so that any irregularity is accommodated. Other large feeding rollers at the centre of the machine continue to carry the timber on and past vertical cutter blocks at C, which plane or mould the edges, weighted pressure rollers keeping the wood down at this point. Finally another horizontal adze block is met at D, finishing the top face. By means of the hand wheel E, the operator can raise or lower the whole of the top feed rollers at once for timber of different thicknesses.

The fixed knife at B is rapidly dulled by its work, notwithstanding that the block at A has roughed off the outside of the timber, and it is therefore fixed in a removable drawer, that can be pulled out and changed rapidly. The rates of feed are variable, ranging from 110 to 115 ft. per minute for soft wood. It may be mentioned that the fixed knife cannot be applied successfully to cutting hard woods. It is set angularly across the machine to give a shearing cut, and the pressure rollers above it are placed to correspond. An extra cutter spindle is sometimes added at the delivery end for *sticking* a light beading on the top of the plank or board. A *shavings cutter* is a useful adjunct to a machine having a fixed knife; it comprises a hopper containing revolving cutters, which cut up the long shavings into short portions, that can be readily sucked up by a pneumatic exhausting system.

Rapid Planers. The *lightning* or *rapid* planers are a special class, using a fixed knife only. The work is carried over it by a large roller covered with indiarubber, and the rate of feed is very high. The class of planing done is that on box boards, lap boards, blind laths, which are light, and which require only a thin shaving off to produce a highly finished surface.

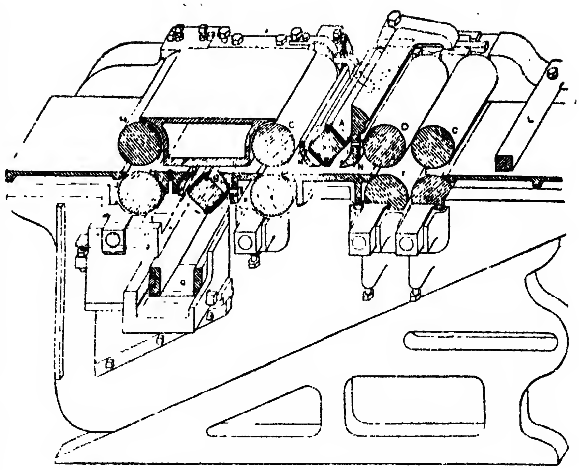
Four-cutter Moulders. Four-cutter machines, designed for producing mouldings only,



59. GENERAL JOINER

resemble the planers in many respects; but the fixed knife is not used. A good idea of a moulder can be obtained from the drawing [63]—John Sutcliffe & Son, Ltd., Halifax—showing a 16 in. by 4 in. machine in elevation, plan, and end view. The cutter block spindles are at A, B, and C for bottom, edges, and top respectively. The fluted feed rollers, situated under covers at D, can be driven at any of six different rates, from 18 ft. to 70 ft. per minute of feed, the variations being produced by sliding spur gears, as seen. The wood is held firmly to the cutters by weighted *pressures,* which can be adjusted to suit requirements. Combined planing and moulding machines are employed for either class of work, as desired.

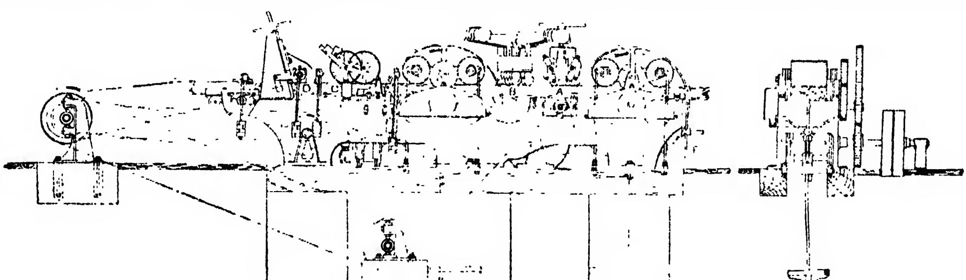
The spindles of these planing and moulding machines run at a very high rate, ranging from 4,500 to 5,500 revolutions per minute, and the cutters must be very accurately balanced in order to produce true work and to avoid damage to the machine through irregular running. The bearings must also be good, with ample surface, and making a close fit without shake, which is fatal to accurate results in planing or moulding.



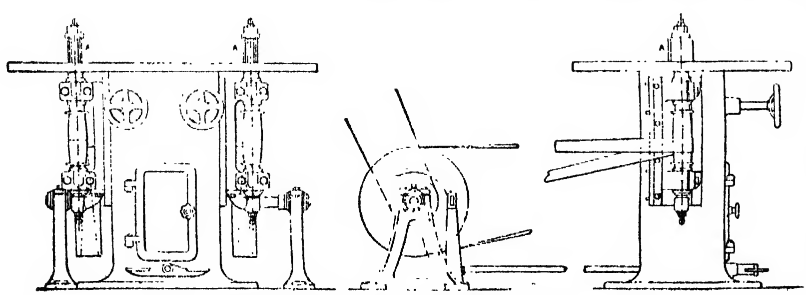
60. SECTIONAL VIEW OF DOUBLE SURFACER

Fourth upper and outfeed roll J. Fourth lower and outfeed roll K. Third lower feed roll L. Guard M. Back pressure bar for upper cylinder N. Front pressure bar for upper cylinder O. Back pressure bar for lower cylinder P. Lower front pressure bar Q. Lower cylinder slide

Vertical Shaper. The *vertical* spindle moulding machine, or *shaper,* is a very different type from the foregoing. It has either one or two spindles, projecting up through a table, on which the work is laid. The spindle carries a moulding iron, and as the work is traversed past, it cuts the surface into a form corresponding with that of the iron. A fence guides the wood in a straight line. Figure 62 shows a double-spindle machine by Messrs. Thomas White & Sons, Paisley, from which it is seen that the spindles AA have long pulleys driven by half-twist belts from the countershaft. Each headstock carrying its spindle is adjustable up and down in slides, the adjustment being obtainable by turning the hand wheels at the front. The treadle in front, near the ground, enables the operator to start and stop the machine by shipping the belt on the fast and loose pulleys at the countershaft. Concentric rings are fitted into the table around the spindles, to allow of putting on differently-sized cutters. The object in having two spindles is to enable curvilinear work to be done expeditiously, by using one or other of the spindles, which revolve in opposite directions, according to the way which the grain runs. Otherwise clean work cannot be ensured. If the machine has only one spindle, that has to be reversed, and a different cutter

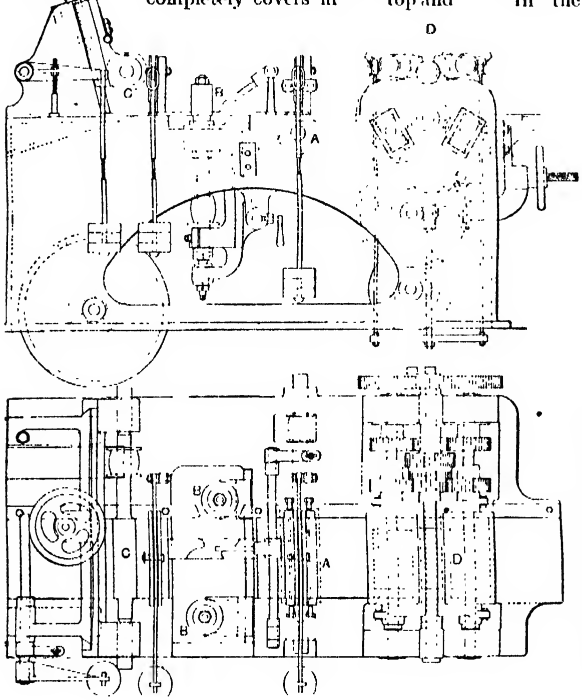


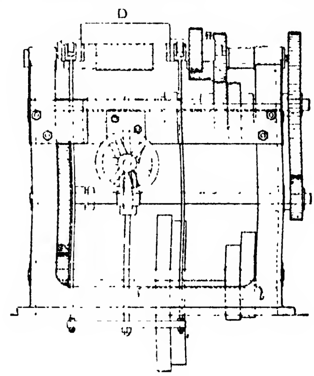
61. FOUR-CUTTER PLANING MACHINE



62. VERTICAL DOUBLE SPINDLE MOULDING MACHINE

block also put on, or else double-edged cutters are used. The working of curves is effected by using a template of the correct outline, placed beneath the moulding, and bearing against a ring encircling the shaper spindle. The template can often be dispensed with and the moulding alone brought into contact with the guide-ring, or collar. It is best to fit a guard over the revolving cutter, as a protection to the operator. A cage made of strips, or of netting, completely covers in top and





63. FOUR-CUTTER MOULDING MACHINE

the sides as far down as the work will allow. There is then no risk of the workman getting his fingers caught through the wood slipping.

A special attachment for cutting dovetails is often fitted to these shapers, comprising a clamp, which holds the wood vertically, and presents it to the dovetail cutter on the end of the spindle. The pitch of the dovetails is determined by a template plate, having notches which lock the clamp at definite positions while the cutter is at work.

Another class of moulding machine, which possesses a greater range than the foregoing, is made with an overhanging arm supporting a vertical spindle, below which a large table is located. In this design the work can be passed *under* the tool, and operations be done on the central portions of a board or panel, such as raising or recessing various patterns, cutting grooves or trenches, in string boards for stairs and shelves. The table can be moved about freely to carry the work, and is fitted with fences.

In the most complete machines a vertical shaping spindle is included, projecting up through the table, by which ordinary mouldings can be worked. The term *variety* moulding machine is commonly applied to this class. In some cases the overhanging arm is fitted with a hinge at the back in order that it may be turned over out of the way when not in use. A very useful application of the vertical spindle is that of preparing core-boxes for patterns, the recessing being done accurately and much more rapidly than by hand methods.

General Joiner. The *general joiner*, or *universal* joiner, or *complete* joiner is a combination machine of great utility in situations where a number of separate machines cannot be installed. It combines [59]—Thomas Robinson & Son, Ltd., Rochdale—a circular saw, with rising and falling spindle, with which sawing, tonguing, grooving and rebating can be done, a band-saw apparatus with 24-in. pulleys, a four-side planing and moulding apparatus, taking timber up to 12 in. by 4 in., a vertical spindle for circular moulding, and a tenoning apparatus. Boring may be done also by attaching a bit to the tenoning spindle. All the motions are derived from pulleys at the left-hand side.

THE SCIENCE OF NAVIGATION

The Instruments Used. The Principles of Navigation and the Several Methods of Determining Latitude and Longitude

By J. P. LORD

THE instruments commonly employed by the navigator, and which are regarded as essential, are the *mariner's compass*, the *chronometer*, the *sextant*, the *azimuth compass*, and a set of charts. To these must be added a Nautical Almanac for the current year, a set of tables, preferably those by Norie, a complete set of azimuth tables, by Burdwood & Davis, a set of Admiralty tide tables and other papers issued by the Hydrographical Department for the guidance of mariners, a Napier's diagram, parallel rulers, stationery, etc.

Instruments. The mariner's compass is a circular card, the edge of which is divided into 32 points, half points and quarter points and also into 360 degrees. Fixed to this card below is one or more small steel bars, magnetised, with the north pole of the magnet to the North point on the card. The whole is then balanced on a sharp point and enclosed in a copper bowl, which is swung on gimbals to keep it nearly horizontal when the ship is pitching and rolling.

The azimuth compass is similar to the mariner's compass, but is constructed with greater accuracy. It is fitted with sight vanes for taking bearings of distant objects, and is placed on the ship in a position which permits it to sweep the horizon.

The chronometer is a clock as nearly perfect as the weakness of man will permit. It is used to show the time at Greenwich at any given moment. It is arranged not to stop while being wound, and is adjusted so as to gain but a fraction or lose but a fraction of a second a day.

The sextant is used for taking vertical and horizontal angles. Its main construction will have been described in the articles on surveying, but the sailor must know how to adjust it himself. Essentially it consists of a graduated arc bearing a telescope and a fixed glass called the *horizon glass*. Attached to the apex of the sector is an arm which bears an index and vernier for reading the angle on the arc, and which also carries another glass, known as the index glass. The index arm and glass are movable, but can be clamped at any point. When an object is looked at through the telescope, with the index of the arm placed to zero, if the instrument is in adjustment the object appears normal.

The adjustments of the sextant are three in number, and are as follow:

(1) To set the index glass perpendicular to the plane of the instrument. Set the index about the middle of the arc, hold the sextant face up, and arc from you, and look into the index glass to see if the true and reflected arcs are in one unbroken line. If they are, the instrument is correct, but if not, the screws at the back of the index glass frame must be turned till the arc forms one clear line.

(2) To set the horizon glass perpendicular to the plane of the sextant. Set the index to 0. Hold the sextant nearly horizontal and look through the telescope and horizon glass at the horizon. If the glass is perpendicular to the plane of the instrument, then the true and reflected parts of the horizon are in one straight line. If the line is broken, then the screw at the back of the horizon glass must be turned till the line is unbroken.

(3) To set the horizon glass parallel to the index glass. Set the index to zero, hold sextant vertically, and look through the telescope at the horizon. If the true and reflected parts of the horizon are in one straight line the adjustment is perfect, but if not, the horizon glass must be moved by its screw till the line is unbroken. If there is no screw for making this adjustment, then the index error of the instrument must be taken. Set the index near 0, hold the sextant vertically, and look through telescope and horizon glass at the horizon. If the line is not perfect, move the tangent screw of the index till the line is unbroken, then read the graduations on the arc, the reading being the index error to be added to all computations if it is off the arc, and to be subtracted if it is on the arc.

Index Error by the Sun. More advanced mariners will obtain their index error from the sun by the following method:

Place the index to about 30′ on the arc. Hold sextant vertically and look through horizon glass and telescope at the sun. On doing so two suns will appear. Bring them edge to edge by the tangent screw, read the arc and note down the reading. Now place index at 30′ off the arc and do the same thing, and write down the second reading. Subtract the smaller reading from the greater, and divide the remainder by two.

The result is the index error. To prove that you are accurate in your observations, add the two readings together and divide by 4. The answer should be the sun's semi-diameter for the day, and should agree with the figures given in the Nautical Almanac.

Compass Corrections. Iron ships are liable to cause the compass to vary, the error or difference from the correct magnetic points being called the *deviation*. The errors set up are of varying kinds, some being due to the fore-and-aft iron, some to the vertical, and some to the transverse iron, while again every iron vessel has a sub-permanent magnetism set up during her building. All these can be corrected for any one spot, but correction for the whole of the globe is outside our power. The modes of adjustment are as follow:

To correct for semicircular deviation caused by ship's own magnetism. See that vessel is upright. Put her head correct magnetic N or S, and place a magnet either before or abaft the compass, parallel to the thwartship line, with its centre on the fore-and-aft line, and the red end on the same side as that to which the compass North is drawn. Move the magnet to or from the compass till the compass needle points correct magnetic N. Swing ship correct E or W, and place magnet either on port or starboard side of compass, parallel to the fore-and-aft line, with its centre on the thwartship line and red end on side to which North point of compass needle is drawn. Move magnet as before till needle points correctly and ship's head is correct magnetic E or W by compass. The deviation from ship's sub-permanent magnetism is then corrected.

To correct for semicircular deviation caused by induced magnetism in vertical soft iron. Put ship's head due magnetic E or W, and place a Flinders bar or bar of soft iron vertically on the fore-and-aft line, before the compass if the north point is drawn aft, and behind it if the N end of compass is drawn forward. Move the bar to and from the compass till ship's head is correct magnetic E or W by the compass.

To correct for quadrantal deviation caused by induced magnetism in horizontal soft iron. Put ship's head on one of the quadrantal points, NE or SW correct magnetic, for instance, and place soft iron balls on each side of the compass in a line exactly at right angles to the fore-and-aft midship line of the ship. Move the correctors to and from the compass till the ship's head and compass agree. This correction does not vary by change of position on the earth's surface, and so ship's standard compasses are usually found with ball correctors in position.

Heeling error is corrected by placing a magnet vertical to the ship's deck beneath the centre of the compass, when the latter is at rest and the ship upright.

On every ship are to be found tables of the deviation of the compass on the principal points,

and these are continually being checked by observations. The deviation tables so constructed are in daily use on every vessel when determining the ship's position.

Rule of Thumb. The art of navigation as practised at sea is really simply the application of a number of arbitrary rules, deduced by mathematicians, and the rules must be learnt by heart for very few sailors could possibly tell you how the rules were obtained, or how their accuracy can be proved. Every sailor who becomes an officer must be able to use logarithms. That is to say he must be able in the tables to find the logarithm of any number or angle and add them together or subtract them as the case may be, and then again from the tables to find what number or angle the logarithm is the logarithm of. He has to make use of sines, cosines, secants, and other trigonometrical functions without knowing what they are. He merely depends on his tables. He will find the logarithms of common numbers on Table 24 in "Norie's Tables," or in Table 64 in "Raper's Tables." Throughout this article we shall assume that the student has access to "Norie's Tables," as they are the ones most generally used.

The first process a navigator must learn is how to find his position by dead reckoning—that is to say, by taking the courses on which the ship has sailed, and the number of miles she has travelled over each, making allowances for deviation and variation of the compass on courses steered and for currents and leeway. This is known as the *day's work*.

The Day's Work. The *day's work* starts with a bearing or departure course. When a ship leaves the land this is usually a point ashore; when as sea it is the position on the previous day, or when last sights were taken.

The Bearing or Departure Course. Take the given bearing and reverse it; consider the number of points it is from North or South and turn them into degrees. Then allow the deviation for the direction of the ship's head. Easterly deviation is allowed to the right hand, and westerly deviation to the left hand. After this allow the variation—easterly variation to the right hand, and westerly to the left. The result is rega ' ' a true course and is entered as such in the traverse table with the distance of the object from which the bearing was taken. After the first day this need not be done, for the course the ship is on is the departure course for the day. The courses on which a vessel sails each hour are entered in the log book, with the direction of the wind and the leeway made. From the deviation table of the ship the deviation on each course is entered in the log, and from the Admiralty chart the variation of the region is also entered, care being taken to enter any change in the variation. This is done by the officer of the watch, and at noon nearest after sailing the *day's work* is continued.

Take the first course sailed and correct it for leeway—if on the port tack to the right hand; if on the starboard tack to the left hand. After this allow the deviation and variation as above for the departure course, and the result is the *true course* sailed. If it is over 90° subtract it from 180 and change N into S or S into N, keeping it E if originally E or W if W.

Do the same with each of the different courses sailed. Then take the *current course* and allow only the variation on it, for the set of the current is usually given correct magnetic and so is not affected by deviation.

When all these courses are corrected enter them one under another in the traverse table. Then take the distances sailed over each course and enter it in distance column of traverse table. Next from Norie Table 2 take out the D. lat. and dep. for each course and distance sailed and place them in their respective columns, and thus the traverse table is completed.

Add up N column and S column and subtract the less from the greater; the result is the D. lat. of the same name as the greater. Add up the E column and then the W column and subtract the less from the greater; the result is the dep. of the same name as the greater. *Dep.* stands for departure, *D. lat.* for difference of latitude, and *D. long.* for difference of longitude, for the meaning of which see dictionary following this article.

Now find latitude in. Write down *Lat. left*, that is lat. of point of land, or lat. of ship's position when last day's work was made up, and below it place the D. lat., previously bringing it to degrees if necessary. If D. lat. and lat. left are same name, add them together; if contrary names, subtract them. The sum or the remainder is the lat. in, of the same name as the greater.

Now find Middle lat. (Mid. lat.). Bring down lat. left below the lat. in, and if of same name, add; if contrary names, subtract less from greater, and divide sum or remainder by 2. This gives Mid. lat.

Then find D. long. Turn to Table 2 (Norie), and with Mid. lat. as a course, and with Dep. in D. lat. column, the number in the Dist. column is the D. long. of the same name as the Dep. If the Dep. is very large and cannot be found in D. lat. column, divide Dep. by 2, proceed as above, and when a result is obtained multiply it by 2 to give D. long.

Or find D. long. by parallel sailing. Add together the log secant of the Mid. lat. and the log of the Dep.; the result is the log of the D. long. This is the most accurate method, and should always be used in high latitudes.

To find the long. in, write down long. left, and below it place D. long.; if of same name, add; if of

Explanation: *Column* to extreme left is used for ascertaining the corrected course.

Upper table is the extract from the ship's log. H is hours, Courses are compass courses. K and $\frac{1}{10}$ are knots and fractions sailed, L gives leeway.

Lower table is traverse table made out as given in the text.

contrary names, subtract. The sum or remainder is the long. in of the same name as the greater. If longitude is greater than 180, subtract from 360, and call remainder Long. in of an opposite name to Long. left.

You have now found your ship's position, having her latitude in and longitude in, and on the chart you can find how many miles she has made good, but it is better to do so as follows. The course is on the top of the page when D. lat. in traverse table is greater than Dep., and on the bottom when it is less. In Table 2 look for a page on which your D. lat. and Dep. correspond, or very nearly so, with those printed. The distance will be found alongside, and the course on the top or bottom of the page as explained. You thus have course and distance, which can be used if you like as a true departure course for next day. An example of a day's work, with the entries in the log, is shown on the previous page.

Latitude by the Sun at Noon. This is an everyday operation at sea, provided the sun is visible at midday. To obtain the altitude the sextant is used. The observer stands facing the sun at about, but rather before, the estimated noon. He holds the sextant vertically, and looks through the telescope and horizon glass at the horizon. Then he moves the arm of the index till he sees the reflection of the sun just touch the horizon. Several times he will have to move the glass, for the sun will seem to shift its position. At last he will hit the moment when the sun seems just stationary on the horizon, and then starts to dart away. At that instant he clamps the index. It is noon. A reading of the arc will then give the observed altitude of the sun.

Now find Greenwich time. Write down year, month, and day, P. hrs., P. min., P. secs. Turn the longitude into time by multiplying by 4 and dividing by 60, and place it below 0h., 0m., 0s. If West long., add; if East, subtract. Result is Greenwich apparent time (or G.A.T.).

To Find Correct Declination. This enters into very many problems and the student must gain great facility in working it. Take out decl. for Greenwich day and variation for one hour, which multiply by the hours and tenths of an hour in the G.A.T., paying attention to the proper making of the decimal point, divide by 60 if necessary, and result is the correction of the declination. If the declination is increasing, as seen from the Nautical Almanac from which it was taken, add the correction to the day declination; if decreasing, subtract the correction. The result is the correct declination.

To Find the True Altitude. Write down the altitude you have observed, and correct it as follows: Apply the index error of your sextant, adding or subtracting according to your determined rule. Look out the "dip" for the height your eye was from the sea in Table 5 (Norie), and always subtract this. Look out "Refraction" in Table 4 (Norie), and always subtract this. Look out "Semi-diameter of sun" for Greenwich day on page 11 of Nautical Almanac. If lower limb was observed, add; if upper, subtract. Look out "Correction for parallax" in Table 6, and add this always. The result is the true altitude of the sun.

Next find "Zenith distance," or Z.D. Subtract true altitude from 90, and mark remainder of opposite name to "sun's bearing"—that is, Z.D. Now find latitude. Below Z.D. put corrected decl. If Z.D. and decl. are of same name, add them; if different names, subtract. The sum or remainder is the latitude, which is always of the same name as the greater of the Z.D. and declination. We give below an example of this method for the student to examine.

Example. On September 22nd, 1898, in Long. 115° 30′ W. the observed altitude of sun's lower limb at noon was 62° 10′ 25″, bearing N Index error 2′ to subtract; height of eye 17 ft. Wanted latitude.

Sept 22d	0h 0 0″	Long	115° 30 W	Observed Alt.	62° 10′ 25″ N.
	7h 42		4′	Index error	2′
Sept 22d	7h 42 0″ G.A.T		60)462° 0′		62° 8′ 25″
			7° 42′	Dip	4′ 2″
					62° 4′ 23″
				Refr	30″
					62° 3′ 53″
Decl for 22d	= N 0° 12′ 22″		58″ 46	Semidiam.	15′ 58″

			7 30″	True alt	62° 19′ 55″
			90° 0′ 0″		
			62° 19′ 55″ N.		
		Zenith Dist.	27° 40′ 5″ N.		
		Corr. Decl	4′ 52″ N.		
			27° 35′ 13″ S Latitude.		

Parallel Sailing. Three factors enter into problems in parallel sailing—namely: (1) The distance between two meridians on a given parallel of latitude, which is Dep. or *meridian distance*; (2) the latitude of that parallel, which is latitude; and (3) the distance between the meridians on the equator or D. long. Any two of these being known, the third can be found by the following formulæ:

Example. A ship sails due east 206 miles from Sandy Hook Light, in latitude 40° 28′ N, Long. 71° 50′ W. What Longitude does she arrive at?

Log departure	..	2·313867
Log sec. Lat. ..	..	10·118739
Log D. Long.	..	2·432606
D. Long	..	4° 30′E.

Long left	73° 50′W.
D. Long	4° 30′E.
Long in is	69° 20′W.

Log D. long. equals Log Dep. added to Log sec lat.

Log Dep. equals Log D. long. added to Log cos lat.

Log cos lat. equals Log D. long. subtracted from Log Dep.

The logarithms of all these factors can be found in the tables, and when an answer is found the number of degrees and hour corresponding to that log can also be found in the same tables.

Mercator's Sailing. Mercator's charts have the meridians of longitude parallel to one another, and the distance between the parallels of latitude varies proportionally to the opening out of the meridians. The only problem in this species of sailing commonly used is to find the course and distance between two places whose latitude and longitude are known.

The rules for working this problem are as follow:

Find D. lat. by subtracting the less of the two latitudes from the greater if of the same name, and adding them both if of different names. Multiply the degrees in the answer by 60 and add in the miles. The result is D. lat.

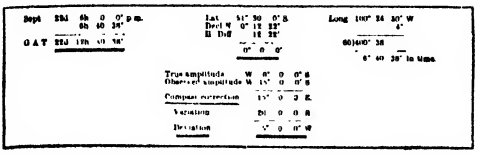
Find meridional difference of latitude, or M.D. lat. From Table 3 (Norie), take out the meridional parts for the two latitudes. Latitudes of the same name subtract; of different names add. Result is the M.D. lat.

Find the D. long. Longitudes of same name subtract; of different names add. Bring result into miles and call it D. long.

TO FIND COURSE. From Log D. long., with index increased by 10, subtract log of M.D. lat. Answer is Log tan of true course. This must be taken out very exactly.

TO FIND DISTANCE. To Log sec of true course, taken out to seconds, add Log D. lat. Result, subtracting 10 from index of log, is the log of the distance. Great care must be used in naming the course.

Example: On September 22nd, 1898, at 6h. 0m. p.m. apparent time on ship, in lat. 50° 30′ S., long. 100° 24′ 30″ W. The sun set by compass S. 75° W. Required true amplitude and error of compass. If variation is 20° E., what is deviation for the then position of ship's head?



True amplitude	W. 0°	0′	0″	S.
Observed amplitude	W. 15	0′	0″	S.
Compass correction	15°	0′	0″	E.
Variation	20°	0′	0″	E.
Deviation	5°	0′	0″	W.

To Find the Compass Course. The compass course is the course shown by the ship's compass when the vessel is really sailing along a true course. Take the true course and below it place the variation. If variation is west, allow it to the right; if east, allow it to the left. Result is magnetic course. Below magnetic course place deviation, and if it is west, allow it to the right; if east, allow it to the left. The result is the compass course, or the course to be given to the helmsman.

Amplitudes. The principal object of taking an amplitude is to obtain the error of the compass. The exact bearing of a heavenly body either just as it is rising or setting is taken by the compass and written down as the observed amplitude. Now find Greenwich apparent time (or G.A.T.) as in the day's work, only, instead of hours, minutes and seconds being PO, O, O, they will be the actual time. If a.m., add 12 hours to the time and take off one day of the date. Next find true declination as before. To find the true amplitude to log sine or sin of true Dec., add log sec of lat.; the sum, rejecting 10 from index, is log sin of true amplitude. If a.m., name it E; if p.m., name it W. If Dec. is N, name it N; if S, name it S.

Having got the true amplitude, compare it with the observed amplitude, and then the difference between them is the error of the compass. The variation for the latitude is known from the chart, when the error has been corrected for variation, and what remains is the deviation.

Azimuth. To find true azimuth, the navigator must be equipped with azimuth tables, and have access to a good azimuth compass. By looking through the sight vanes of the azimuth compass, he takes the bearing or the object, be it sun or star, and reads on the card the observed azimuth. At the same time he takes the time on ship. Next he finds the Greenwich mean time (or G.M.T.) as follows. Write down year, month, day, hours, minutes, and seconds of ship time, and if it is a.m. at ship add 12 hours, and take off a day of date. Turn longitude into time, and if it is W., add; if E., subtract. Result is G.M.T. Find the equation of time from page 11 of the month in Nautical Almanac for the Greenwich day of the G.M.T., and also the variation in one hour of the same day from page 1 of the same. Multiply the variation in 1 hour by hours and tenths in G.M.T., and add result to the equation if it is decreasing. This gives true equation. Find the true declination as before.

To the time at ship apply the corrected equation of time. The result is the apparent time at ship.

Now take the tables of azimuths and enter them with the latitude, and be careful to notice if the latitude and Dec. are of the same or of different names. Then opposite apparent time at ship will be found true azimuth. This is named the same as the latitude—E in morning and W in afternoon. This compared with observed azimuth will give the compass connection, and thence the deviation, the variation being known.

Longitude by Chronometer. The latitude is generally taken daily at noon, whenever practicable, and to get the latitude at the time sights are taken for longitude by chronometer. The navigator must find the D. lat. as in the day's work, up to the time he is going to take sights. If a.m. change the name of the D. lat., and if p.m. change the name of the dep., which he will also have to take out. After which get latitude in and D. long., as in day's work. Now take the altitude of the sun, just as if it was noon, but the lower limb need only to be brought to touch the horizon, and the index arm clamped. At that moment the time by the chronometer is noted. The arc of the sextant is read, and the reading noted down as observed altitude. The chronometer time is also noted down. The navigator first turns his attention to the chronometer time. He turns this into astronomical time and applies the error of the chronometer, either gaining or losing as the case may be. Now from observed altitude he obtains true altitude as in lat. at noon, and gets polar distance and equation of time from the tables. Next write down the true altitude, below it place the lat. and polar distance. Add the three together and divide by 2. The result is called *half sum*. From half sum subtract true altitude. The result is remainder. From Table 25 take out the following logs to seconds: Log sec of latitude, log cosec of polar distance, log cos of half sum and log sine of remainder. Add the four logs together and cast out the tens in the index. Look out the log in Table 31, and it will be found to be the hour angle, or time from the nearest noon.

Now if it is a.m. on ship, subtract hour angle from 24 and deduct a day from the date; if p.m., put hour angle as time with same date as on ship. This gives us apparent time on ship.

Find mean time on ship. Below apparent time on ship place corrected equation of time and apply it as indicated in almanac, page 1 of month. The result is mean time on ship.

Now find longitude. Below mean time on ship place mean time at Greenwich, putting down days as well as hours. Subtract the less from the greater. The remainder turned into degrees is the longitude of the ship at the moment the sight was taken. If the Greenwich time is less than ship time, longitude is E., if larger longitude is W.

Longitude by Chronometer and Azimuth Combined. This is not a very popular problem with officers, but is required by the Board of Trade for examination purposes, so we shall indicate how it is obtained. Proceed as in longitude by chronometer till the true altitude and polar distance have been found. Find half sum, and the remainder, which call chronometer remainder. Obtain sun's hour angle from Table 31 as before, and thus get longitude. Now subtract the polar distance from half sum, or half sum from polar distance, and call *azimuth remainder*. Add together the log sec of altitude, log sec of latitude, log cos of half sum, and log cos of azimuth remainder; cast off 20 from the sum of the indices and divide the rest of the sum of the logs by 2. Result is the log sine of half the true azimuth, which take out from Table 25 to nearest half mile,

and multiply by 2. The result is the true azimuth. On the left hand of the azimuth put N. if latitude is S and S if latitude is N. On the right hand put E if a.m., and W if p.m. on ship.

Example: On September 1st, 1898, at about 0h. 30m. a.m., mean time in lat. at noon 47° 20′ N., and long. by account 166° 14′ E., the observed altitude of sun's lower limb was 39° 49′ 5″, bearing by compass S.E. Height of eye 17 ft. Time by chronometer 10h. 15m. 20 sec., which was 6m. 50 sec. slow on mean noon at Greenwich on May 1st, and losing 3·5 seconds daily, the ship having made 30 miles on a true south course between time of observation and noon. Required longitude at noon, and supposing variation to be 5° E., required true azimuth and deviation for direction of ship's head.

Charts and their Uses. Charts are of two recognised kinds—namely *true charts* and *magnetic charts*, the former having the compass printed on the chart showing "true North," while the latter shows magnetic North. To find the course to be steered between two points, join them by a faint line, and draw a faint line parallel to this through the centre of the compass. If the chart is a true one, you must look on it for the variation nearest to the marked course, and apply this to the course shown on the compass, W variation to the right, and E to the left. This will give the magnetic course. To this apply the deviation of the ship's compass on that particular course, and the answer will be the compass course to be steered. To obtain the distance between the two points measure the line and transfer the measurement to the graduated meridian, when it can be read off at once.

Again, with a ship on a compass course, to obtain the true bearings of observed objects or points on the chart the compass bearing must be corrected by applying the deviation and variation in order to obtain their true bearings. These true bearings are laid off on the chart compass if a true chart, or the magnetic bearings laid off if the chart is magnetic, and where lines parallel to these bearings but passing through the observed points intersect will be the position of the ship. The longitude and latitude of that position can be read off on the border of the chart.

A third use of the chart is to find the position of the ship by two observations of the bearings of the same object. The compass bearings must both be turned into magnetic or true bearings according to the sort of chart and then lay these bearings off from the point, and let the fine lines cut the line of course as marked on the map. Take distance ship covered between bearings, and from point where first bearing cuts line of course measure off that distance. If the ship were actually travelling along that course, the distance would correspond with the line of second bearing; but she is not, so through the point where the distance reaches to draw a line parallel to the first line of bearing and where this cuts the second line of bearing will be the position of the ship.

The small figures placed on the chart indicate the depth of water at low water of ordinary spring tides: the Roman numerals show the time of high water at full and change of moon.

Tides. The time of high water at any place can be taken out from the Admiralty Tide Tables, but if these are not available, to the time of high water at full or change add 49 minutes for every day elapsed since full or change. The result is time of p.m. high water approximately.

To Correct Cast of Lead. From Admiralty Tide Tables find times of high water on the day at the place you are nearing. Take the tide nearest to the time you are sounding. Find the height constant by subtracting the spring rise of the port you select from the Port of Reference spring rise, as given in the Admiralty tables. This you add to the reference port rise if the height at selected port is more than that of port of reference, or subtract if less. Thus you get height of high water at your nearest port, and from this subtract the half spring rise there. The result is the height of high water above half tide. Now double the time from high water, and if over 6 hours subtract from 12. Consider this a course. Bring height of high water above half tide to inches, and consider this a distance. In Norie Table 2 with this course and distance find the corresponding D. lat. Consider this as inches, which must be added or subtracted from the half spring rise according as the time from high water is less or more than three hours, the result being the correction to be applied to the sounding taken with the lead.

Stellar Navigation. The student will learn under Astronomy how to distinguish the principal stars [see page 6116], and he may find help from Rosser's "How to Find the Stars," which is almost a sailor's classic. We shall only deal with how to use the stars for navigation.

To find mean time at which a given star will be on meridian of the observer. Take Norie Table 44, or Raper Table 27. Look and see if time of meridian passage of star is more or less than 12 hours on the day given. If more than 12, count it as the previous day for looking in the Nautical Almanac: if less, count in the same day. From the Nautical Almanac take out star's right ascension, R.A., for the nearest day, also take out the sidereal time, from page II of the month, for the day you are working with. From the star's R.A. subtract the sidereal time, adding 24 to the R.A. if necessary. Result is mean time of star's meridian passage. From Norie Table 37 or Raper 24 take out the minute and seconds corresponding to the mean time nearly. Subtract them from the mean time nearly, and result is mean time the star will pass the meridian at Greenwich. Find longitude in time, and take from Norie or Raper, same tables, the minutes and seconds corresponding to longitude in time. Apply this correction to time star is on meridian of Greenwich; West longitude subtract, East longitude add. Result is mean time star is on the meridian of the observer. If result is less than 12 it is p.m., if more, reject 12 hours and call remainder a.m.

The apparent time a star will be on the meridian of the observer can be found by inspection in Norie Table 44 or Raper Table 27.

To find the R.A. of the meridian, apparent time being known, write down astronomical time at ship, underneath it place sun's R.A. from Nautical Almanac for Greenwich day, and the correction for the hours and minutes of Greenwich time calculated from the variation in 1 hour of the sun's R.A. From the sum reject 24, if sun is more than 24 hours, if not the answer is the R.A. of the meridian. A star is to the east of the meridian if its R.A. is more than the R.A. of the meridian; it is to the west if its R.A. is less than that of the meridian. A star passes the meridian to the north of an observer if its declination is to the northward of observer's latitude; it passes south if the star's dec. is southward of the observer.

Longitude by Chronometer and Star's Altitude. The altitude of a star is taken in the same way as the altitude of the sun. Find Greenwich mean time as in longitude by chronometer. Correct the star's observed altitude for index error, dip and refraction, as for sun, and thus get true altitude. From Nautical Almanac take star's R.A. and declination, and get the polar distance. Take also sidereal time for Greenwich date, correcting it for the hours and minutes of the Greenwich time by Norie Table 38. The correction is always to be added to the sidereal time, and the sum is mean sun's time. Now find the star's hour angle in exactly the same way as for the sun. If the star is to the east of the meridian subtract the hour angle from 24 and the remainder will be the westerly hour angle.

Find mean time at ship. Place star's westerly hour angle beneath the R.A. and add. Sum is R.A. of meridian, from which subtract mean sun's R.A., borrowing 12 hours if necessary. Remainder is mean time on ship. Now for longitude. Place Greenwich mean time underneath mean time on ship, and subtract the less from the greater. Convert remainder into degrees, etc., for longitude which will be east or west according as the Greenwich time is less or more than ship's time.

To Find True Azimuth of Stars. Find the mean time at ship, or apparent time, as may be most convenient. Then find hour angle of star, which, if more than 24, reject the 24, and if more than 12 but less than 24, subtract it from 24. In the time azimuth tables find the star's hour angle in the right-hand column of the page, under P.M. Name the azimuth according to the rules at the foot of the page in the tables.

Reduction to the Meridian. This is a very accurate method of finding the latitude by the altitude of a star or the sun. In this problem we have to find the difference between the meridian altitude and the true altitude of the observed object. First find the apparent time at Greenwich, and then the corrected declination. Then find the true altitude as we have aleady learnt how to do. Now to find the correction for the meridian altitude. Then take out the following logs from the tables.

Time from noon log from Table 31. Log cos latitude by account, log cos declination, log cosec of estimated zenith distance, which zenith distance you get by adding the latitude estimated and the declination if of different names, and subtracting them if of same name. Add the four logs together and cast out the tens from the index. The result is the log sine of half the reduction, which must be taken out from Norie Table 25 and multiplied by two. This reduction is always to be added to the true altitude, and will then give the meridian altitude.

Take the meridian altitude and subtract it from 90; the remainder is the meridian zenith distance, which is named of an opposite name to the bearing, S when bearing is N; N when bearing is S. Below the new Z. D. place the corrected declination. If of the same name add, if of different names subtract. The result is the latitude of the same name as the greater of the Z. D. and declination. This is the latitude at the time of taking the observation.

Sumner's Method for Finding Latitude and Longitude. This is rather a complex method of finding the position of a ship when in doubt, and no moon sight obtainable. Two altitudes of the sun's lower limb are taken, the time between them noted and also the run of the ship during that time. Two latitudes, between which the ship is fairly certain to be, are assumed: Chronometer times of both observations must also be taken. Here are the rules.

With the first Greenwich mean time find sun's declination and polar distance and equation of time. Correct first observed altitude and obtain true altitude. With this true altitude, the lesser assumed latitude, and the polar distance, find hour angle, as in longitude by chronometer, and from hour angle deduce a longitude, which call A. With same true altitude and greater assumed latitude proceed as before and find second longitude, which call B.

With the second observed altitude and Greenwich mean time do exactly the same, finding longitude E with lesser, and longitude F with greater assumed latitudes. Now take a chart and on parallel of lesser latitude lay off the first of the longitudes, namely A. Call the point 1. On the second assumed latitude lay off longitude B, and call point 2. Join 1 and 2, and that gives line of position for first altitude, the direction of which can be obtained from the compass on the chart. Take any point in the line of position and from it lay off the courses and distance the ship has made in the interval between the two observations. Through the end of this distance draw a line parallel to the line 1 2, and call this line KL. Lay off the other longitudes E and F on their assumed parallels of latitude, naming the points 3 and 4. Join 3 and 4, which gives us the line of position for the second altitude. Where the line 3 4 crosses the line KL is the ship's position when the second altitude was taken. To find the sun's bearing at the time of taking the first altitude, draw a line from the ship's position at right angles to the line of position, to the eastward if the first observation was taken a.m., but to the westward if taken p.m.

Latitude by Altitude of Polar Star. The Polar Star is not situated at the North Pole, but about $1\frac{1}{4}°$ from it, so certain corrections have to be made to the observed altitude according to latitude, time, etc. These corrections are known as first, second, and third, and can be found in the Nautical Almanac. First find Greenwich time, and thence sidereal time of observation of star's altitude. Correct observed altitude for index error, dip and refraction, and from this altitude deduct 1′, giving the reduced altitude. With sidereal time of observation take out first correction from Nautical Almanac, with it proper sign, and apply it to the reduced altitude. Result is approximate latitude. With true altitude and sidereal time take out second correction and add it to the approximate latitude. With the day of the month and sidereal time take out third correction, which is also added to the result from the last addition to the approximate latitude. The result is required latitude of ship which is always North.

Latitude by Meridian Altitude of Moon. Find moon's meridian passage. On page 4 of month of Nautical Almanac, take out upper meridian passage for astronomical day, and, if longitude is west, for day following; but if longitude is east, for day previous. Subtract the less from the greater. The result is daily retardation. Apply this to longitude in time, getting proportion of daily retardation, or correction for retardation. This is added to meridian passage of astronomical day if longitude is west, but subtracted if longitude is east. Result is time moon is on the meridian of ship.

Moon's Declination. In the Nautical Almanac the moon's declination is given for every hour of the day, and the variation in ten minutes. Take out these quantities for the Greenwich day and hour, and multiply the variation for one minute by the minutes and tenths thereof in the Greenwich time beyond the hours. Divide by six if necessary. The result is the correction to be added if the declination is increasing, or subtracted if it is decreasing. The result is the corrected declination. The semi-diameter and horizontal parallax are found as follows: From Nautical Almanac take out both for the day, for noon if Greenwich time is less than 12, but for midnight if more. Find the difference for the day by subtracting one amount from the next and multiply by the hours and tenths of an hour the Greenwich time is past noon or past midnight; divide answer by 12. This gives the correction for semi-diameter or for horizontal parallax, the process of correcting both up to this point being identical. Look in Table D. of Norie's Tables, and find the augmentation for the semi diameter, and add it to the corrected semi-diameter. In Table E (Norie) find the reduction of the horizontal parallax, and subtract it from the corrected horizontal parallax.

Take the observed altitude, which is taken in the same manner as that of the sun, apply index error, subtract the dip, subtract the refraction, add the augmented semi-diameter if altitude of lower limb was taken, but subtract if upper limb was observed. Then add the parallax, and the result is the moon's true altitude.

To find the latitude, subtract the true altitude from 90, and name it the opposite way to the bearing of the moon. This is the zenith distance. Apply declination as in sun's altitude, and thence obtain the latitude.

Napier's Diagram. This is an ingenious diagram by means of which the deviation of a ship's compass can be found sufficiently accurately for practical purposes. The bearings of a distant object are taken with the ship's head at eight different equidistant points of the compass. The mean of the eight bearings is held to be the correct magnetic bearing of the object. To find the mean of the bearings we have three possible cases to consider. (1) If all the bearings are named alike. In this case add the bearings together, divide by eight, and name the result the same as the bearings. (2) If some bearings are named N. and some S. Take all the north bearings separately from 180 or all the south bearings from 180, whichever is easier. Add the bearings together, divide by eight, and name the bearing the same as those you have not altered. And (3) some bearings are east and some west. Add all east bearings together, and all the west. Subtract less from greater. Divide remainder by eight, and name result same as greater.

To Find Deviation. In the first two cases the difference between the correct magnetic bearing and each of the bearings of the standard compass is the deviation for each point of the ship's head. In the third case when the correct magnetic bearing and the bearing by the standard compass are both east or both west, subtract the less from the greater. If they are of different names, add them together. When the correct magnetic bearing is to the right hand of the standard bearing, the deviation is named east; if to the left, it is west.

Now take the diagram, and with dividers take from the centre line of Napier's diagram the number of degrees in the deviation for each of the eight points. Mark each on its proper line, and through the points thus obtained draw a flowing line, which will be the curve of the deviation. With this curve given a correct magnetic course you can find the compass course as follows: Place one leg of the dividers on the given course on the centre line and extend the other leg to the curve on or parallel to a plain line. Keep the leg on the curve, and move the dividers round till the other leg cuts the centre line in another place. The number of degrees from north or south there indicated is the compass course. To find correct magnetic course from a given compass course is only a reversal of the above proceeding. Given the direction of the ship's head, and the compass bearings of two distant points to find their correct magnetic bearings. Place one leg of the dividers on the direction of the ship's head on the centre line, and extend the other leg to the curve on or parallel to a dotted line. Lift dividers carefully, place one leg on the first given bearing on the centre line, and lay the other on the centre line, upwards if deviation for ship's head is west, and downwards if it is east. The number of degrees indicated will be the correct magnetic bearing from north or south towards east or west for that bearing. The other can then be dealt with in the same manner.

Instruments. We shall close this short set of lessons in navigation—all higher problems coming into the region of astronomy or mathematics—with a few brief remarks on the three principal instruments essential to safe navigation in their order of importance—namely, the compass, the sextant, the chronometer standard compass. Since upon the compass chiefly the safety of a vessel depends, it is most important that it should be of the best design and workmanship. Its position should be sufficiently distant from any particular masses of iron, especially those of a movable nature, and where an all-round view of the horizon can be obtained. The lubber line must be exactly in the fore-and-aft line, the pivot pin accurately centred, and the card evenly balanced in order to ensure satisfactory results.

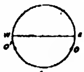
In the sextant an important point to be observed is that the vernier should fit perfectly flush on the face of the arc, and that the divisions are truly and cleanly cut. The instrument with 8-in radius is perhaps most serviceable, and neutral tinted glass is preferable for all screens. In fine clear weather take observations from the most elevated platform, and in foggy weather from the lowest point attainable. For stellar observations properly fitted binoculars are a boon. Carefully wipe glasses after using.

For long voyages three chronometers are deemed necessary. Select instruments by well-known makers, and have them rated for temperature. They should be secured in a specially constructed box, having padded sides and glass top, in a part of vessel free from vibration and as far removed from iron structural parts as possible. No compass or magnet should be near them. Wind punctually at same hour every day, and compare rates.

Continued

A SHORT DICTIONARY OF TERMS USED IN NAVIGATION

AMPLITUDE—The amplitude of an object is the arc of the horizon between the east and west points and the object when rising or setting. In 1, OE and OW are amplitudes of O rising and setting.



1.

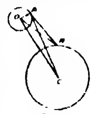
Apparent Altitude—The apparent angular height of the object's centre above the sensible horizon.

Apparent Time—The angle at the pole between the meridian passing through the sun and the meridian of the observer, reckoned westerly.

Arc of a Circle—A portion of its circumference.

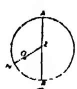
Astronomical Time—The time reckoned from noon to noon, and used in astronomical calculations.

Augmentation of Semi-diameter—The apparent increase in semi-diameter arising from decreased distance of observer from the object as it rises. Or, again, it is the difference in the semi-diameter brought about by the observer not being situated in the very centre of the earth. In 2, angle C is nautical semi-diameter; angle at R is augmented.



2.

Azimuth—Of a celestial body this is the arc of the horizon included between the north or south points and a vertical circle, drawn through the object. In 3, NZB is Azimuth of O for observer on AB.



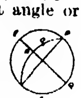
3.

CIVIL TIME—From midnight to midnight, the time in common use.

Compass Course—The angle a ship's fore-and-aft lines makes with the compass needle; otherwise, the track of the ship as shown by the compass.

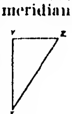
Complement of an Angle or Arc—The amount by which that angle or arc differs from 90°.

DECLINATION—The arc of a celestial meridian between the equinoctial and the object [4 OR].



4.

Departure—The distance in nautical miles which a ship has made good east or west of the meridian sailed from. In 5, XY is meridian sailed from, XZ is ship's course, and YZ is departure, XY a meridian, XZ ship's track.



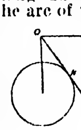
5.

Deviation of Compass—The angle the compass needle makes with the magnetic meridian, and caused by the iron in the ship.

Difference of Latitude (written *D. lat.*)—An arc of a meridian between two parallels of latitude.

Difference of Longitude (written *D. long*).—The difference of longitude between any two spots is the arc of the equator between the meridians of the two places.

Dip of the Horizon—The angle at the observer's eye between the visible and sensible horizons [HOS in 6].



6.

ECLIPTIC—The great circle in the heavens in which the sun appears to move among the stars. In 7, XY is the ecliptic.

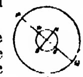
7.

Equation of Time—The difference between mean time and apparent time, and by its use the one can be converted into the other, and vice versâ.

Equator—A great circle supposed to be drawn round the earth 90° from each pole.

Equinoctial—The plane of the equator extended to the heavens and making a great circle therein. In 8, PQ is the equinoctial.

Error of Compass—The angle the compass needle makes with the true meridian.



8.

FIRST POINT OF ARIES—An imaginary spot in the heavens where the sun's apparent path crosses the equinoctial, from south to north.

GREATER CIRCLES—Those whose planes pass through the centre of a sphere [9].

9.

HOUR ANGLE—The angle hour of a star or other celestial body is the angle its meridian makes at the pole with the meridian of the observer. In 10, P is pole, PN meridian, O is body, NPA is hour angle.

10.

LATITUDE—The distance of any place north and south of the equator measured on a meridian.

Leeway—The angle a ship's track makes with her fore-and-aft line.

Longitude—The longitude of a spot is the arc of the equator between the first meridian of longitude and the meridian of the spot.

MAGNETIC COURSE—The angle a ship makes with the magnetic meridian.

Magnetic Meridian—The direction a perfect compass would point if in no way affected by local magnetic forces.

Magnetic Poles—The magnetic poles are situated, the North in lat. 70 N. and long. 97 W., and the South in lat. 73 S. and long. 147 E.

Mean Time—The time which would be shown by the sun if he revolved in the plane of the equator with the mean angular velocity with which he revolves in the ecliptic.

Meridian—A great circle passing through the poles and cutting the equator at right angles. In 11, NOS is a meridian.

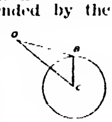
11.

NAUTICAL MILE—The length of a minute of arc of the meridian. It varies slightly with the latitude.

OBLIQUE ANGLE—One greater or less than a right angle; if greater, it is called obtuse, and if less, it is acute.

Observed Altitude—The angular height read from the observer's instrument.

PARALLAX—The angle at the centre of a celestial body subtended by the earth's radius at the position of the observer. In 12, the angle at O is parallax.



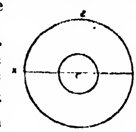
12.

Polar Distance—The arc of a celestial meridian between the object and the celestial pole. It is the complement of the declination [4, OP].

Prime Meridian or First Meridian—The meridian from which longitude is reckoned. For Englishmen, this is Greenwich.

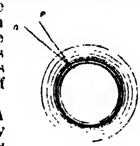
Prime Vertical—The vertical circle which passes through east and west points of the horizon.

RATIONAL HORIZON—A plane passing through the centre of the earth, every point of which is 90° from the observer's zenith. In 13, Z is zenith. XCY is rational horizon.



13.

Refraction—The bending of a ray of light towards the perpendicular when passing through the air. In 14, O is real place, P is apparent place of object.

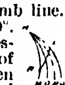


14.

Rhumb Line—A curve cutting every meridian it meets at the same angle. In 15, RL is a rhumb line.

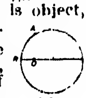
Right Angle—An angle of 90°.

Right Ascension—Of a celestial body this is the arc of the celestial equator between the First Point of Aries and the meridian passing through the object. In 16, ARO is object, A, First Point of Aries.



15.

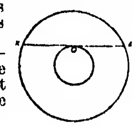
SEMI-DIAMETER—The angle at the observer's eye, subtended by the radius of a celestial object [R in 2].



16.

Sensible Horizon—A plane to which a plumb line at the observer's position is perpendicular, as XOZ [17].

Sidereal Time—Reckoned from the time the First Point of Aries passes the meridian.

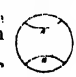


17.

Small Circles—Those which do not pass through the centre of a sphere. [18, A and B].

Spherical Angle—An angle formed by the intersection of two great circles [19].

Supplement of Angle or Arc—The amount an angle differs from 180°.



18.

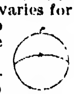
TRUE ALTITUDE—The true height above the rational horizon.

True Course—The angle a ship's course makes with the true meridian.

19.

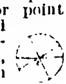
VARIATION OF COMPASS—The angle the magnetic meridian makes with the true meridian. It varies for different places, and is to be found marked on the charts.

Vertex of a Great Circle—That point on it nearest to the pole. In 20, X is the vertex, P the pole.



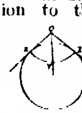
20.

Vertical Circles—Great circles passing through the zenith or point immediately overhead, and perpendicular to the horizon. In 21, Z is zenith, and all lines passing through it are vertical circles.



21.

Visible Horizon—The circle limiting the observer's view at sea. It increases in proportion to the observer's height above the water. In 22, O is the observer, XYZ the horizon.



22.

ZENITH DISTANCE—The zenith distance of a celestial object is the arc of a vertical circle between the object and the zenith of the observer.

Suffixes

Of all the suffixes used to modify the meanings of Esperanto words there are none which are so often used, and which possess such remarkable power, as the pair *ig* and *iĝ*. They are chiefly employed in the construction of verbs, as is shown by the following examples.

IG. The suffix *ig* signifies to render, to cause to be done, to make. It has the power of making an adjectival root-word a transitive verb:

Forta, strong; *fortigi*, fortify (make strong). *Bona*, good; *plibonigi*, improve, make better.

From noun roots transitive verbs may be formed:

Nulo, nought (zero); *nuligi*, nullify. *Ŝtono*, stone; *ŝtonigi*, petrify.

An intransitive verb receiving this suffix becomes transitive:

Stari, stand; *starigi*, erect, make stand. *Kuŝi*, lie down; *kuŝigi*, lay down. *Boli*, boil; *boligi*, make boil.

If added to a transitive verb the result is another transitive verb:

Presi, print; *presigi*, cause to be printed. *Kompreni*, understand; *komprenigi*, cause to be understood.

IĜ. The suffix *iĝ*, on the other hand, signifies to become, to get. An adjectival root to which this suffix is applied becomes an intransitive verb:

Ruĝa, red; *ruĝiĝi*, become red, blush. *Grasa*, stout; *grasiĝi*, get stout.

IĜ added to a noun-root makes an intransitive verb:

Polvo, dust; *polviĝi*, become dust. *Amaso*, crowd; *amasiĝi*, become amassed.

An intransitive verb receiving *iĝ* becomes another verb of the same class:

Sidi, sit; *sidiĝi*, become seated. *Bruli*, burn; *bruliĝi*, become burning.

Added to transitive verbs, *iĝ* makes intransitive verbs:

Fermi, shut; *fermiĝi*, become shut. *Fini*, finish; *finiĝi*, become finished.

These two suffixes may also be used as separate verbs, when the result is nearly the same as when affixed.

Examples: *Igi lin feliĉa estas mia deziro*, To make him happy is my desire; *Poste la vetero iĝis pli bona*, Afterwards the weather improved.

The use of *ig* and *iĝ*, however, is by no means confined to the construction of verbs. Adverbs, nouns, adjectives and participles (active and passive) may all be produced by the use of the characteristic endings of these parts of speech. The passive participles *at*, *it*, *ot*, naturally cannot follow the suffix *iĝ*:

Examples: *Fortigante*, in making strong; *pliboniĝo*, improvement; *nuligita*, having been nullified; *ŝtoniga*, possessing power to petrify; *polviĝante*, in becoming dust; *amasigota*, about to be crowded together; *kredige*, in a make-believe manner; *edziĝo*, act of becoming a husband, wedding; *sidiĝinte*, after having become seated.

The numbers and some of the prepositions and fixed adverbs also give employment to *ig* and *iĝ*.

Examples: *Unuigi*, unite; *duobliĝi*, become doubled; *pliigi*, make more; *foriĝi*, become absent, leave; *eligi*, omit, leave out; *kuniĝante*, in coming together; *kvaronigi*, divide by four.

The remaining suffixes are: *ĉj*, *nj*, *moŝt*, *um*.

ĈJ denotes an affectionate diminutive of a masculine name, of which it follows the first two or three letters.

Examples: *Patro*, father; *paĉjo*, papa. *Vilhelmo*, William; *Vilĉjo*, Bill, Billy.

NJ has the same meaning in feminine names as above.

Examples: *Patrino*, mother; *panjo*, mamma. *Florenco*, Florence; *Flonjo*, Flo.

MOŜT denotes titles of all kinds.

Examples: *Reĝo*, king; *Lia reĝa moŝto*, His Majesty. *Princo*, prince. *Via princa moŝto*, Your Royal Highness. *Via moŝto*, Your worship.

UM has no definite meaning and is seldom used. The principal words formed by its aid are given below:

Kolo, neck; *kolumo*, collar. *Varma*, warm; *malvarmumo*, cold in head. *Plena*, full; *plenumi*, fulfil. *Oro*, gold; *orumi*, gild. *Arĝento*, silver; *arĝentumi*, plate with silver. *Aero*, air; *aerumi*, air a room, bed or clothes. *Ami*, love; *amindumi*, make love. *Dato*, date; *datumi*, date a letter. *Kruco*, cross; *krucumi*, crucify. *Vento*, wind; *ventumilo*, fan.

Compound Words

A large number of new words may be formed by suitably conjoining the root-words found in the Esperanto dictionary. The qualifying word or root-word is placed first, while the last word indicates the part of speech of the compounded word.

Examples: *Samideano*, a person imbued with the same idea (used in reference to their co-workers by Esperantists); *poŝtkarto*, postcard; *lernolibro*, instruction book; *dramaŭtoro*, dramatic author; *okulvitroj*, eye-glasses; *bonkora*, good-hearted; *laŭdezire*, according to desire; *vaporŝipo*, steamship.

Such words are not to be found in the foregoing vocabularies as their construction is left to the ingenuity of the student.

Abbreviations

Occasionally, for the sake of simplicity, and to avoid undue repetition of full words, the following abbreviations are used.

Sro., Mr.; *Sino.*, Mrs.; *Fino.*, Miss; *Dro.*, Doctor; *Prof.* Prof.; *Kio.*, Company; *Espo.*, Esperantisto; *k. t. p.* (*kaj tiel plu*), and so on; *k. c.* (*kaj ceteraj*), etcetera; *t. e.* (*tio estas*), that is; *ekz.* (*ekzemple*), for example; *Nro.*, number; *B. E. A. Brita Esperantista Asocio.*

The sign "&" should not be used; it is meaningless in Esperanto.

Vocabulary

anĝel', angel
ark', arch, bow
barel', keg, barrel
ber', berry
bind', bind (books)
deviz', device, motto
drog', drug
enu', be weary of

toler', tolerate
velk', fade
venk', conquer
vest', clothe

Exercise XX.

1. Dro. Zamenhof, la altestimata aŭtoro de Esperanto, naskiĝis la trian de Decembro, mil okcent kvindek naŭa. La hufbatoj de ĉevaloj aŭdiĝis. La fero fandiĝos. Ne ŝanceliĝu, sed tuj luigu tiun ĉambron al la fandejestro. En la aŭtuno la bruniĝantaj folioj falas de la arboj. Kvankam li estis forte vundita, kaj samtempe venkita, li ne mortis. La skribaĵo estas tie ĉi, sed oni devas sekigi ĝin per sorba papero. Ŝi toleris kaj suferis multon, sed ŝi ĉiam estis modelo de pacienco. Ĉu tio estas korktirilo, kio kuŝas sur la kanapo? Mi pensas, ke ne. La floroj, kiuj estas plantitaj en la plantejo, odoras dolĉe. Al malbonfarantoj, neniam prosperas. Mi estas devigata limigi miajn elspezojn, ĉar mi nun iĝis malriĉa. La raporto pri la kunsido estos sendata senpage.

2. Here is the sign by which I shall be recognised. In the public square is to be found a tall column, which the mayor erected to the honour of a well-known townsman. I will have the instruction books bound to-morrow. The water has become putrid, and is not drinkable. He hired an office at 15s. per week. Becoming angry, he put on his overcoat and disappeared. What do you mean? I was obliged to put a stop to his speech. At daybreak the sun rises and at the fall of eve it goes down. Did you inhale the odour of those growing flowers?

NOTE. Use the *ig* and *iĝ* suffixes where possible.

Time

Various methods are used to denote the time:

3 o'clock, *la tria* (*horo*); 3.15, *kvarono de la kvara* (*horo*); 3.35, *tridek kvin minutoj de la kvara*, or *dudek kvin minutoj antaŭ la kvara*; 3.30, *duono de la kvara* (*horo*). But the simplest way is, perhaps, to use railway method, thus: 3 o'clock, *la tria* (*horo*); 3.15, *la tria* (*kaj*) *kvindek* (*minutoj*); 3.45, *la tria* (*kaj*) *kvardek kvin* (*minutoj*).

English Prepositions

The following sentences and phrases are for translation:

At (*laŭ*) your desire I wrote the letter. One of (*el*) us must be wrong. I am a faithful servant of (*al*) the King. A book of (*pri*) proverbs. The best way of seeing (*por vidi*) the town. He is a professor of (*ĉe*) the school. My love for (*al*) children. On (*ĉe*) my arrival. The smallest room of (*en*) the house. City (of) London. Month (of) May (*prepositions omitted*). Mr. N. of (*el*) the city (of) York (*Urbo Jorko*). Ring of (*el*) gold. The love of (*al*) God. God's love (*Amo de Dio*). He is a man of (*kun*) taste. A friend of mine (*Unu mia amiko*). A labour of love. Regiment of (*da*) soldiers. He fought with (*kontraŭ*) the thief. Mute with (*pro* or *de*) wonder. It is sold at (*po*) threepence the (for each) pound. I put it at (*por*) his disposal. At (*en*) London. This bill is payable at (*post*) 30 days. Somebody shot at (*sur*) me. They cried for (*pro* or *de*) joy. For (*dum*) a moment he was silent. He stayed at Paris for (*dum*) a week. I cannot carry it for (*tra*) such a great distance. She cried for (*pro*) fear that she would not see him again. He upbraided me for having gone away (*pro tio, ke mi foriris*). Catalogue will be sent on (*laŭ*) request. Southend on (*apud*) Sea. We shall arrive by evening (*vespere*) in (*en*) London. He ran three miles in (*dum*) the hour.

Key to Exercise XIX.

Li, neatendite, alvenis en Londonon lastan nokton. Ĉe la

mezo de mia ĝardeno kreskas pirujoj, prunujoj kaj grosujetoj. Krom tiuj, vi trovas ĉiujn specojn de legomoj. La servistino ĵus metis la manĝilarojn sur la tablon, sed kie estas la supujo, la salujo, la piprujo kaj la sonorilo? Vekite, la tajloro malfermis la okulojn, kaj vidis la seruriston staranta apud li. Estante nature timema, li iom balbutas, kiam ajn oni riproĉas lin. Kurinte rapide al la stacidomo, li ĝuste trafis la vagonaron, kiam ĝi (ĵus) ekiris. La leteroj estas senditaj afrankite. Kia stranga ŝvelaĵo estas sur via vizaĝo! Tiu ĉi verko estas dediĉita al mia plej amata amiko. Jen estas la monujo kaj la juvelujo, kiujn mi trovis sur la ŝtuparo apud mia oficejo. Multajn dankojn! Tiu ĉi cigaringo tre similas mian. Transpasante la straton, la infano subite falis sub la radojn de kaleŝo. Ŝarĝite de la ŝarĝistoj, la ŝipo eliris el la haveno. La tajloro garantiis, ke ĉi-tiu surtuto estas farita el la plej bona drapo. Remante, mi rompis unu el la remiloj. La fabelo, pri kiu li estis traktanta, ne estas entute vera. Turnante la okulojn al la vasta maro, mi vidis la ŝipon malrapide formovantan, ĝis kiam ĝi malaperis. Feliĉe la terura mulitado inter Rusujo kaj Japanujo nun ĉesis, sed ni ĉiam pripensos tiujn mortintaĵn militistojn, kiuj vane oferis siajn vivojn pro siaj landoj.

KEY TO EXERCISE XX.

1. Dr. Zamenhof, the highly esteemed author of Esperanto, was born on the 3rd December, one thousand eight hundred and fifty-nine. The hoof-beats of horses were heard. The iron will become melted. Do not hesitate, but at once let that room to the foundry master. In the autumn the brown-becoming leaves fall from the trees. Though he was badly wounded, and at the same time became defeated, he did not die. The writing is here, but it must be dried with blotting-paper. She tolerated and suffered much, but she always was a model of patience. Is it a cork-screw that lies on the sofa? I think not. The flowers, which were planted in the plantation, smell sweet. Evildoers never succeed. I am obliged to limit my expenses, as I have now become poor. The report of the meeting will be sent free of payment.

2. Jen estas la signo, per kiu mi rekoniĝos. En la placo, troviĝas alta kolono, kiun la urbestro starigis je la honoro de tre konata urbano. Mi bindigos la lernolibrojn morgaŭ. La akvo putriĝis, kaj ne estas trinkinda. Li luis oficejon po 15 ŝilingoj por ĉiu semajno. Koleriĝinte, li surmetis sian surtuton kaj malaperis. Kion vi volas diri? Mi estis devigata ĉesigi lian paroladon. Je tagiĝo la suno leviĝas, kaj je vesperiĝo ĝi subeniras. Ĉu vi flaris la odoron de tiuj kreskantaj floroj?

NOTE. The student is advised to get English-Esperanto and Esperanto-English Dictionaries. (British Esperanto Association, 13, Arundel St., W. C.: 1/8 each.)

ESPERANTO *concluded*

GREEK

By G. K. Hibbert, M.A.

SECTION II. SYNTAX

The Dative Case

As we have seen, the Greek dative stands for three distinct cases: 1. Locative, 2. Instrumental, 3. The Dative Proper. We will now deal with these more fully.

1. The Locative. The locative survives in a few forms as a distinct case, the ending being ι short; but, generally, the locative coincides in form with the dative. It denotes (*a*) place where, (*b*) time at which.

PLACE WHERE. With names of towns—as: *Πλαταιᾶσι*, at Plataea (locative form); or *Πλαταιαῖς* (dative form). With names of countries—as: *Ἑλλάδι*, in Greece. It often denotes the sphere of action, whether in a locative form (as *οἴκοι*, at home) or in a dative form (as *δόμῳ*, in the house; *οὐρανῷ*, in heaven). From the locative, denoting "place where," is derived the use of the locative to denote direction, or the place of arrival, after a verb of motion—as: *χαμαὶ πεσεῖν* (from *πίπτω*), to fall to the ground; *γῇ ἔκειτο*, He lay on the earth; *ἐδέξατο χειρὶ κύπελλον*, He took a cup in his hand.

TIME AT WHICH. This is found in Greek only in dative forms; there are no locative forms for time—*e.g.*, *τρίτῳ ἤματι*, on the third day; *γήρᾳ*, in old age; *νουμηνίᾳ*, at the new moon, on the first of the month; *ὑστέρῳ χρόνῳ*, in after time.

2. The Instrumental. This case primarily denotes "association with," and hence "attendant circumstances" and "relation." The name "instrumental" is misleading, as the idea of instrument is subordinate.

(*a*) THE ASSOCIATIVE INSTRUMENTAL denotes association with a person, common after *ἕπομαι*, follow; *μίγνυμι*, mix; *ὁμιλέω*, consort with; *μάχομαι*, fight; *διαλέγομαι*, converse; *κοινός*, common; *ἴσος*, equal; *ὅμοιος*, like; *ὁ αὐτός*, the same—as: *οὗτός ἐστιν ὁ αὐτὸς ἐκείνῳ*, This man is the same as that.

(*b*) OF CIRCUMSTANCES ATTENDING THE ACTION—as: *ἦλθον πλήθει οὐκ ὀλίγῳ*, They came with no small crowd; *ἔπλεον δεξίῳ κέρᾳ ἡγουμένῳ*, They sailed with the right wing leading; *μίαν ναῦν αὐτοῖς ἀνδράσιν εἷλον*, They took one ship men and all (lit. with the men themselves). This has three special uses: 1. To denote the agent of a person—as: *θεοῖς σεσωσμένος*, saved by the gods (lit. with the help of the gods); *ὠφελητέα σοι ἡ πόλις ἐστιν*, The city must be benefited by you (verbal adjective); *παρεσκεύαστο τοῖς Κορινθίοις*, Preparations had been made by the Corinthians (usually after a verb in the perfect, or the verbal adjective; this is generally rendered by *ὑπό* and the genitive). 2. To denote the means or instrument—as: *ὁρῶμεν τοῖς ὀφθαλμοῖς*, We see with the eyes; and after *χρῆσθαι*, to use (which always takes the dative), meaning literally to serve oneself with—as: *χρῆσθαι ἱματίῳ*, to use (*or* wear) a garment. 3. To denote reason, cause, or ground—as: *τοῖς πεπραγμένοις φοβούμενος*, fearing on account of what had been done; *οὔτε πενίᾳ οὔτε ἀσθενείᾳ τετίμηται οὐδείς*, No one is honoured on account of poverty or weakness; *ἀποθνήσκει νόσῳ*, He dies of disease.

(*c*) OF RELATION, defining the action of a verb or the application of a noun. Of this there

are two special uses to denote Manner and Space. 1. *Manner*: as, σιγῇ, in silence, silently; βίᾳ, forcibly; τῷ ὄντι, in reality; ταύτῃ, thus; μανίαις ψαύων, tempting (the god) in his madness. Under this head may be classed the "Instrumental of Measure," denoting difference of extent—as: πολλῷ μεῖζον, much greater (lit. greater by much); τῇ κεφαλῇ ἐλάσσων, a head shorter; τοσούτῳ ἄμεινον, so much the better. 2. *Space:* either of space over which motion takes place, or of time through which anything lasts—as: τῷ χρόνῳ, in course of time; ἀγήρῳ χρόνῳ δυνάστης, ruler through endless (lit. ageless) time.

NOTE on the Instrumental Case: Homer has many archaic forms in -φι or φιν, which are properly instrumental—as: βίηφι, by force, but are also used as locatives—*e.g.*: ὄρεσφι, on the mountains. More loosely still, they are used as genitives or datives, as κατὰ Ἰλιόφι τείχεα, for Ἰλίου.

3. The Dative Proper. This is used in Greek only of a person, the person affected by the action, although in Latin it is used of a thing as well. It may either depend on a verb or not. 1. *Depending on a verb:* The verb may be either transitive—as: δίδωμι, give—*e.g.*, δός μοι τοῦτο, Give me this; or intransitive—as: ἀρέσκω, please; εἴκω, yield; πιστεύω, trust; πείθομαι, obey; ὀνειδίζω, reproach; βοηθῶ, help; πρέπει, it is becoming; δοκεῖ, it seems, etc., all of which are followed by the dative—*e.g.*, πιστεύω τοῖς φίλοις, I trust my friends; πρέπει μοι λέγειν, It befits me to speak. This dative is especially used of the possessor after the verb *to be* and similar verbs—as: τρεῖς δέ μοί εἰσι θύγατερες, I have three daughters. 2. *Not depending on a verb:* (*a*) Dative of Interest—as: πᾶς ἀνὴρ αὑτῷ πονεῖ, Every man labours for himself; ἐμῇ κεφαλῇ περιδείδια, I fear for my head. (*b*) Dative of Respect—as: θεοῖς τέθνηκεν, His death is the gods' concern. This dative is sometimes indistinguishable from the possessive genitive, except by some slight idea of the person being *concerned* in the situation—as: ἦρχον τοῦ ναυτικοῦ τοῖς Συρακοσίοις, They commanded (governs genitive) the navy of the Syracusans. (*c*) Participial Dative, either limiting the action—as: ἐν δεξιᾷ ἐσπλέοντι, On the right as one sails in (lit. With respect to one sailing in); συνελόντι, or, ὡς συνελόντι εἰπεῖν (participle of συνάιρεω), to speak concisely (lit. for one making it concise); ὡς ἐμοί, in my opinion; μακρὰν γὰρ ὡς γέροντι προυστάλης ὁδόν, Thou didst undertake a long journey for an old man; or predicatively after a verb like *to be*—as: αὐτῷ βουλομένῳ ἐστίν, He wishes it (lit. It is to him wishing it). (*d*) Ethic Dative, of the person sympathising or affected (personal pronouns only)—as: πῶς ἡμῖν ἔχεις; How are you (we wish to know)? ἀνάβαινέ μοι τὴν κλίμακα, Climb the ladder, I pray; τίς τέθνηκέ σοι; Who of your friends is dead?

NOTES. There is a peculiar use of the dative found in statements of time—*e.g.*, ἡμέραι ἦσαν τῇ Μυτιλήνῃ ἑαλωκυίᾳ (perfect participle of ἁλίσκομαι) ἑπτά, There were seven days since Mytilene had been captured. The dative follows many verbs compounded with prepositions—as: ὑπόκειται τὸ πεδίον τῷ ἱερῷ, The plain lies below the temple.

Attraction of the Relative

The relative pronoun in Greek is especially marked by attraction of case—*i.e.*, it either attracts its antecedent to its own case (Inverse Attraction), or is itself attracted to the case of its antecedent (Attic Attraction, as being in Attic the normal construction). The latter is by far the more frequent.

INVERSE ATTRACTION—as, οἴχεται φεύγων ὃν ἦγες μάρτυρα, The witness whom you brought has gone fleeing away (for ὁ μάρτυς ὃν ἦγες). This is especially frequent when the principal sentence is completed subsequently—as: θῆκαι ὅσαι ἦσαν τῶν τεθνεώτων πάσας ἀνεῖλον, They removed (ἀναιρέω) all the sepulchres of those who had died (θῆκαι for θήκας). Another instance of this attraction, common in prose, is the phrase οὐδεὶς ὅστις οὐ, There is no one who not—*i.e.*, everybody (ἐστί being understood). In the nominative there is no attraction, but in the oblique cases, whenever ὅστις is governed by a verb or some other word, οὐδείς is attracted into the case of ὅστις—as: οὐδένα κίνδυνον ὅντινα οὐχ ὑπέμειναν, There was no danger that they did not endure (for οὐδεὶς κίνδυνος ἦν ὅντινα, κ.τ.λ.); οὐδενὸς ὅτου οὐκ ἂν πατὴρ εἴην, There is no one whose father I might not be (for οὐδείς ἐστι, κ.τ.λ.).

ATTIC ATTRACTION. This usually occurs only when the relative would naturally have been accusative—as: ἀπὸ τῶν πόλεων ὧν ἔπεισε, From the cities which he persuaded (ὧν being for ἅς); τοῖς ἀγαθοῖς οἷς ἔχομεν, With the good things which we have (οἷς for ἅ). Especially when the antecedent is omitted—as: ἥμισυ οὗ διενοεῖτο, Half of what he intended (οὗ for ἐκείνου ὅ, Of that thing which); σὺν οἷς ἔχω τὰ ἄκρα καταλήψομαι, I will seize the heights with the men whom I have (οἷς for τοῖς ἀνδράσι οὕς); πρὸς οἷς ἐκτήσαντο, In addition to what they gained (οἷς for τούτοις ἅ). More rarely, and always with antecedent omitted, a relative is attracted from genitive to accusative, or from dative to genitive—as: ἀφ' ἧς ὠμόσατε ἡμέρας, From the day on which you swore (for ἀπὸ τῆς ἡμέρας ᾗ ὠμόσατε); and hardly ever from nominative to genitive—as: ὧν ἂν δόξῃ πέρι (for περὶ ἐκείνων ἃ ἂν δόξῃ), Concerning those things which may seem good to us. [Note the difference in accent when a preposition *follows* its noun: πέρι and περί.]

A similar construction is found with relative adverbs—as: διεκομίζοντο ὅθεν ὑπεξέθεντο παῖδας καὶ γυναῖκας, They brought over their wives and children from the places in which they had deposited them for safety (ὅθεν, from which, standing for ἐκεῖθεν ὅπου, from there where, *or* from the places in which).

NOTE. A peculiar attraction takes place in certain phrases with οἷος, such as: πιστεύω οἵῳ σοὶ ἀνδρί, I trust such a man as you (for τοιούτῳ οἷος σύ); τοῖς οἵοις ἡμῖν χαλεπόν ἐστι, It is hard for people like us (for τοιούτοις οἷοι ἡμεῖς, for such as we are).

Negatives

There are two negatives in Greek, οὐ and μή. It is rather hard to understand thoroughly the difference between them; only by noticing their usage carefully whenever they occur will the

student become quite conversant with their use. The following remarks give the broad outlines.

οὐ is specific, μή is general; οὐ denies, μή forbids or deprecates. In other words, οὐ is used in negative *statements* (including interrogative sentences), μή in negative *conceptions* (including purpose, consequence, prohibition and condition). What is said of οὐ and μή applies also to their compounds, οὐδείς, μηδείς, οὐδέ (not even), μηδέ, οὔτε (nor), μήτε, οὔποτε (never), μήποτε, etc.

In principal clauses οὐ is used in assertions, μή in commands and wishes. In subordinate clauses οὐ is used in causal and temporal sentences, μή in final (*i.e.*, expressing purpose) and conditional sentences. In indirect or reported speech—*i.e.*, Oratio Obliqua—the regular negative is οὐ, though some exceptions occur. (The Oratio Obliqua will be dealt with subsequently.)

Examples: πυρὸς ἑκὼν οὐχ ἅπτομαι, I do not willingly touch fire; εἰ ἐκεῖσε ἀπῆλθον, οὐκ ἂν εὗρον αὐτήν, If I had gone there, I should not have found her; οὐ βούλεσθε ἐλθεῖν; Don't you wish to go? οἰόμενοι τὴν βουλὴν οὐ ψηφιεῖσθαι, Thinking that the senate would not vote; ἐπειδὴ οὐχ εἷλον, ἀπεχώρησαν, As they could not take it, they went away. ἀπῆλθον ἵνα μὴ ἴδοιμι αὐτόν, I went away in order that I might not see him; μὴ τοῦτο δράσῃς, Do not do this; μηκέτι ζῴην ἐγώ, O that I may live no longer! εἰ μὴ τοῦτο δρῴην, μαινοίμην ἄν, If I were not to do this, I should be mad; ᾔτησα μὴ δρᾶν, I asked him not to do it.

When used with single words, οὐ is definite, μή indefinite. Thus: οἱ οὐκ ἀγαθοὶ πολῖται, Certain definite citizens who are not good; οἱ μὴ ἀγαθοὶ πολῖται, Any citizens who are not good; οἱ οὐ νοσοῦντες, Certain special not diseased persons; οἱ μὴ νοσοῦντες, Those who are not ill, the class of not diseased persons; τὸ μὴ καλό, Whatever is dishonourable; τὸ μὴ δύνασθαι, inability; τὸ μὴ ὄν, non-existence; οὔ φημι, I say not, I deny. In direct questions οὐ expects the answer *Yes* (Latin *nonne*), μή expects *No* (Latin *num*). Sometimes the fuller form ἆρα οὐ or ἆρα μή is found. Thus, ἆρα μή (or simply μή) βούλεσθε ἐλθεῖν; You don't wish to go, do you?

There seems very little difference between the use of οὐδέν and μηδέν as nouns (= nothing), but after the article the forms beginning with μή are alone used—as: οὐ γὰρ ἠξίου τοὺς μηδένας, For he used not to value men that were nobodies.

In Greek, as a rule, two negatives do not nullify each other and make a positive; they rather strengthen the negation. Thus, "I never heard anything anywhere from anybody" would be οὔποτε ἤκουσα οὐδὲν οὐδαμοῦ οὐδενός, "I never heard nothing nowhere from nobody." μὴ δίδου μηδὲν μηδενί, Do not give anything to anybody. So with οὐδέ, not even—as: οὐδεμία γυνὴ οὐδὲ πειρᾶται, No woman even tries.

After a word of negative meaning, Greek often has a negative expression where other languages would have an affirmative. 1. After a comparative—as: πόλιν ὅλην διαφθεῖραι μᾶλλον ἢ οὐ τοὺς αἰτίους, to destroy the whole city rather than the guilty; the idea being that in all comparisons the very notion of preference also implies rejection or denial. 2. After a verb of negative meaning (*e.g.*, deny, dispute, hinder, distrust), where μή with the infinitive is used for the infinitive alone—as: They hindered me from coming, ἐκώλυσάν με μὴ ἐλθεῖν; I deny that he did it, ἀπαρνοῦμαι μὴ ἐκεῖνον δρᾶσαι; and even after a noun—as: ἡ ἀπορία τοῦ μὴ ἡσυχάζειν, the impossibility of keeping quiet.

μὴ οὐ. When such a verb of negative meaning as we have just considered is itself negatived by οὐ, Greek requires the negative οὐ to be put in the subordinate clause as well, so that in the latter clause we get the combination μὴ οὐ—as: οὐκ ἐκώλυσάν με μὴ οὐκ ἐλθεῖν, They did not hinder me from coming; οὐκ ἀπαρνοῦμαι μὴ οὐκ ἐκεινὸν δρᾶσαι, I do not deny, etc.; τί μέλλει μὴ οὐ παρουσίαν ἔχειν; What hinders him from being present? (*i.e.*, nothing hinders).

οὐ μή. This is used (1) interrogatively with the future indicative to express a strong prohibition—as: οὐ μὴ ἐξεγερεῖ; Will you not not-rouse? —*i.e.*, do not rouse; οὐ μὴ φλυαρήσεις; Will you not stop talking nonsense?—*i.e.*, stop talking nonsense. (2) With the subjunctive, mostly with the aorist—as: οὐ μὴ ἔλθῃ, There is no chance of his coming; οὐ μὴ ληφθῶ, There is no chance of my being caught. This expression is probably the negative of μὴ ληφθῶ in its Platonic sense of "I shall probably be caught," which was a revival of the Homeric use of the construction as meaning "I fear I shall be caught." The original meaning of μὴ ληφθῶ was "May I not be caught!" whereas in Plato the same construction becomes a cautious assertion (μὴ φαῦλον ᾖ, It will probably prove bad); hence οὐ μὴ-ληφθῶ, There is no reason to suspect I shall be caught.

Oratio Obliqua (Indirect Discourse)

Students of Latin have the advantage of understanding this construction; they have the disadvantage, however, of bringing to the study of the Greek construction certain preconceived ideas which, though excellent from the point of view of Latin, are inconsistent with the Greek idiom. Everyone knows what direct speech is: "I am well," "Who are you?" "Do this!"—these are examples respectively of direct statement, direct question, and direct command. Now if we wish to quote someone as using these expressions, we may either quote them *directly*—as: He said, "I am well"; He asks, "Who are you?"; He commands, "Do this!"; or *indirectly*—as: "He said that he was well"; "He asks who you are"; "He orders you to do this." With this latter indirect use we are now concerned.

I. Indirect Statement. In Latin the natural way of expressing this is by means of the accusative with the infinitive; in Greek this is only *one* of the natural ways.

1. Accusative and Infinitive. This is used after verbs of *saying* and *thinking* to express the English "that . . . . ."—as: He said that the laws were unjust, ἔλεγε τοὺς νόμους εἶναι ἀδίκους; Thinkest thou that I am unhappy? νομίζεις δυστυχεῖν ἐμέ; Also after impersonal verbs—as: "it was agreed that," "it happened that," "it was proposed that," etc. The negative used here is οὐ, not μή.

In the following two points the accusative

and infinitive construction in Greek differs from Latin—

ACCUSATIVE WITH PARTICIPLE. After verbs of *feeling* and *knowing* (perception as opposed to statement proper) the accusative with the participle, and not with the infinitive, is the rule—as: οἶδα αὐτὸν λυπηρὸν ὄντα, I know that he is troublesome; τυράννους ἐκπεσόντας ᾐσθόμην, I perceived that the tyrants had been expelled; τὸν Μῆδον ἴσμεν ἐκ περάτων γῆς ἐλθόντα, We know that the Mede came from the ends of the earth; οἶδά σε ἀγαθὸν ὄντα, I know that you are good.

INFINITIVE ATTRACTION. If the subject of the Infinitive (or participle) is the same as the subject of the principal verb, it is put in the *nominative*, instead of in the accusative, by a kind of attraction—as: Ἀλέξανδρος ἔφασκεν εἶναι Διὸς υἱός, Alexander used to assert that he was the son of Zeus; πλούσιοι οἰόμεθα ἔσεσθαι, We think that we shall be rich; αἰσθανόμεθα γελοῖοι ὄντες, We perceive that we are ridiculous; οἶδα ἀγαθὸς ὤν, I know that I am good. Notice that in these examples the pronouns "that *he*," "that *we*," etc., are not expressed. There is no need to express them, unless there is an especial emphasis laid on the pronoun, as, for example, οὐκ ἔφη αὐτὸς ἀλλ' ἐκεῖνον στρατηγεῖν, He said "Not I, but you, are general" (lit., He said that not himself but that man was general; here we have the two constructions, nominative with infinitive, and accusative with infinitive); ἐκείνην μὲν καλὴν ἔφη εἶναι, αὐτὸς δὲ αἰσχρός, He said that she was beautiful, but that he himself was ugly. This construction makes Greek beautifully clear; it avoids all the clumsiness of the English reported speech, in which it is often difficult to make out the persons to whom the various pronouns refer—as: "He said that he would soon teach him better manners, and if he did not take care he would have to look to himself, for he was determined to put a stop to his impudence."

2. Instead of the accusative with the infinitive it is equally good Greek to translate the English "that" by ὅτι or ὡς followed by the verb in a *finite* mood. The negative here too is οὐ. Examples: λέγει ὅτι γράφει, He says that he is writing; εἶπεν ὅτι γράφοι, He said that he was writing; λέγουσι ὅτι ὁ βασιλεὺς σφᾶς ἔπεμψεν, They say that the king sent them; ἔλεξαν ὅτι ὁ βασιλεὺς σφᾶς πέμψειε, They said that the king had sent them.

From these examples it will be noticed that after a main verb in a Primary tense (*i.e.*, Present, Future, Perfect), the verb in the ὅτι clause remains in the same mood and tense as in the corresponding direct statement; but after a Historic main verb (*i.e.*, Aorist, Imperfect, Pluperfect) the verb in the ὅτι clause becomes *optative*. This is the strict rule, but frequently, for the sake of vividness, the rule is relaxed, and instead of the optative in the latter case, the indicative is found, the actual tense and mood used by the speaker being thus preserved in the reported speech. Examples: ἔλεγον ὅτι ἐλπίζουσι σὲ καὶ τὴν πόλιν ἕξειν μοι χάριν, They said that they hoped you and the state would be grateful to me (the original mood and tense "they hope" instead of optative by strict sequence); ἧκε δ' ἀγγέλλων τις ὡς Ἐλάτεια κατείληπται, Some one was come reporting that Elatea had been taken ("Elatea has been taken," perfect indicative passive of καταλαμβάνω, instead of optative); εἰπόντες ὅτι πρέσβεις πέμψουσιν, ἀπῆλθον, They went away, saying that they would send ambassadors ("they will send," instead of πέμψοιεν, as strictly required). Here are two examples showing the strictly regular use with optative: ἐπειρώμην αὐτῷ δεικνύναι ὅτι οἴοιτο μὲν εἶναι σοφός, εἴη δ' οὔ, I tried to show him that he thought he was wise, but was not so; ὑπειπὼν ὅτι αὐτὸς τἀκεῖ (τὰ ἐκεῖ) πράξοι, ᾤχετο, Hinting that he would himself manage things there, he departed.

3. After verbs expressing *emotion*—*e.g.*, θαυμάζω, wonder; μέμφομαι, blame; ἀγανακτῶ, be indignant; αἰσχύνομαι, be ashamed; the Greeks used εἰ (if) instead of ὡς or ὅτι—as: θαυμάζω εἰ μὴ ἀσμένοις ὑμῖν ἀφῖγμαι, I am astonished that my arrival should be unwelcome to you. The negative here is always μή.

So far we have been dealing only with the principal clause in Indirect statement. We must now see what happens in a dependent or subordinate clause. Here again the Latin student must beware; for whereas in Latin the verb in a dependent clause in oratio obliqua is subjunctive, in Greek the subjunctive is never due to oratio obliqua. In Greek the rule is much simpler: if the principal verb is primary the dependent clauses stand exactly as they would if the statement were direct; if the principal verb is historic, all dependent verbs in the indicative or subjunctive should strictly become optative, though for the sake of vividness they are frequently retained in the indicative or subjunctive unchanged. Examples: ποιήσειν φησὶν ὃ μήτ' αἰσχύνην μήτ' ἀδοξίαν αὐτῷ φέρει, He says he will do whatever brings neither shame nor discredit to him (φέρει is exactly what it would be in direct speech); ἀπεκρίνατο ὅτι μανθάνοιεν ἃ οὐκ ἐπίσταιντο, He replied that they were learning what they did not understand (where ἐπίστασθε, indicative, you do not understand, becomes optative, though it might have remained indicative); ἔφασαν τοὺς ἄνδρας ἀποκτενεῖν οὓς ἔχουσι ζῶντας, They said they would kill the men whom they had living (ἔχουσι, indicative, retained, rather than changed into ἔχοιεν; their actual words were ἀποκτενοῦμεν οὓς ἔχομεν).

NOTE 1. The word "saying" or "thinking" need not be actually expressed in Greek in order to throw what follows into the accusative and infinitive construction. It is enough if the idea of saying or thinking is suggested only—as: ἐθάρσυνέ τε καὶ οὐκ εἴα τῷ γεγενημένῳ ἐνδιδόναι· τὴν μὲν γὰρ γνώμην αὐτῶν οὐχ ἡσσῆσθαι (Thuc. VI., 72), He encouraged them and would not allow them to yield in face of what had happened; for (he said) it was not their spirit that was broken (the idea of "saying" is suggested by ἐθάρσυνε).

NOTE 2. The accusative and infinitive is often employed after the article τό, making the sentence into a kind of substantive—as: τὸ ἁμαρτάνειν ἀνθρώπους οὐδὲν (ἐστι) θαυμαστόν, The [fact] that mortals err is not surprising; διὰ τὸ ξένος

εἶναι οὐκ ἂν οἴει ἀδικηθῆναι; Do you think you would not be wronged on account of your being a stranger? (Note the nominative ξένος; see Infinitive Attraction above.)

II. Indirect Question. This is very simple, the usage following the rule of the indirect statement with ὅτι—the verb in the indirect question being indicative or optative according as the main verb is primary or historic. And here, as there, the indicative may remain after a historic main verb for vividness. Examples: ἔρομαι τί δράσει, I ask what he will do; ἠπόρουν τί ποτε λέγει, I was at a loss to know what he meant (λέγει should strictly be optative, but the words of the actual direct question are allowed to remain, τί λέγει, What does he say?). Similarly if the direct question is a deliberative subjunctive, the subjunctive can remain after a historic main verb, instead of becoming optative—as: ἐβουλεύοντο εἴτε κατακαύσωσιν εἴτε τι ἄλλο χρήσωνται, They were deliberating whether they should burn them or dispose of them in some other way.

III. Indirect Command or Petition. The same rules apply here. Examples: κελεύει σὲ δρᾶσαι τόδε, He orders you to do this (negative μή); ἐκέλευσεν ὅ τι δύναιντο λαβόντας μεταδιώκειν, He ordered them, taking what they could, to pursue (his actual words were "take what you can," ὅ τι ἂν δύνησθε, and the subjunctive δύνωνται might have been retained here for vividness instead of optative); προεῖπον αὐτοῖς μὴ ναυμαχεῖν Κορινθίοις, ἢν μὴ ἐπὶ Κέρκυραν πλέωσι, They instructed them not to fight the Corinthians at sea, unless these should be sailing against Corcyra (subjunctive πλέωσι here retained instead of optative πλέοιεν).

Middle Voice

The Middle Voice, though reflexive in meaning, is not simply reflexive. Arising out of the reflexive use, there are many extended applications. The action is directed *towards* the agent, and hence we get three main applications of the middle, to denote action (1) upon, (2) for, and (3) within oneself.

1. Action upon Oneself. The agent is the indirect object of the action—as: δέχομαι, I take to myself; ἕννυμαι, I put clothes on myself; φέρομαι, I carry off for myself, I win (φέρω, simply *I carry*); τιμωροῦμαι, I redress my own wrongs, I take vengeance on (τιμωρῶ, I redress another's wrongs). The strictly reflexive use of the middle is not common in Greek; it is found with a few verbs like λούομαι, I wash myself; τρέπομαι, I turn myself, etc. But, while τύπτω means *I strike*, τύπτομαι does not mean "I strike myself." In other words the object is almost always indirect, not direct.

2. Action for Oneself, the Causative use of the middle; getting something done for oneself—*e.g.*, δανείζω, I lend, δανείζομαι, I get money lent me, I borrow; μισθόω, I let, μισθοῦμαι, I get something let to me, I hire; γράφω, I write, γράφομαι, I get a man's name written down, I accuse; ποιεῖν, to do, ποιεῖσθαι, to get done; θύω, I sacrifice; θύομαι, I get a sacrifice offered; παρατίθεμαι δεῖπνον, I have dinner served me.

3. Action within Oneself. The action is centred in the agent, and the reflexive sense is often very faint. This is found (*a*) in verbs of motion—as: ἔρχομαι, go; πέτομαι, fly; οἴχομαι, depart; φαίνομαι, appear (as opposed to the active φαίνω, I show); (*b*) in verbs of feeling or thinking—as: αἰσθάνομαι, perceive; οἴομαι, think; ἐπίσταμαι, know. Of the same kind is the reciprocal middle, used only in the plural—as: διαλεγόμεθα, we converse with one another; ἀμειβόμεθα, we interchange; διακελεύονται, they cheer one another on.

Peculiar Uses of the Middle in Certain Verbs

Active	*Middle*
ἀποδίδωμι, I give back ..	I sell
λύω, I release	I ransom
σπένδω, I pour a libation	I make a truce
ποιῶ, I value	I estimate
τίθημι, I put	I consider
σκοπῶ, I look at	I reflect on
ἐπιτίθημι, I put on	I attack
κοιμάω, I lull	I sleep
παύω, I stop some one ..	I cease

In all these it is easy to see how the different shades of meaning arise, if we bear in mind the essential idea of the middle voice. But in many cases there seems for all practical purposes to be very little difference in the use of the middle and of the active—as: ἰδεῖν and ἰδέσθαι, to see.

SECTION III. TRANSLATION

Vocabulary

gnat, κώνωψ (ὁ)	face, πρόσωπα (τά)
I came, ἦλθον	round, περί, governs accusative
neither ... nor, οὔτε ... οὔτε	own, ἴδιος, α, ον
I fear, φοβοῦμαι	until, ἕως οὗ
I scratch, ξύω	I am angry, ἀγανακτέω
I bite, δάκνω	thus, οὕτως
husband, ἀνήρ (ὁ)	I conquer, νικάω
I like, wish, θέλω	snare, δεσμός (ὁ)
hairless, ἄτριχος (from θρίξ, τριχός, hair, and ἀ denoting negation, a very common prefix in Greek)	spider, ἀράχνη (ἡ)
	paltry, εὐτελής, ες
	animal, ζῷον (τό)
	strong, ἰσχυρός
	power, δύναμις (ἡ)

A gnat came to a lion and said: "I neither fear thee, nor art thou stronger than I. For what is thy power? (say, For what to thee is the power?) Dost thou scratch with thy (the) claws and bite with thy (the) teeth? This even (καί) a woman does, fighting (μαχομένη, participle) with her (the) husband (dative). But I am much stronger than thou, and if thou wishest, let us go (ἔλθωμεν, subjunctive mood) even to war." And the gnat bit the hairless face of the lion round the nostrils. The lion scratched himself with his own claws, until he was angry. Thus the gnat conquered the lion and went away (ἀπῆλθε). But he fell into the snare of a spider, and lamented (ἀπωδύρετο) that he (had) conquered a lion, the strongest wild-beast, but was destroyed (ἀπώλετο) by a paltry animal, the spider.

PROFITABLE VEGETABLES AND FRUITS

Successful Cultivation of the Principal Vegetables. Market Packages. Why English Fruit-growing is not Profitable. Fruit Trees and Bushes. Packing Fruit

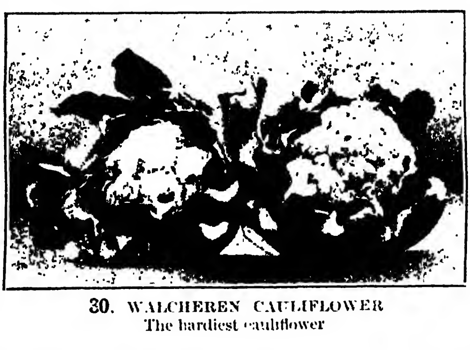
Continued from page 6534

By H. H. HAVART

A GOLDEN rule for success in profitable vegetable-growing, both in the private garden and for market purposes, is never to let the same crop grow on the same piece of ground two years in succession. When first the land or garden is taken in hand it should be divided into three sections: on one of these the root crops, such as carrots, parsnips, potatoes, etc., should be planted; on the second, the cabbages, peas, and beans; and on the third, the light salad crop, such as lettuces and radishes. In the second year the contents should be changed: the root crops should go where the salads have been; the salads to the cabbage patch; and the cabbages to where the root crops were the previous year. In the third season yet another change round should be made, each piece of land raising the crop it has not hitherto borne. These remarks do not, of course, apply to asparagus, while mushrooms, tomatoes, cucumbers, and seakale are generally most profitably grown under glass.

Artichoke and Asparagus. There are two kinds of artichoke, the globe and the Jerusalem. Of the former the leaves are eaten, and of the latter the roots. The globe artichoke is raised from seed sown in early spring, and planted out 2 ft. apart every way. Deep, rich loam is the best soil, and coal ashes and seaweed are valuable as manures. These artichoke beds must have a deep covering of litter during the winter months. The Jerusalem artichoke is misnamed, as it is a native of North America. This artichoke should be planted in early spring about 18 in. apart, and in any well-drained soil. It requires little or no attention after planting, though, if the soil is very poor, a little sulphate of ammonia may be applied.

Asparagus is a very profitable crop, but the reason that it is so expensive is because the capital and labour bestowed upon it must be locked up for at least four years before any return is shown. A rich, moist loam is necessary for the successful cultivation of asparagus, and it should be deeply dug, or even ploughed if a large area, several months before planting. In making a start it is best to procure one-year-old plants and put them in during the months of March or April, according to the season. Three years elapse before a main crop is ready to cut, though a few stalks may be obtained the second year. The asparagus bed should have a liberal dose of manure each autumn, and sprinklings of salt about once a month during the growing period. The roots should be in rows about 2 ft. apart, and 4 in. to 6 in. deep. If well looked after in the matter of autumn manuring, an asparagus bed will continue to yield a paying crop for upwards of twenty years.



30. WALCHEREN CAULIFLOWER
The hardiest cauliflower

Beans and Root Crops. The three chief varieties of beans are French, runner, and broad. The methods of growing are very similar: they may either be sown under glass in boxes in early spring and planted out, or sown in the open ground during March or April, followed by successive sowings at intervals of a fortnight to get continuous supply. Any loamy soil suits beans, but it should not be too crowded. Beans should be planted 6 in. apart, in rows, with 5 ft. between each row. Where grown in large quantities they are generally trained up sticks, but in small gardens they will thrive admirably against a wall or fence on horizontal strings or wires.

Root crops include the beetroot, carrot, leek, onion, parsnip, and turnip. The bulk of the seed of these vegetables is sown in spring, though later sowings are made for successional crops. The best soil is a loamy one that is not too rich, and the presence of sand in it is usually found to be beneficial. Fresh manure is not desirable, as, in the case of the carrot and parsnip, it has a tendency to produce forked roots. The manuring should be done immediately the previous crop has been lifted. The usual method of sowing is in rows about 9 in. apart, and the young plants are afterwards thinned to about a foot between each. The hoe should be used liberally between the rows during the growing season, to keep the surface soil stirred. Where grown on a large scale for market purposes about 5 lb. of seed of either variety is sufficient to sow properly an acre of land—to use more than this is to be wasteful. When the plants are about two months old a dressing of nitrate of soda should be applied, and the onion bed will benefit by a sprinkling of soot. It may be mentioned here, as a solitary exception to the rotation of crops that onions and leeks will thrive in the same ground year after year.

The Brassicas. Broccoli, Brussels sprouts, cabbage, cauliflower [30], and kohl rabi are all members of the great Brassica family, and though requiring to be sown at different times of the year are very similar in their requirements for successful cultivation. The soil must be well dug, and deeply, before they are planted, and the most economical plan is to sow the seed first in a small bed, or even in boxes, and plant the young plants out about 2 ft. apart every way. This is better than sowing the seed on the land itself in the first place, and thinning out afterwards, as by the latter method a large number of plants have to be wasted. Where cabbages, or

similar crops, are grown in large quantities for market it is, of course, necessary to devote a considerable area of land to their cultivation. These large plantations are usually broken up by means of the plough, and at the same time a generous dressing of horse manure is applied, as this encourages a full, rich growth.

Celery. To get celery at its best, seed should be sown as early in the year as possible in boxes, either in the hothouse or in a cold frame, according to the time at which it is desired to mature the crop. When planted out in the late spring, a deep, rich, heavily-manured soil is essential, and the plants should be placed in ditches or trenches at least 1 ft. in depth, the plants themselves being about 9 in. apart. These trenches must be gradually filled in with soil as the plants make growth, for it is only by this means that the stalks can be kept white and crisp. This process is known as "earthing up," and is carried out three or four times at intervals before the celery is fully grown. Plenty of water should be given every other day until the celery is earthed up for the last time, when all water should be withheld.

31. SEAKALE PACKED FOR MARKET

Salad Vegetables. Unless grown largely for market purposes it is doubtful if *cucumbers* are worth growing at all. Certainly they should be dispensed with where the space under glass is limited. Seed can be sown at any time during the first half of the year, according to the time at which the cucumbers are wanted. They must be planted in pots or pans of rich soil, and grown on in heat until the middle of May, when they should be planted out in a frame, or a heated bed, if an early crop is desired. The cucumber likes much moisture at the root, and a rich, loamy soil.

Lettuce may be had practically all the year round by growing in a gentle heat in the winter, and making successive sowings out of doors in the spring and summer. The seed should be sown about 1 in. deep in good, rich soil, and the seedlings thinned out to about 8 in. apart every way. When grown in large quantities for market, 1 lb. of seed is sufficient to sow an acre of land. When lettuces are being forced in frames, or heat, the temperature should never be allowed to fall below 65° F.

32. PEA GRADUS
The finest sort for market and private growing

Mushrooms. The best material of which to form a mushroom-bed consists of stable manure, half droppings and half litter, which should be first of all well turned over every day for about three weeks. The following method of culture, recommended by Messrs. Carter, is an excellent one: "The material should be put into a heap, the measurements of which should be, when made up, 2 ft. 6 in. at bottom, 2 ft. 6 in. high, and 6 in. wide at the top, and any length required, the whole to be firmly put together. After making the bed, put stakes down the centre, by which to gauge the heat, and cover all with long litter; after three or four days, pull out the stakes, and when the temperature is at about 80° the bed is ready for spawning. Break the bricks of spawn into pieces about the size of a hen's egg, and put into the bed about 8 in. apart. Cover the whole with fresh, fibrous loam, and beat it well, making the surface quite firm; lightly water, and smooth the surface with the back of a spade; finally cover up with long litter and Russian mats to keep away light, and excessive moisture. Mushrooms may also be grown in any shed or cellar where the temperature does not fall below 45°; the best site for a bed is a hard, dry floor. A moderate size bed would measure 5 ft. 6 in. by 4 ft. 6 in. by 1 ft. When made up and well pressed down, in about six weeks mushrooms should show, and the bed should then have a light watering with tepid water about every ten days, as success depends upon maintaining an even temperature."

Peas, Potatoes, Radish, and Rhubarb. Rich soil and plenty of water are the two chief requisites for successful pea-growing, and where systematic sowing is practised it is possible to gather this vegetable from May to November. A little lime in the ground is an advantage, and the peas should be put in, about 3 in. apart, in rows 2 ft. from each other, lettuces and radishes being sometimes planted in between. Peas may, with advantage, be forced under glass in a vinery after the grapes are cut, and before new growth commences. When sowing peas in May or June for late crops it is best to soak them in water for an hour or two before putting into the ground [32].

The ideal soil for *potato* culture is a well-drained, light, sandy loam. Wet soils must be avoided, as they have a tendency to spread potato disease. Potatoes planted by the middle of October in pots in a rich soil and a heated greenhouse will be fit for consumption at the end of the year, though they will not, of course, attain to any great size. They occasionally fetch very high prices in the market but cannot be looked upon as a paying crop, as the demand is very uncertain. Main crop potatoes may be planted early in April, about 12 in. apart, in rows 2 ft. away from each other. The use of the hoe is beneficial, and the potatoes should not be dug until the foliage has commenced to wither.

Radish is a crop which may be had all the year round by sowing in frames during the autumn and winter, and in the open air in spring and summer. Radishes do best in a rich soil, as the growth is quicker under such circumstances. Radishes in a poor soil are apt to be stringy, and hot and rank in flavour.

Rhubarb should be planted in the late autumn or early winter, in mild weather, in good, well-drained soil. The best way to increase it is by division of the roots, and an early crop may be obtained by covering portions of a plantation with boxes or barrels. Much, indeed, of the so-called forced rhubarb is raised in this way; but it may be had at almost any time during the year by forcing it in a temperature of about 70° F.

Seakale and Spinach. The best method of culture for *seakale* [31] is that recommended by the author of "Vegetables for Profit": "A good sandy loam is best suited for this crop. Richness is essential, and the area must be well drained, for, although a moisture-loving plant, no stagnant water must be allowed to accumulate. For this purpose the land must be deeply worked. An open situation is desirable in order to bring the crowns on in a vigorous manner; at the same time it should be as sunny as possible. After manuring, the area should be deeply ploughed in the early autumn, and the furrows left open throughout the winter. In the early spring harrow down and level. All weeds must be rigidly suppressed, and the ground made quite clean and friable before planting. If the soil be particularly light, roll after levelling, so as to make it firm. Mark out in rows 1½ ft. apart."

33. ESPALIER PEAR ON A WALL

Spinach is of very rapid growth, hence a sowing of it may be made at almost any time on ground that would otherwise lie idle for a few weeks, and a profitable crop obtained. Small patches of ground, however, should be employed in this way, as the demand for spinach is somewhat limited. A deep, moist soil is the best, and the seed should be soaked in water for a day before planting. Spinach should be sown in rows about 1 ft. apart, and very thinly.

Tomatoes and Herbs. To grow *tomatoes* to any extent, especially if for market, it is necessary to cultivate them under glass. In a few favoured spots against a sunny wall or fence they will ripen out of doors; but in our uncertain climate outdoor tomato culture, except as a hobby, is a risky and costly experiment. Seed should be sown in spring, and the boxes or pans containing it given a sunny position in the greenhouse. As soon as the seedlings are large enough to handle they should be planted out in the very small pots known as "thumb" pots, and subsequently into others of 5 in. in diameter. The tomato does not want a rich soil—old potting mould is quite good enough for it: neither is it wise to use animal manure. When the fruit is beginning to swell, a little chemical fertiliser may be used with advantage.

Mint, thyme, sage, parsley, lavender, rosemary, and tarragon are the *herbs* most generally in demand at the present day. For household use patches of them may be sown at any time during the spring in ordinary garden soil, where space can be found in the kitchen garden. Growing herbs, drying them, and doing them up in neat packets or bottles for sale, is a branch of gardening that may well be taken up by ladies, as it is a clean and not unprofitable occupation when once a connection is established. By making one sowing of herbs, say, in April, and another towards the end of June, a constant supply all the year round is ensured.

Packing for Market. As in the case of fruit, it is a great mistake to mix vegetables of different qualities together in one receptacle. It pays far better in the end to take the trouble of sorting the goods out into first and second qualities, and notify the salesman of this at the time of despatch. Much is gained, too, from a commercial point of view, by clearing the earth from root crops, as far as possible, before sending them away. A purchaser will always be inclined to give a higher price for vegetables so treated than he would for others upon which he would have to spend a lot of time in removing dried earth before he could expose them in his shop window. The majority of packages for the London and provincial markets are provided by the salesman who handles the goods. The nature of these packages necessarily varies a good deal according to what they are destined to hold. Local custom also determines their form to some

extent, but the following are those in most general use.

Bushel. A round basket 15 in. in diameter by 8 in. in depth, and holding ½ cwt. of potatoes or plums, or about 5 pecks of peas, or about 48 lb. of soft fruit.

Flat. An oblong, shallow basket, used for packing cucumbers, and holding from two to three dozen.

Half-bushel. A basket of the same shape as a bushel, but 12½ in. in diameter by 6 in. in depth.

Handle-basket. A basket chiefly used for packing grapes or tomatoes, and holding from 10 lb. to 12 lb. of the latter. It is somewhat oval in shape, and, as its name implies, has a handle over the centre.

Pad. An oval basket larger at the top than the bottom, and usually met with in one of two sizes, holding 1 cwt. or ½ cwt. of potatoes respectively. Cabbage and lettuce are often marketed in pads.

Punnets. These are the familiar baskets made of shavings, and are of the following regulation sizes: Mustard and cress: diameter, 5 in.; depth, 2 in. Mushroom: diameter, 7 in.; depth, 1 in., holding about 1 lb. Radish: diameter, 8 in.: depth, 1 in. Seakale: diameter at top, 8 in.; bottom, 7½ in.; depth 2 in.

Sieve. Another name for a bushel.

Many vegetables are sold by the bunch. A bunch of herbs is a handful; a bunch of carrots about 3 doz.; turnips, 2 doz.: leeks, 1 doz. Bundles of such things as rhubarb and asparagus vary according to the season. What is generally known as a bundle of radishes is technically called a "hand," and 6 "hands" go to a bunch in the wholesale trade. A roll of celery is either 8 or 12 heads, according to whether it is washed or unwashed. A score of lettuce or cabbage is 22, and a tally 60.

Fruit-growing. Profitable fruit-growing may be divided into two sections--growing for private use, and for the public market. In the former case the profit is arrived at by the saving which is effected in fruiterers' bills. A well-managed private garden of any dimensions should be able to produce all the fruit required for the household, except such tropical things as oranges and bananas, and though such a feat may tax the resources of the establishment where the tastes of the household run largely in the direction of nectarines and apricots, it should not be difficult of attainment where the hardier fruits are favoured.

Competition in the Fruit Market. It is frequently stated that fruit-growing for market cannot be carried on profitably in this country, owing to competition from the Channel Islands, France, the United States, and our own colonies. Under present conditions this may be true to some extent, but it is for the British fruit-grower to alter these conditions. The foreign fruit growers send good, up-to-date sorts, carefully picked and packed, to compete with home-grown fruit. The majority of our own growers are content to meet this competition with fruit from worn-out trees and bushes, which ought to have been grubbed up and burnt years ago, and such fruit is generally thrown higgledy-piggledy into dirty bushel baskets.

34. DWARF ESPALIER APPLE TREES

35. BLACK HAMBURGH GRAPES
Packed for market

Improving England's Wasted Orchards. The author of "The Wasted Orchards of England" admirably sums up the situation, as far as fruit-growing for profit is concerned, in his little book: "It is undoubtedly to the improvement of existing orchards that attention should first be directed, for even with a moderate change the value of the English orchards could be increased very largely. . . .

"Trees that have become so old and decrepit as to be past recovery should be swept away, for they serve no useful purpose, but simply become a harbour for insect pests of various kinds.

"All trees that possess a moderate degree of vigour might be greatly improved by having their heads moderately and judiciously thinned, and their roots dressed with either natural or artificial fertilisers, good farmyard manure being the best of the former, and super-phosphate of lime, muriate of potash, kainit, and nitrate of soda the best of the artificials. If the varieties are worthless, as in the majority of cases they are, and the trees are healthy, the orchards can be converted into a profitable state at a small outlay by grafting them with the finer cooking or dessert varieties suitable for the country. . .

"No apple or pear tree in a thrifty state should be cut down because the variety is indifferent, but should be grafted, as such trees, when grafted rather high up to admit of a score of such grafts being put in, form large and fruitful heads much more quickly than do newly-planted trees."

Many fruit trees are grown in different forms, according to their position, and the quantity of fruit desired. In a large market garden the apple, pear and plum are best grown in the large form of tree known as a standard, as this enables bush fruits, such as gooseberries and currants, to be grown underneath them, and thus effects an economy of space. Apples, etc., are themselves grown in bush form [36] in gardens of limited area where a good deal of fruit is required, while another form in which these trees may be trained is with their branches stretching out horizontally from the main stem (known as espaliers), radiating upwards in a fan shape, or

trained to a sort of combination of the two, called the pyramid. The fan and pyramid shaped trees are generally used against walls, with bird netting [33], while the espalier is most useful where the fruit and kitchen garden have to be combined, as the low-growing, horizontal habit of the trees renders them suitable for planting at the edges of beds filled with vegetables [34].

The Apple and Apricot. The apple may be planted in practically any soil that is not too heavy or clayey. A good rich loam is the best for most sorts, and a heavy soil may be improved by digging it out to a depth of 2½ ft., and putting in a layer of sand or road sweepings. The end of October or the beginning of November is the best time to plant, and the holes which are to receive the trees should be dug out a week or two before they are put in. After planting, the ground around the main stem of the tree should be covered with a layer of horse manure to prevent the winter frost reaching the roots. Pruning, which should be carried out the following autumn, should not be too severely done, only sufficient shoots being cut away to allow light and air to get to those which remain. Bush [36] and pyramid trees will require pruning every year, but the large standard trees not more than once in three years.

36. APPLE-TREE GROWN AS A BUSH
(Prince Albert)

The presence of lime in an otherwise loamy soil is an advantage when planting apricots. They need the shelter of a wall when grown in the open in our climate, and are best planted in late autumn, the same time as other fruit trees. A south, or south-eastern, aspect is best for them, and they do not require too much in the way of artificial stimulant. The flowers must be protected from late frosts in the spring—a layer of old fishing-net being usually sufficient for this purpose. When grown under glass the culture is the same as that of the peach.

Cherries and Figs. The most economical way of growing cherries is as standards, though, where space is available, a few of the choicest eating varieties may be given a position as fans or pyramids against a south wall. The soil most suitable for them is a deep, well-drained loam, with a dry subsoil, and pruning should not be overdone.

The fig is a much neglected fruit. A well-drained soil and a wall in a sunny situation are its chief requirements, but the soil must not be too rich, or otherwise leaves, and not fruit, will be produced. Figs need ample space, as they grow rapidly, and the fruit should be thinned as soon as it attains the size of a nut, otherwise a lot of hard, immature figs will be obtained instead of properly developed fruit. They may be grown in pots under glass in the ordinary way, starting them in February in a temperature of about 50° F.

Grapes and Melons. Profitable grape culture is impossible out of doors in this country. In favourable situations during exceptionally fine summers the fruit will often ripen, but it must not be looked upon as a profitable crop, and is best grown in the open air merely for its ornamental value. Under glass, vines may be planted in the late autumn, if dormant; or in the late spring if in a growing condition. A well-drained soil of loam mixed with lime, and a sprinkling of bone meal, is the best mixture to employ, shading the vines for the first few weeks from the full effects of the sun. A temperature of from 45° F. to 55° F. is sufficient at first, increasing gradually to 70° or even 80°, as the summer comes. Thinning grapes is a very necessary operation, and consists of snipping off small, badly-formed individual fruit when they are in an early stage of development, so as to allow those remaining on the bunch to swell properly. While the grapes are developing, give frequent doses of weak liquid manure. Grapes are sent to market in shallow baskets, each holding from six to ten bunches according to size [35].

To grow melons as a paying crop they should have a house to themselves. The seeds should be sown in pots at the beginning of the year, and kept in a temperature of at least 65° F. When they are about a month old they may be planted out in their permanent quarters, a hot bed, which consists of stable manure over which good rich loam has been spread and firmly pressed down. The temperature should then be gradually raised to 75° F. as the fruits develop, and they should be liberally supplied with water. To obtain properly-developed fruit, melons must be artificially fertilised by taking pollen from the male flower and placing it upon the stigma of the female. Melons fruit from five to six months after planting, and a succession may be obtained by later sowings.

The Peach and Other Trees. Where the peach can be grown out of doors, as it is possible to do in warm spots, its culture is the same as that of the apricot; usually speaking, however, it must be grown under glass. Peaches should be planted in September against the wall of the house, or trellis, at a distance of about 10 ft. to 12 ft. apart. A good, deep, rich, loamy soil is its favourite, but where this is not available ordinary garden soil with lime rubble added to it, and a few wood ashes, form an efficient substitute. The tree should commence at a minimum temperature of 45°, rising gradually to 85° as the fruit swells. At this period copious watering is necessary. To get the best fruit, the tree should be thinned freely—in fact, a space of 9 in. every way should be left between individual fruits.

The pear thrives under practically the same conditions as the apple, and is usually grafted on to the quince stock, though sometimes on to another

pear. Where the latter is the case a greater depth of soil is required for successful cultivation, as the roots of the pear reach further than those of the quince. Early pears should be gathered and eaten almost immediately; but late, or what are known as winter, pears should not be left on the tree after the middle of November. At about this period they should be picked, and stored in a cool room.

The plum, damson, and greengage are most accommodating fruit trees as regards soil. The plum flourishes, indeed, as far as fruit bearing is concerned, better in a light soil of moderate depth than in a deep, rich one. Plums are generally increased by budding or grafting, but greengages and damsons may be grown direct from the stone, planted late in the autumn. To get dessert plums to the highest pitch of perfection they should have the shelter of a wall, and, preferably, a southern aspect. When grown as standards they should be planted about 18 ft. apart every way. Care must be taken to keep the roots cool in hot weather by means of mulches.

The Strawberry and Bush Fruits. To have a supply of strawberries over the longest possible period it is best to have at least two plantations--one facing south or south-west for the early crops; and another in any sunny quarter for the later kind. Any ordinary loam will suit this fruit; but, as "The Strawberry Manual" says, "In the preparation of beds that are intended to be occupied for some years, thorough cultivation is desirable, and in the case of soil that is not in satisfactory condition it is essential. Bastard trenching is then the safest proceeding, turning the soil to the depth of two spits (20 in.), keeping the bottom spit down, and breaking the subsoil if it is at all hard or 'panned.' A heavy dressing of farmyard or stable manure (20 to 30 tons per acre) should be well incorporated in the soil as the work proceeds, and if a bed is carefully prepared in this way it will, with annual supplies of manure, give good results over as long a period as strawberries can be profitably kept upon the same land." The best time to plant is in the late summer or early autumn, when the danger of drought is practically over, and a distance of 2 ft. apart every way is the safest one for the plants. When the flowers are formed, a layer of straw should be placed upon the surface of the ground, upon which the fruit can rest and ripen, and also to protect it from being mud-splashed by heavy rains. All gathering of fruit should be done in the early morning.

For forced strawberries the soil in the pots should consist of loam with a little sand, and the addition of some bone meal. The pots must be well drained, and should be started in November in a temperature of 45°, advancing gradually to 70°. When the fruit begins to swell, nitrate of soda, or nitrate of potash, in the proportion of one ounce to two gallons of water, may be used as a stimulant.

The Bush Fruits. The currant, gooseberry and raspberry flourish under very similar conditions—the black currant preferring a spot which is more moist and shady than the others. To obtain the best results, bushes should not be planted too closely together, as, if this is done, it is impossible for them to develop properly and yield a good crop of fruit. About 5 ft. apart every way is a safe rule to remember, and from 2 ft. to 3 ft. for raspberries. Planting and pruning should be done in the autumn, and, for the reasons of light and air just mentioned, the latter operation should be performed so that the centre of the bush is left open. The orthodox garden loam, especially if a trifle sandy, suits all these fruits well. The profitable life of a fruit-bush is rarely more than six years, and at the end of this time it should be replaced with young ones.

Storing and Packing Fruit. For use during the winter and early spring months it is necessary to store quantities of apples and pears. The common practice of doing this, by relegating the fruit in heaps to the floor of an outhouse, and covering it with straw, is wrong and wasteful, and generally leads to the bulk of the supply becoming rotten and worthless. The proper way to store such fruit is upon tiers of wooden shelves in a building erected, or adapted, for the purpose, so that a current of air can circulate freely through all parts of it. The middle of November is quite late enough to gather fruit for store purposes, and all that is unsound should be rejected. It should also be gone over at intervals of, say, a fortnight, and any that show signs of decay picked out and thrown away, as otherwise there is danger of the whole stock becoming infected. For the same reason the apples and pears should not be allowed to touch each other if possible.

Apples and pears are usually packed for market in bushel baskets, or, in the case of apples, barrels which hold about three bushels each. The fruit should be carefully sorted into different qualites before packing, and the omission to do this is one of the reasons which has led the English grower to suffer so much at the hands of his foreign competitors.

The bulk of the bush fruits are also sent to market in bushel baskets, except in the case of a few of the choicest dessert varieties, which come in small strawberry baskets called "punnets." The punnets are packed in shallow trays each holding six or a dozen boxes, and these trays are again fitted into a larger box. The main crop of strawberries is marketed in "pecks," baskets holding about 12 lb. of fruit.

Packing Nectarines and Peaches. The utmost care must be used in handling and packing peaches and nectarines, as the slightest bruise, often indeed the mere pressure of a finger, is sufficient to set up decay. The orthodox market peach box is 2 ft. long, 14 in. wide, and 4 in. deep. The author of "The Book of the Peach," Mr. H. W. Ward, F.R.H.S., gives the following excellent directions on the subject of packing peaches: "The wood-wool should be placed inside the individual boxes to the thickness of 2 in. or 3 in. Then (the fruits having been previously wrapped in squares of tissue paper sufficiently large to admit of the ends being twisted together immediately over the crowns of the individual fruits) make an opening in the wood wool with the fingers at the end left-hand side of box sufficiently large to deposit a fruit therein, repeating the operation until the box is filled with fruit, being careful to leave a partition of wood-wool between each row of fruit every way in packing, in order to ensure the fruit reaching its destination in perfect condition. Put a sprinkling of the wood-wool over the fruit thus packed before fastening down the lid of the box. Shallower boxes may be used for packing nectarines in, as the fruits are smaller than peaches. In packing peaches for market, strips of tissue about three inches wide are used instead of square pieces. These, being doubled, are wrapped two or three times round the individual fruits half-way up, and then deposited that depth in the wood-wool in the manner indicated above. A double sheet of tissue is then placed over the packed fruit, followed by a layer of wood-wool of the proper thickness to admit of the lid shutting down closely on the box."

THE CAMERA & ITS WORK

Taking, Developing, and Printing Photographs. Enlarging. The Profitable Side of Photography

Group 5

PHOTOGRAPHY

Following PAPER-MAKING from page 6563

By J. M. GIBBON

WE should begin with a camera that is simple to manipulate and cheap to work. The older books recommend us to start with a stand camera. This may be all right if we start photography in winter, when most of our exposures have to be taken indoors or in dull weather. But summer is the best season to begin photography, and for summer the hand camera is the thing. We start, therefore, with a hand camera of the box form. We can use this as a stand camera quite easily, as even the cheapest makes have now an arrangement for time exposures as well as snapshots. Some of these cameras can be had as cheap as 5s. But if we reckon up the cost, we find that it is cheaper in the end to begin with a quarter-plate camera, giving pictures 4¼ in. by 3¼ in., and using glass plates, not celluloid or similar films. Plates of this size cost very little more than the smaller sizes, and are only half the price of films. The worst of a roll of films is that we have to wait till the whole set of six or twelve has been completed before we can develop, and in our impatience to complete the roll we are tempted to take snapshots that we do not really want. This is a most insidious way of running up the expense. Again, flat films are more expensive than glass plates.

The Modern Hand Camera. A number of excellent hand cameras of quarter-plate size, with twelve sheaths for plates, can be had for a guinea each. If we look about, we can get one of last year's make for still less. By the time these words appear in print it will be easy to get cameras of the 1906 make at a reduction, as dealers desire to clear their stocks for 1907. Secondhand cameras can be got still cheaper, but it is inadvisable to buy a guinea camera of a make earlier than 1905, as the fierce competition has made many improvements in small hand cameras during the last two years. The guinea hand camera has now, as a rule, diaphragms for "stopping down," an excellent shutter, focussing glasses (usually called magnifying glasses), and even a colour screen for landscape photography. The lenses also are greatly improved. One make (the No. 1 Clito) has even a rack and pinion focussing arrangement, the box form covering a bellows beneath. This is, perhaps, best of all, as it is better to focus with a single lens than by placing the so-called magnifying glasses in front. We must, however, get our dealer to guarantee our camera as light-tight, so that if we find any pin-holes or cracks which let in the light and spoil our negatives, we can get another camera in exchange. This the dealer will do in the hope of retaining our custom for photographic materials.

What will photography cost us, and what materials shall we require? Provided we have, to start with, a camera, a ruby lamp (from 1s. upwards), and three dishes (which may be had at 5d. each in xylonite), it should work out, allowing for failures, at about 1½d. per print.

The Nature of the Camera. But before we go on to the practice of photography we ought to understand the meaning of the terms in common use among photographers, some of which we have already used, and we ought to know how it is that the camera enables us to take photographs at all.

Take our guinea box-form camera and examine it. In the front end there is a hole in which a curved glass is inserted. This curved glass is the *lens*. At the back end is an arrangement for holding the plates. When the camera is closed, the only light that can reach the front of these plates must come through this lens, and the reason why the glass of the lens is curved is that this curvature concentrates the light on the photographic plate. The lens is covered up with a metal disc called the *shutter*. We press a knob and the "shutter" moves aside for a moment to let in the light and to make our "exposure."

Now the concentrated light coming through the lens forms an image on the photographic plate corresponding to the image which we receive through the eye. For the eye itself is only a kind of lens, and scientists have actually been able to take photographs through the eyes of animals placed in specially prepared cameras.

All the colours of Nature are reproduced in this image which comes through the lens. We can see this for ourselves in cameras which have a ground glass at the back end, or in the *view-finder* of our guinea camera, which shows a similar image to that thrown on the photographic plate.

How a Negative is Made. Now, to understand how a negative is made, we must understand how light and colour affect the photographic image. Here is a rough description which will serve our purpose. Light is reflected from objects in Nature as different colours, according to the particular rays absorbed and reflected [see page 3728]. Now the ordinary photographic plate is more rapidly affected by—is more "sensitive" to—some colours than others. Suppose we are photographing a landscape made up of a blue sky, a yellow house, and a girl with a red dress. The photographic plate is most sensitive to the blue. Then comes the yellow and, last of all, the red. Of course, the quantity of light conveyed by any of these colours may vary according to the strength with which these objects are lighted—for instance, by a sunbeam—and so modify this general truth.

Now the sensitive stuff (itself of a yellowish-white colour) fixed on the glass plate has been affected by being exposed to the colours, but so slightly that the affection is not visible to the eye. This is where the "development" comes in. The sensitive plate, after exposure, is taken into a dark-room and treated with certain chemicals. These chemicals darken the parts that have been affected, and clear away the rest. The result is that where the blue sky hit the sensitive plate we have the darkest marks; where the yellow house, we have medium darkness; and where the red dress, we have it much lighter. Where there was hardly any colour at all, as in deep shadows, we have the plate quite transparent. This, then, is the *negative*, in which the coloured image is reduced to a reversed and transparent image in black and white.

The Print. Now we have to make the *print.* A piece of specially-prepared paper is laid close against the negative, so that the light can reach it only through the negative. The light naturally passes most quickly through the most transparent parts of the negative and most slowly through the darkest parts. The result is that the paper is darkened most at the most transparent parts of the negative (where the shadows and the red dress were), then at the part corresponding to the yellow house, and, least of all, at the part corresponding to the blue sky, which remains almost white. In this way we get the print of our photograph. In tabular form we may express it thus:

Nature	*Negative*	*Print*
Blue	Dark	White
Yellow	Darkish	Darkish
Red	Light	Dark
Deep shadow	Transparent	Black

The Dark-room. Don't imagine that the "dark-room" is merely the drawing-room with the blinds drawn down. It is a room from which every chink of daylight or gaslight is excluded. Nearly every house has some little room or pantry or bath-room which can be used as a dark-room. Any room, of course, can be used as such at night. But a dark-room can be made for use by day by covering the windows with two coatings of the specially prepared red cloth sold by photographic dealers at from 10d. to 1s. per yard, and then by stopping up the chinks and the keyhole in the door.

Some plates are more susceptible to light than others. These are called *faster.* We should use fast plates from the very beginning. They cost no more, and they are so well made nowadays that they are just as easy to manipulate. There is less chance of under-exposure with a good fast plate, and the beginner is inclined to under-expose. If the light is too strong, we can easily *stop down.* Our guinea camera has probably three "stops" or holes in metal discs in front of the lens, which "stop out" superfluous light. The smallest hole—probably marked "*f* 22"—should be used on the brightest of bright summer days, but for an ordinary sunny day the middle sized hole—probably marked "*f* 11"—will do.

If fast plates are used, particular care must be taken that the dark-room in which the camera is loaded and the plates are developed is absolutely free from any light except that of the ruby lamp, or the red light that comes through the windows covered with the special cloth already described. The least trace of other light would probably ruin the plates. Good fast plates by most makers can be had at 1s. a dozen. These are usually wrapped inside the box in three parcels of four each, and in the packets of four are two pairs of negatives, arranged so that in each pair the sensitive sides of the negatives lie against each other. In this way we can tell in a dark-room, even without the aid of a lamp, which is the sensitive side of the negative. The sensitive side must, of course, face outwards and towards the lens in the sheath and in the camera.

The first snaps we should take in sunlight only. Leave the grey days for the man with a sixteen-guinea camera. Nine-tenths of the best photographs are made out of sunlight and sparkle, and the sunny photograph is the easiest to develop and to manipulate.

Cleanliness. Here are four rules that we should write and paste up on our door:

Keep your hands clean.
Keep your dishes clean.
Keep your lamp clean.
Keep your camera clean.

Suppose we have made one or two exposures, and wish to develop our negatives. What developer are we to use? There are dozens available, but we do not need to know of more than one or two. Hydroquinone is usually recommended for beginners, because it does not stain the fingers and the same dish will develop many negatives. Pyro-soda is, however, a far better developer, and if we rub our fingers with lanoline before developing, and wash our hands afterwards, they will not be stained. Another developer which combines the brightness of pyro-soda with the cleanliness and durability of hydroquinone is ortol; but country chemists do not always stock this. It is rather more expensive than pyro soda, but as it can be used both for gaslight papers as well as for negatives, it has its advantages.

It is far cheaper to make up our own solutions. If we look up the price-lists of the average London dealer, we will find that hydroquinone and pyro-soda are sold in solution in bottles at 1s. 3d. for 20 oz. If we buy these developers even in made-up powder form, and make up our own solutions, we can get 48 ozs. for 1s. If we buy the chemicals separately by the pound we can save still more. We can buy 16-oz. medicine bottles from our chemist for twopence each, and as these medicine bottles are marked out on the back into equal parts corresponding to "tablespoonfuls," we can measure the quantity of our solutions with ease and economy.

If we do not wish to go to the expense of buying scales, we can get our developer in tabloid form, accurately measured for us and made up. The Tabloid Brand pyro-soda gives us 40 oz. for 1s., and so too, with the hydroquinone. A point to remember in connection with our home-made solutions is that there must be no grains of powder floating about. The powder must be perfectly dissolved, otherwise we shall have spots on our negatives.

An Economical Developer. Here is a simple formula for a developer:

Pyro-soda.—No. 1: Sulphite of soda, 6 oz. (sold at 8d. per lb.); water, 32 oz.; pyrogallic acid, 1 oz. (sold at 10d. per oz.); citric acid, added after the solution of the sulphite of soda, in sufficient quantity to turn blue litmus paper red (sold at 2d. per oz.).

No. 2: Carbonate of soda, 3 oz. (sold at 5d per lb.); carbonate of potassium, 1 oz. (sold at 7d. per lb.); water, 32 oz.

Keep these solutions separate till just before development. An ounce of each combined in a dish with another two ounces of water will develop two or three quarter-plates in rapid succession. When the developer begins to get very brown, throw it out of the dish and mix some more. In hot weather more water may have to be added, otherwise the developer acts too quickly. In cold weather less water should be added. The No. 2 solution is the accelerator, and may be increased when the image is slow in appearing. Any number of variations on this formula—and, indeed, almost every formula for almost every developer—may be found in the "British Journal Photographic Almanac" (price 1s. 6d.), the most useful of all annuals. If we calculate, we find that by making up our own solutions we get 144 oz. of pyro-soda

for 1s. 4½d., instead of the 20 oz. for 1s. 3d. sold in bottles by the retail chemist. Of course, it is not necessary to make up such large quantities at once, but these proportions should be kept approximately.

The Process of Development. How, now, is the developing carried out, and what do we see? The plate is immersed, sensitive side upwards, in the developing solution, and the dish is gently rocked, care being taken that the whole surface is covered. We can tell which is the sensitive side of the glass, as it has a "matt" (dull) surface, whereas the glass side is glossy. Very soon we see dark spots appearing on the light surface, and then a reverse image of the picture we have taken builds itself up. This gradually darkens all over till the image is lost again in darkness. The negative is fully developed when we can see a suggestion of the image on turning the negative over carefully and looking at the glass side. Experience with a few negatives will soon show the depth to which it should be developed.

Fixing the Negative. When the negative has been sufficiently developed, it should be rinsed in a basin of clear water, and then "fixed" by immersion in a dish filled with a solution of "hypo," still in the dark-room. A pound of hypo (sodium thiosulphate) costs 2d., and when dissolved in 60 oz. of water—or proportionately—makes the fixing solution. The negative is left in the fixing solution till it is perfectly clear and transparent, all trace of white on the back being cleared away. Leave it five minutes longer still, for safety's sake. In hot weather, when the sensitised surface of the glass is apt to frill, the plates should be immersed in a 20 per cent. solution of alum, and rinsed, before fixing. Never use warm water. The developing dish must be used for developing only, and a separate dish used for fixing.

Now that the negative is developed and fixed, it must be washed, as the hypo has to be removed. Put it in a basin of water, which is slightly tilted under a tap, and keep the water running for at least thirty-five minutes. Don't turn on the tap too hard. There are specially-made dishes for washing, but a basin does quite well. The negative may be taken out of the dark-room for examination after it is fixed and before washing, but it should be washed as soon as possible, otherwise crystals will form on the surface. Remember that the sensitised surface is very easily scratched and spoilt by finger-marks. Hold the negative gingerly.

When the negative is washed, we lean it on a shelf against the wall to dry. At the end of five minutes we shift it slightly, as we find a small pool forming at the base of the negative. We must not print from the negative till it is quite dry. As a rule, a negative left over-night will be dry in the morning. If we wish to dry our negative quickly, we immerse it in methylated spirit for ten minutes, and it will be dry in half an hour.

Printing. In printing it is usual to begin with the paper called "P.O.P." There are dozens of good makes, and that with matt surface is more artistic and stands more knocking about than the glossy kind. The negative is placed in a printing-frame (costing about 5d.), glass side downwards. The prepared side of the paper (it curls inwards) is placed in contact against the upper (sensitised) side of the negative. An insertion at the back holds everything in position, and the frame is placed in the window-sill or open air to print. We follow the directions on the back of the paper we buy for the depth to which we must print. If we are to use the "combined toning and fixing" bath, we must probably print a little deeper than the picture which we ultimately expect, as a certain amount is cleared away in the solution.

The combined toning and fixing bath is simpler than the two separate baths, and, with care, can be made to produce almost as permanent results. But if we want really permanent results, we had much rather choose the more artistic process of carbon printing, described later on in this course.

If the combined bath is used, no preliminary washing, as a rule, is necessary. If we use the two separate baths, the prints must be immersed in water till it becomes milky. Formulæ for making up the solutions for the separate baths are supplied with the various kinds of paper. As each maker has his own formula, we do not repeat any here, so as to avoid confusion. After the bath, or baths, the prints must be washed for about an hour in running water, and always kept moving, as they will not wash properly if allowed to lie on the top of each other.

We find it much cheapest to buy our combined toning and fixing bath in powder form. The retail chemist will sell us this bath in bottles containing about 16 oz. for 1s., but we can make 32 oz., for instance, from the 1s. tin of the Agfa "neutral toning and fixing salts." If we wish to make up the whole of our own solution, a formula follows.

Combined Toning and Fixing Bath. Chloride of gold, 2 gr. (usually sold in tubes containing enough for five or six such baths, and costing about 1s. 9d. each); nitrate of lead, 10 gr.; chalk, ½ oz.; hypo, 4 oz.; water, 20 oz. Shake the solution, and use the clear portion when it has settled.

If we have only evenings to spare for printing we may try the gaslight papers. Here the exposure is made by holding the printing frame at a short distance from an artificial light, for some time, which varies according to the make of the paper. Follow the directions always attached to the cover of the packet. The paper is then developed as if it were a negative, in a developer such as ortol, which is conveniently made up from the tabloid brand of chemicals. This is cheaper than the gaslight developers sold by the makers of the various papers, and quite as good. After developing, the paper is fixed in a hypo solution and washed, just like a negative.

The self-toning papers should also be tried for the sake of variety. These, as a rule, require only to be fixed in a hypo solution, and often give artistic results.

Taking Portraits. Nothing is more difficult than to take a good portrait, either indoors or out of doors. But at the same time nothing gives us more pleasure when we have really succeeded. Very often the out-of-door snapshot gives the most living impression. But at the same time this is apt to lack dignity, and the portraits that give the most lasting pleasure have repose. The exposure for an interior portrait depends on the lighting of the room, and can be gauged only by experience. Try three seconds to begin with. In portraiture, especially with a cheap camera, the great danger lies in the perspective. The hands or the feet come out too large, and big feet are apt to end in bad tempers. The reason why the ordinary lens distorts is too elaborate to explain here. But it exists. The safest way of avoiding this distortion is to keep the sitter as nearly as possible in a plane parallel to the front of the camera. For instance, if we have a fascinating young lady in a

deck-chair, we do not plant her facing us, with her face towards us and her head leaning back, unless we wish her No. 3 shoes to appear in the photograph as larger even than her matinée hat. Rather place the chair sideways. A standing pose, as a rule, avoids distortion. The nearer the camera is to the sitter the more danger there is of a freak photograph. On the other hand, if we are too far away, we are apt to have the portrait too small. The Bond Street photographer gets over this difficulty by having an expensive "long-focus" lens. With our guinea camera we must select our poses to suit our short-focus lens. A maxim to keep in mind is: "Not too near, yet not too far."

The choice of background is very important. It must be remembered that the camera is apt to pick out more detail than the eye notices. So far as possible, it is advisable to look out for backgrounds that are quite simple, and do not interfere with the interest in face or figure. The colour of the background is also important. Greens and reds and yellows come out darker than we should expect. A background of green leaves in a garden picture is often disappointing for this reason. A little experience and observation will soon teach us what to avoid in this direction. In interiors, greys come out more as we should expect than do pure or vivid colours.

A Natural Pose. As to the attitude of the sitter, a natural attitude is far the most interesting even though it may not be found in any picture by Reynolds. Far too many "posey" portraits are made nowadays. We are apt to forget that the poses found in the great portraits of a hundred years ago were natural to the costume of the day. Modern dress suggests new graces. If we must study pictures for poses, we should rather go to a modern painter such as George Henry, A.R.A., whose portraits may be seen at the Academy or New Gallery, and are often reproduced. But, best of all is to do what the great portrait painters themselves have done, study Nature and the natural pose.

In portraiture, both indoors and out of doors, the value of backed plates (costing 3d. per dozen extra) is incalculable. The backed plate undoubtedly retains more detail and more subtlety of gradation than the unbacked. The cost is very little more, and anyone who once begins to use backed plates will very soon use no other. A camera in which backed plates are used requires most careful dusting, as the material used in many kinds of backing is apt to rub off, and ultimately produce spots, unless the camera is kept rigidly clean.

As already explained, the up-to-date cheap hand camera of to-day can be used with success for interiors as well as snapshots, as there are arrangements for time exposures and for the accurate focussing of near objects. Where the object is to show part of the room in which a person is sitting or working, the lens must be stopped down to at least "*f* 11," otherwise part of the picture will be out of focus. In a small room, or where there are near objects, a still smaller stop must be used. The value of the backed plate will be appreciated if a window or highly lighted article, such as a silver ornament, comes into the picture.

Hints for Development. If the picture flashes up too readily in the developing dish, and we suspect over-exposure, we can slow down the development by rapidly and gently wiping the surface with a piece of cotton-wool dipped in a 10 per cent. solution of potassium bromide. In developing negatives of interiors, we should always have this handy. Even in the case of backed plates, a window is nearly always over-exposed and shows hallation—a blurred appearance round the edge of a light object. With the cotton-wool and potassium bromide, we can arrest development locally. Our knowledge of negatives can be acquired only by experience, but the more we know, the more we value this power of local treatment in the earlier stages.

As the modelling of a face depends so much on infinitely slight gradations, the more detail we can keep in the negative the better. We can simplify afterwards, if we like, by the use of special papers in printing. But a negative is never the worse for detail. To secure this detail, slower development is advisable in the case of portraits and interiors. The developer may be weakened to half strength.

Our guinea camera has probably a "colour screen," a piece of yellow glass which may be inserted in front of the lens. This greatly improves a landscape photograph, and is especially useful for dull days. The exposure, however, must be increased three or four times in length, and isochromatic plates should be used.

Flashlight. We can take portraits in the evenings by flashlight. For these the ready-made flashlight candles may more safely be recommended than magnesium ribbon or powder. These require no apparatus, and are easy and safe to use. The tendency is to under-expose in the shadows, so that as much reflection as possible may be thrown on the sitter from newspapers or light wallpapers. The farther away from the sitter, the weaker is the light: but at the same time the light should be placed in a position so as not to fall directly either on the lens or on the eyes of the sitter.

In the case of portraits, vignetting can often be used with advantage. We can easily make vignetting cards for ourselves. We cut an oval or circle of a little less than the desired size out of a piece of dark coloured paper—for instance, the black paper in which P.O.P. is wrapped—then we snip round the inside edge of this circle or oval, and push up the edge made in this way into a sort of frill. We print with this frilled oval or circle in front of the frame. The frill softens the edges of the resulting vignetted picture.

Intensification and Reduction. By the time we have taken a few dozen negatives we realise that some are over-developed and too dense, and some are too thin. These can be remedied by "reduction" and "intensification," processes which are really very easy, though they entail the use of poisons.

For intensification, the solution most commonly stored by the chemist is the uranium intensifier. A better intensifier, which, however, must be handled with great care, as it is very poisonous, is the mercury and ammonia intensifier. This is used by most professional photographers, but will not be sold readily by chemists to young people. The negative is immersed in a saturated solution of bichloride of mercury—four pennyworth will go a long way, and it can be used over and over again—until it is bleached. It is then washed for at least thirty-five minutes in running water. We then immerse it in a very weak solution of ammonia—10 minims of strong ammonia to 10 oz. of water—till it is quite blackened again. All negatives must be thoroughly clear of hypo before intensification.

The cheapest, and in many respects the best of reducers is ferricyanide of potassium, a poison that must be handled with care. A pennyworth will go a long way. It is usually sold in small

crystals. One small crystal suffices for a quarter-plate dish of water. The negative need not be cleared of hypo before reduction, and a little hypo should be added to the solution. Watch the negative carefully. As soon as it is reduced to the required density, we wash it at once under a tap for half an hour and leave it to dry. A negative that is already dry must be soaked in water till the film is soft again before intensification or reduction. Negatives that have been dried with methylated spirit do not reduce or intensify so well as those dried in the ordinary way.

Enlargements by Daylight. When we have made some successful pictures with our guinea camera we are sure to become more ambitious, and anxious to make larger pictures. To do this it is not necessary to get a larger camera, but we can supplement our quarter-plate with an enlarging camera. There are two kinds of cameras for enlarging, one for daylight and the other for artificial light. A daylight camera which will enlarge from quarter-plate size ($3\frac{1}{4}$ in. by $4\frac{1}{4}$ in.) to whole-plate ($6\frac{1}{2}$ in. by $8\frac{1}{2}$ in.) can be bought for 7s., so the initial expense is not very great. We must, however, buy larger dishes for the larger size of paper. Two whole-plate dishes will be required, costing about 11d. each. A packet of twelve sheets of bromide paper, whole plate size, costs 2s. We can therefore roughly estimate the cost of each print at 4d. to cover the cost of the enlarger and the waste. In the daylight enlarger of fixed focus, enlarging from quarter-plate to whole-plate, the light passes through the negative and then through a lens, so that the image is projected upon the printing paper fixed at the other end.

Enlarging bromide paper is, as a rule, very sensitive to light, so that the packet should be opened and the enlarging camera loaded only in the dark-room. Those who have already mastered gas-light printing by contact will make successful enlargements at once, as the same kind of paper is used. The length of exposure depends on the strength of the light and the speed of the paper. Owing to the expense of waste, it is well to make test exposures in the camera with small pieces of paper before risking a whole sheet. The makers of paper now recognise this by enclosing an extra piece, quarter-plate size, which may be used for preliminary test. If we are used to the ortol developer, we may use it for our enlargements. If not, we may try amidol.

Formula for amidol: amidol, 80 grains (sold at 2s. per oz.); sulphite of soda, 2 oz.; water, 12 oz.; bromide of potassium, 15 grains.

This has to be made up fresh for each printing, and deteriorates in about two hours. The bromide of potassium makes the developer a little slower, but brightens the prints. A negative that may print rather thin and flat with P.O.P. may give bright prints in an enlargement if we under-expose and use a strong solution.

Artificial Light Enlarging. But by far the most satisfactory method of enlargement is by artificial light. Here our light is always of the same strength, whereas daylight is constantly changing. Another great advantage is that we can control the printing. For instance, we may have a negative of an interior lit up by a window or flashlight on one side. By placing a piece of cardboard in front of the thinner portions of the negative, we can to a large extent rectify this unevenness of lighting, and make a presentable print.

Another advantage about the artificial enlarging lantern is that it may be used as a magic-lantern, and we can amuse our friends by throwing our pictures on the screen.

The cost, however, of the artificial lantern enlarger is greater than the other, since a "condenser" or large lens for concentrating the light has to be used. This in itself is so expensive that a reliable enlarger can hardly be bought new for less than three guineas. We can, however, often pick one up secondhand for rather less. The photographer who wishes to go in for Press or professional portrait work later on will find this artificial light enlarger absolutely necessary.

In the enlarger for use with artificial light the light, which is usually an incandescent or electric light, preferably the former, is behind the condenser, and the condenser concentrates the light on the negative. Through the negative the light passes on to the lens, and the image is thrown into focus on bromide paper either fixed on a slide or pinned on a board fixed upright at the requisite distance. We require no elaborate stand for our enlarger, but can prop the spare leaf of our dining-room table against the wall of the dark-room and set the enlarger on two wooden chairs of equal height. An arrangement for focussing enables us to enlarge to any size or in any proportion we desire. If by any chance we have tilted our camera by mistake, and so got the lines in the wall of a house slanting, we can stop down the lens in the enlarging camera and tilt the support of the paper slightly so as to correct this awkward mistake. We can very often improve our negative by enlarging only the interesting portion of it. A sharp negative will enlarge many diameters without showing any trace of enlargement. Experienced tourists know this, and often prefer to take with them only a quarter-plate camera, knowing that they can enlarge their good negatives to any size at home.

Hints for Enlarging. The lens in the enlarging camera should always be stopped down a little as this tends to give a brighter print. The utmost care should be taken to keep the hands perfectly clean in printing, otherwise the paper will show stains. It is always advisable to "clear" an enlarged print, as the paper, especially if of glossy surface, is inclined to show markings, due in no way to the operator. This clearing solution is the same as the reducing solution (ferricyanide of potassium), mentioned already. Dip a piece of cotton-wool in this, and gently rub the surface of the paper while still damp. This will clear the whites wonderfully, and will even remove slight yellow stains due to previous carelessness.

We can focus accurately on the paper by placing in front of the lens a yellow glass cap which is removed for the exposure. These caps are stored by any dealer who has enlarging cameras. All white light, however, should be excluded from the room, as the bromide paper used for enlarging is sensitive to the light, far more so than is generally supposed. If we want to be sure of good prints, we must run no risks. Do not expose the print after development to any other than the light shown through this yellow glass till the print has been at least five minutes in the hypo (fixing) solution, or we risk getting it fogged.

Lantern Slides. Lantern slides are very easily made without special apparatus by contact printing. They are really positive prints made on glass instead of a paper support. We will probably find among our negatives a number in which a square of $3\frac{1}{4}$ in. makes a good picture. This is the size of the lantern-slide. Prepared plates for

lantern-slides are sold at 1s. per dozen, and the positive is made by contact in the same way as in the case of gaslight papers. It is, however, well to clear the slides for the sake of improved transparency after development and fixing, and before washing. Here is a well-known formula for clearing solution:

Protosulphate of iron, 3 oz. (sold at 3d. per lb.): alum, 1 oz. (sold at 2d. per lb.); citric acid, 1 oz. (sold at 2d. per oz.): water, 20 oz., or in proportion. The depth to which a lantern-slide should be developed can be gauged only by experience. If, however, we study a good lantern-slide such as we often see in an optician's window, or such as are sold for educational purposes, we can save ourselves much trouble and waste.

If we wish to secure the whole of our negative on our lantern slide we can still do so without special apparatus. We must block up the whole of a window lighting a room with dark-brown paper, leaving only a hole the size of our negative. Into this hole the negative is fixed, say, by means of sticking-plaster over the corners. We must now photograph this negative on a prepared lantern-plate, focussing accurately and getting the image as near $3\frac{1}{4}$ in. at its widest part as possible. We should stop down our lens to at least f 22, and back our plates with backing-paper, which may be bought at 6d. a box. The lantern-slide plates will fit into the sheaths of our camera, but must, of course, be fixed in the middle of the sheath, otherwise the picture may overlap the plate.

The positive plate has to be mounted before it is a complete slide, otherwise the film would be quickly destroyed by the heat of the lantern. Cover-glasses, made of very thin glass, and of the same size ($3\frac{1}{4}$ in. by $3\frac{1}{4}$ in.) are placed so as to cover the sensitive side of the positive, and the two glasses are bound together by binding strips round the edges. This binding is quite easy to do.

More Advanced Work. Although a great deal may be done with a quarter-plate combined with an enlarging camera, we may be pardoned if we grow still more ambitious. The average lens, even in expensive quarter-plate cameras has so short a focus that distortion is difficult to avoid. By "focus" we mean the distance in the camera between the centre of the lens and the photographic-plate. The human eye is said to have a lens corresponding to one of 16 in. focus, but the quarter-plate camera is satisfied with $4\frac{1}{2}$ in. or 5 in. It is, of course, possible with a focussing camera to adapt a telephoto lens, such as the "Adon," to overcome this objection, but for many reasons we should do better still with a good half-plate camera. It is a good plan to get a camera with a double anastigmat lens, in which the front and back portions of the lens (each of different focuses) can be used separately or in combination, giving us the choice of using short or long focus lens at will. Thus, a combined lens which has a focus of $6\frac{1}{4}$ in. may consist of a front portion with focus of 14 in. and a back portion with focus of 9 in. The camera that is to hold such a lens must, of course, have a bellows capable of extending to 14 in.

In the case of portraits, the longer the focus the better. A curious fact also is that a large lens seems to give more modelling and to get round the objects more than a small lens of the same focal length.

Carbon printing and the subsidiary processes so much affected by artistic workers are hardly worth attempting in less than half-plate size. It is, of course, possible to make enlarged negatives, and to print from these; but, after all, the best method of making enlarged negatives is by the carbon process itself.

Carbon Printing. The chief makers of carbon tissue—the Autotype Co., and Elliott & Sons supply such elaborate directions that it is unnecessary here to give more than a brief outline of the process. A good plan is to experiment with the Trial Set supplied by the Autotype Co., or the Sample Set supplied by Elliott & Sons.

The principle and method of carbon printing are so simple and the results so artistic that we can well understand why it has taken the foremost place both in amateur and in professional photography. We may begin by explaining how the image is made in the carbon tissue. It has been discovered that gelatin combined with bichromate of potassium becomes more or less insoluble according to the amount of light to which it is exposed. When a prepared gelatin tissue is exposed to the light under a negative it becomes insoluble in depths which vary according to the strength of the light which the negative allows to pass through its parts. A small amount of light passes through the whole of the negative, and therefore the whole of the surface of the tissue

A SUCCESSFUL SNAPSHOT

ENLARGEMENT OF SNAPSHOT ON OPPOSITE PAGE

(Observe the clearness of detail after enlargement)

is affected and becomes insoluble. The problem is, how are we to get to the lower layers of the tissue, so that we can dissolve away that which has not yet been affected by the light? This is done by transferring the tissue from the paper on which it is originally mounted to a new support, face downward. When this transfer is made, the soluble portions now exposed can be cleared off by the application of warm water, and the positive image —made of insoluble gelatin—brought to view.

The Single Transfer. In the single-transfer method of carbon printing—the simplest, and therefore the best to begin with—the image is reversed from left to right, but very often this does not matter. The sensitive tissue is usually made up twice a week by the companies that supply it, and should be used within nine days, as it does not keep. Prints should be made in dry weather only. The safe edge mask—supplied in the Trial Set—must always be applied round the edges, otherwise the transfer

is apt to be unsatisfactory. No image is seen at first in the printing, so that an actinometer for measuring exposures has to be used. A simple actinometer is supplied with the Trial Set. The time required for printing is considerably less than that for P.O.P., and the action of the light continues—at a reduced rate—after the tissue has been taken out of the frame. We may turn this continuing action to advantage in the case of prints which are suspected of under-exposure. If these are kept for twenty-four hours before development they may turn out all right.

The single-transfer paper is slightly larger than the mounted carbon tissue. It is placed face upwards in a tray of cold water at about 60° F., and all air bubbles must be carefully removed. We should have a depth of at least 1½ in. of water in the tray. Then the exposed tissue is placed face downwards in the water, and the fingers gently slid along the surface underneath to remove air bubbles. The tissue will flatten out, and then begin to turn up at the edges. The tissue and the transfer paper are now brought into contact under water and taken out together, and then squeegeed into perfect contact with a scraper squeegee, such as is supplied with the Trial Set. The two sheets are now put between blotting paper and laid under a heavy weight, such as a large book. This secures uniform pressure. All the prints are treated thus, and left under pressure for about half an hour, or till the back of the transfer paper is turned yellow.

Developing with Water. For development, two baking tins, costing about a shilling each, will do. But we must not use these tins afterwards for baking, as bichromate of potassium is a strong poison, and the success of our printing should make us desire to live a little longer. Fill this tray with water heated to 90° F. to 100° F. The gelatin soon begins to ooze out at the edges. Then transfer the sheets to a tray of slightly hotter water, 100° F. to 110° F., about 1½ in. deep. Holding the combined sheets under water, lift up a corner of the tissue sheet and gently strip it off. If it does not strip off readily, leave it a little longer and try again. The gelatin is now transferred to the new support, and the lower soluble layers are exposed and can be treated. The transfer paper, to which the tissue now adheres, is placed on a slab or flat dish at an inclined angle, and laved with water at 100° F. to 110° F. by means of a teaspoon. Gradually the image will appear as the soluble part is washed away. We lave it till it is a little lighter than we desire the finished print to be. The water can be kept at an even temperature by placing the tray on a gas stove with the gas jet at the proper height. If the tissue has been over-exposed it does not easily dissolve, and still hotter water must be used. This, however, must be used with care, as it is apt to cause blisters.

The great charm of carbon printing is that local development can be carried out so easily. A sky that would otherwise be lost can be saved by developing the upper portion of the picture in cooler water than the lower, and over-exposed portions can be reduced by careful laving with hot water, or the local application of sulphocyanide of ammonia—sold at 3d. per oz.

When the print has been sufficiently developed, it must be cleared and hardened. A filtered 5 per cent. solution of powdered alum in water is the bath. This clears away the yellow stain and hardens the film, after which the prints should be washed for half an hour in running water, and then hung up with clips to dry.

Double Transfer and Modifications. In the double-transfer method, a temporary support is used instead of the single-transfer paper, and from this temporary support the image is transferred to a final support. This double transfer restores the image to its natural position. For making enlarged negatives, a special transparency tissue is made, which requires half more exposure than the ordinary kind. This is transferred by the single-transfer process to a glass support, and printed through an enlarging camera on to a negative of the size required. The image is reversed to its natural position by keeping the tissue side of the glass towards the source of light.

Modifications of the carbon process avoid transfer, but usually require us to sensitise our own solution. On the whole the old method is the most satisfactory of all printing processes, and we do not grudge the slight extra trouble.

The Press and the Editor. Photography for the press contains more of the element of uncertainty than any other branch of the craft. If we are actually on the staff of a paper, this uncertainty is, of course, diminished, but between the freelance and success a thousand chances intervene. Still, it is one of the most interesting, and often one of the most profitable forms of using the camera. A very skilful and successful photographer for the press acknowledges that after paying all expenses, he clears about £500 a year. It must be remembered, however, that he is at the top of the tree, and has fifteen years of hard work behind him.

The main point to remember is that we cater not so much for the public as for our editor. We must give him the kind of print and subject he wants, not what is intrinsically best. Very often we shall find our best work thrown on our hands, owing to his personal tastes, or the space he may have at his disposal. "Better luck next time," we must say, and try again.

In the first place, it is advisable to make our prints not less than half-plate size, and with a glossy surface, which may even be squeegeed. The reproduction the editor may make may be only 3 in. by 4 in., but he personally likes to see the prints large. For this reason, most Press photographers use a half-plate camera, so that they can readily run off contact prints, and in many cases they print through the enlarging camera on glossy bromide paper, submitting pictures whole-plate size. The glossy surface is not really necessary for reproduction, and some engravers actually damp the paper to get rid of the gloss before making their block; but few editors know this, and prefer the print which apparently shows most detail. There are, of course, exceptions, and "Country Life," for instance, takes artistic photographs even on rough surfaces. This extreme, however, is only possible in the case of a magazine with exceptionally fine printing.

Camera for Press Work. The most convenient all-round camera to use is a light, folding half-plate camera with focal plane shutter, giving exposures down to 1,000th part of a second, and either slides or a magazine containing 12 plates. Our outfit will cost us about £20. The lens should be able to work well at $f/6{\cdot}3$, or if possible, $f/5$, and the finer the lens the more likely we are to achieve success under all conditions of weather. We must be prepared to make bright, contrasty pictures at seven in the morning on a rainy day. One of the most successful press photographers uses a lens with 10 in. focus, but this requires more experience

in accurate focussing than, say, a Goertz-Anschütz with lens of 7 in. focus. Some get over the difficulty by having both a long and a short focus lens. This, of course, requires a camera that can be adapted to different lenses. It must be remembered that, especially in sporting photography, we have to snap at a distance from the object required, and yet our figures must be as large as possible. We do not recommend the reflex type of camera for general work. Many of the most skilful photographers do not even use a finder, but gauge by experience the view taken by the angle of their lens, and point the camera breast-high at the person or object required. In snapshotting celebrities, this is often the only practical method. We have to keep our eye glued to our victim, and at the same time have the whole field in view, otherwise we may miss the characteristic attitude, or someone will step in front at the critical moment. In a crowd we may even have to hold our camera above our head.

A SUCCESSFUL SNAPSHOT OF ACTION

In addition to the snapshotting of news events, there is also the vast field of magazine work. Skill in portraiture is also a great advantage, as the illustrated newspaper of to-day becomes more and more personal in its interests. One successful photographer has made a speciality of doing for the press artistic portraits of celebrities at home or in their natural surroundings. The chief London photographers naturally acquire numbers of portraits which are in demand with editors. So much is this the case that they sometimes have to retain a special staff for running off prints for the press.

Celebrities. So much are celebrities photographed nowadays, that few copyrights are worth more than ten guineas at the outside. The usual fee for reproductions of photographs of any sort by an illustrated paper is 10s. 6d. per print for reproductions up to 6 in. by 4 in., and a guinea beyond that size. Reduction in price is frequently asked and granted for a series or set of photographs, but the half guinea is a useful standard, fair alike to editors and photographers. Occasionally an editor

ENLARGEMENT OF THE SNAPSHOT SHOWN ABOVE
(The detail is so good that every face shows up like a portrait)

will offer to buy exclusive rights in a photograph for a definite period, when we may get from one guinea to ten guineas. Such occasions and such editors are rare.

Chance, of course, may turn a portrait into a goldmine. Thus, the photograph made by Elliott & Fry of General Baden-Powell, a few days before he started for the war, was reproduced in millions; but in these days of peace a new photograph of this hero would not get much more than five guineas in copyright fees, if so much.

Advanced Flashlight. The Press photographer must be master of flashlight work, as the subjects required—especially in magazine work—have often to be taken under difficult lighting. A small room may be lit up sufficiently by magnesium powder, or a flashlight candle, but it is advisable to know how to manipulate more powerful flashlights. There are several kinds of explosive powders used in advanced flashlight work, but the safest, and at the same time one of the most brilliant, is *argentorat* (price 5s. for 4 oz.), which has the merit of not being set alight by percussion. It is so highly inflammable that it must be handled with great care, and must not be lighted with a match held in the hand. Also, it must not be used in a closed lamp, such as is used with magnesium powder, but in an open metal tray. A handy portable lamp for use with these special flashlight powders is the Weiss lamp (price 30s.), in which a match, close to the powder, is ignited by pulling a string. Another lamp ignites the powder by means of an electric spark.

So vivid is the light of a powder such as argentorat that people jump out of their seats, and they should therefore be cautioned in advance that there is no danger. The flash is so rapid that the photograph is taken before the movement occurs. The smoke is, unfortunately, a great nuisance, and our flashlight may occasionally bring up the fire brigade on a false alarm. Scrape the ash carefully off the tray after each flash, otherwise your later flashes will be accompanied by loud explosions.

Enlarging is particularly valuable in the case of snapshot work, where we are often compelled by circumstances to stand too far from the desired object. We can amend this by enlarging only the important part of the negative.

Sale and Speed. Country photographers often find it convenient to sell prints through the press photographic agencies. These send representatives round the chief editorial offices, charging 15 per cent. to 25 per cent. commission. In the case of news photographs, where there is no time to run off many prints, these agents are very handy, as one editor may have special reasons for refusing good prints, for which another has space.

In the case of news pictures, speed is half the battle. Pictures of an event that happens on a Monday morning should be submitted, if possible, the same afternoon. Methylated spirit of good quality enables one to dry prints and negatives rapidly. P.O.P. prints can be made rapidly by the developing process. In this the paper—which should be put in the frame in a dark-room—should be printed only till the detail in the high lights is faintly shown, and then developed in the dark-room with a black developer such as hydroquinone (not pyro), treated all the time with the same care as a negative.

Mr. C. F. Bowden, of Bowden, Bros., perhaps the most skilful sporting photographer in this country, has kindly sent us the following hints for those who intend going in for such work.

1. Get your figures as large as possible. Avoid having a heavy background of trees when taking fast exposures. They look artistic in the finder, but don't reproduce well owing to under-exposure.
2. Don't keep changing your brand of plates. Start with a good make, and use only the fastest for extreme exposures. It does not do to use the slower, and cheaper make, as the results cannot be obtained with these.
3. When developing, avoid using too much ruby light. The less the better.
4. Don't be impatient with very fast exposures when developing. Anybody can press the button and take a picture in a 1,000th part of a second; but it is not everybody who has the patience to develop a plate for an hour or two, as is often the case in winter.
5. A lens working at a large aperture, say f/5·6, is essential.
6. Don't press the shutter release on camera with a jerk.
7. Rehearse in your mind what you are going to do; and when the moment arrives, do it.

Professional Portraiture. The best guide to those who intend to take up professional portraiture is naturally one who has himself succeeded. Mr. E. C. Elliott, of the firm of Elliott & Fry, gives some practical advice on the subject. "Don't try at first to get into a big London house," he says. "Get into a good moderate-sized provincial house where everything is done under one roof. At Elliott & Fry's, for instance, every department is specialised, and it would be difficult for one to get that general grasp of a business which is essential for a man who intends eventually to set up for himself. After one has realised what one is best fitted for, one may decide to specialise, for instance, as an operator or a printer, a retoucher, or finisher. The Professional Photographers Association has started an excellent system of certificates of merit for assistants, awarded after examination. If you decide to set up for yourself, you must be up-to-date and a little bit before it. I don't know that it is advisable to start with a partner. Partnerships are very uncertain things, and I think that, at any rate to begin with, a clever man with a capable staff can manage by himself. Wherever you are, you must adapt yourself to your locality. A seaside or suburban photographer has quite a different clientele from that of Elliott & Fry, and yet may do excellent business. The things to remember are, that whatever your kind of photography may be, you should try to be good of your kind, and that you should not cut prices. You must be up-to-date in the getting up of mounts, in your printing methods, framing and displaying, while such small details as price-lists, packing of pictures, labels and notepaper should be studied, with a view to making them as attractive as possible. Every young professional photographer—in fact, every photographer young or old—would do well to become a member of and support the Professional Photographers Association, and so have at his disposal in all matters of difficulty which may arise the help and advice of a committee of the most experienced men in the profession. Much friction and litigation is avoided through the good offices and advice of this committee in the many delicate and sometimes complex matters that are brought before them by members. If you obtain a standing which enables you to obtain celebrities as sitters, you must be absolutely scrupulous as regards copyright both towards your sitters and towards the editors."

BIBLIOGRAPHY OF PURE & APPLIED CHEMISTRY

PURE CHEMISTRY.—GENERAL TREATISES.—"Dictionary of Chemical Solubilities, Inorganic," by A. M. Comey (Macmillan, 15s.); "Elementary Chemistry, Lessons in," by Sir H. E. Roscoe (Macmillan, 4s. 6d.); "History of Chemistry From the Earliest Times to the Present Day," by E. Meyer (Macmillan, 15s.); "Historical Chemistry, Essays on," by T. E. Thorpe (Macmillan, 8s. 6d.); "Practical Chemistry, A Course of," by W. A. Shenstone (Edward Arnold, 1s. 6d.); "Watts' Dictionary of Chemistry," 4 vols., by H. F. Moreley and M. M. Muir (Longmans, Green & Co.).

PHYSICAL CHEMISTRY.—"General Chemistry, Outlines of," by W. Ostwald (Macmillan, 10s.); "Phase Rule, The," by A. Findlay (Longmans, Green & Co., 5s.); "Physical Chemistry, Textbook of," by R. A. Lehfeld (Edward Arnold, 7s. 6d.); "Physical Chemistry for Beginners," by Ch. M. Van Deventer (Edward Arnold, 2s. 6d.); "Thermal Chemistry, Elements of," by M. M. P. Muir (Macmillan, 12s. 6d.); "Theoretical Chemistry," by W. Nernst (Macmillan, 15s. net.).

INORGANIC CHEMISTRY.—"Elements of Inorganic Chemistry," by W. A. Shenstone (Edward Arnold, 4s. 6d.); "Inorganic Chemistry, An Introduction to the Study of," by J. Remsen (Macmillan, 6s. 6d.); "Inorganic Chemistry for Beginners," by Sir H. E. Roscoe (Macmillan, 2s. 6d.); "A Treatise on Chemistry," by Roscoe and Schorlemmer (Macmillan, vol. I. Non-metallic Elements, 21s., vol. II. Metals, 31s. 6d.); "Inorganic Chemistry, A Manual of," by T. E. Thorpe (William Collins, Sons & Co., Ltd., vol. I. Non-metals, vol. II. Metals); "Inorganic Chemistry, A Textbook of," G. S. Newth (Longmans, Green & Co., 5s.).

ORGANIC CHEMISTRY.—"Chemical Synthesis of Vital Products," by R. Meldola (Edward Arnold, vol. I., 21s. net.); "Organic Chemistry," by W. H. Perkin, junr. and F. S. Kipping (W. & R. Chambers, Ltd., 6s. 6d.); "A Laboratory Manual of Organic Chemistry," by Lassar-Cohn (Macmillan, 8s. 6d.); "Organic Chemistry, An Introduction to the Study of," by J. Remsen (Macmillan, 6s. 6d.); "Practical Methods of Organic Chemistry," by L. Gattermann (Macmillan, 8s. 6d.); "Organic Chemistry, An Introduction to the Study of," by J. Wade (Swan, Sonnenschein & Co., 8s. 6d. net).

SOLAR AND STELLAR CHEMISTRY.—"Chemistry of the Sun," by J. N. Lockyer (Macmillan, 14s.).

APPLIED CHEMISTRY.—GENERAL TREATISES.—"Chemistry for Engineers and Manufacturers," by B. Blount and A. G. Bloxam (Charles Griffin & Co., vol. I., 10s. 6d. net., vol. II., 16s. net.); "Chemical Technology, Manual of," by R. O. Wagner and Sir W. Crookes (J. & A. Churchill, 32s.); "Chemical Technology," by C. E. Groves and W. Thorp (J. & A. Churchill, vol. I., Fuel, by E. J. Mills and F. J. Rowan, 30s., vol. II., Lighting, by W. Y. Dent and Others, 20s., vol. III., Gas lighting, by C. Hunt, 18s.); "A Dictionary of Applied Chemistry," by T. E. Thorpe (Longmans, Green & Co. (vol. I. and II., 42s each; vol. III., 63s.).

ANALYTICAL CHEMISTRY.—"Gas Analysis, Handbook of Technical," by C. Winkler (Gurney & Jackson, 10s. 6d.); "Lubrication and Lubricants," by L. Archbutt and R. M. Deeley (Charles Griffin, 21s.); "Mineral Oil Analysis, The Laboratory Book of," by J. A. Hicks (Charles Griffin & Co., in press); "Painters' Laboratory Guide," by G. H. Hurst (Charles Griffin & Co., 5s.); "Chemical Analysis, Select Methods in," by Sir W. Crookes (Longmans, Green & Co., 21s. net); "Gas Analysis, Methods of," by W. Hempel (Macmillan, 7s. 6d.); "Micro-chemical Analysis, A Manual of," by H. Behrens (Macmillan, 6s.); "Analytical Chemistry," by N. Meuschutkin (Macmillan, 17s. net.); "Quantitative Analysis," by F. Clowes and J. B. Coleman (J. & A. Churchill, 10s.); "Qualitative Analysis," by R. Fresenius (J. & A. Churchill, 15s.); "Quantitative Analysis," by R. Fresenius (J. & A. Churchill, vol. I., 15s.), vol. II., parts 1 to 3, 2s. 6d. each; "Laboratory Teaching," by A. G. Bloxam (J. & A. Churchill, 6s. 6d.); "Volumetric Analysis," by F. Sutton (J. & A. Churchill, 18s. 6d.); "Commercial Organic Analysis," by A. H. Allen (J. & A. Churchill, vol. I., alcohols, starch, sugars, etc, 18s., vol. II., part 1, oils, fats, and glycerin, 14s., vol. II., part. 2, petroleum, coal-tar products, 14s., vol. II., part 3, phenols, aromatic acids, resins, and essential oils, 20s., vol. III., part 1, tannins, dyes, colouring matters and inks, 18s., vol. III., part 2, amines, nitrogenous bases, antipyretics and alkaloids, 18s., vol. III., part 3, vegetable alkaloids, bitter principles, cyanogen derivatives, 16s., vol. IV., proteins and albuminous substances, 18s.).

ACIDS AND ALKALIES.—"Sulphuric Acid and Alkali," by G. Lunge (Gurney & Jackson, 3 vols., £2 12s. 6d., £2 2s. and £2 2s.); "Coal-tar and Ammonia," by G. Lunge (Gurney & Jackson, £2 2s.); "Alkali-makers' Handbook," by Lunge and Hurter (Whittaker & Co., 10s. 6d.); "Ammonia and its Compounds," by Grossman (Harper & Brothers, 2s. 6d. net.); "Ammonia and Ammonium Compounds," by Arnold (Sampson Low, 5s.).

OILS (FIXED), FATS, AND RESINS.—"Oils, Fats, and Waxes, Chemical Technology and Analysis of," by Lewkowitsch (2 vols. Macmillan & Co., 36s. net); "Fats and Oils Industries, Laboratory Companion to," by Lewkowitsch (Macmillan, 6s. net); "Oils, etc., Analysis of," by A. C. Wright (Crosby Lockwood & Son, 9s. net); "Oils, Fats and Waxes," by C. R. A. Wright and C. A. Mitchell (Charles Griffin & Co., Ltd., 25s. net); "Soaps, Candles and Glycerin, Modern," by L. L. Lamborn (Crosby Lockwood, 30s. net); "Soap Making, Art of," by A. Watt (Crosby Lockwood, 7s. 6d.); "Soap Manufacture," by W. L. Gadd (George Bell & Sons, 5s.).

ESSENTIAL OILS AND PERFUMES.—"Essential Oils and Artificial Perfumes, Manufacture of," by E. J. Parry (Scott, Greenwood & Son, 12s. 6d. net); "Perfumes and Their Preparation," by G. W. Askinson (E. & F. N. Spon, 12s. 6d. net); "Cosmetics," by J. Koller (Scott, Greenwood & Co., 5s. net).

PAINTS AND POLISHES.—"Lubricants, Shoe Polishes and Leather Dressings, The Manufacture of," by R. Brunner (Scott, Greenwood & Son, 7s. 6d. net); "Paint, Manufacture of," by J. Cruickshank Smith (Scott, Greenwood, 7s. 6d. net); "Lake Pigments, Manufacture of," by F. H. Jennison (Scott, Greenwood, 7s. 6d. net); "Resins and Balsams, Analysis of," by K. Dietrich (Scott, Greenwood, 7s. 6d. net); "Painters' Colours, Oils, and Varnishes," by G. H. Hurst (Charles Griffin & Co., 12s. 6d.); "Paint and Varnish, Industrial and Artistic Technology of," by A. H. Sabin (Chapman & Hall, Ltd., 12s.).

GLUES AND ADHESIVES.—"Glue and Glue Testing," by S. Rideal (Scott, Greenwood & Son, 10s. 6d. net); "Sealing-waxes, Wafers, and other Adhesives," by H. C. Standage (Scott, Greenwood, 5s. net); "Glue, Gelatin and Allied Products," by T. Lambert (Charles Griffin & Co., 5s. net); "Cements, Pastes, Glues and Gums," by H. C. Standage (Crosby Lockwood & Son, 2s. 6d. net).

INKS.—"Ink Manufacture," by S. Lehner (Scott, Greenwood, 5s.); "Ink, The Manufacture of," by C. A. Mitchell and T. C. Hepworth (Charles Griffin & Co., 7s. 6d. net); "Oil Colours and Printing Inks," by L. E. Andes (Scott, Greenwood, 5s. net).

TAR AND WOOD DISTILLATION.—"Coal Tar Colours, The Chemistry of," by Benedikt (George Bell & Sons, 6s. 6d.); "Synthetic Dyestuffs," by J. C. Cain and J. F. Thorpe (Charles Griffin & Co., 16s. net); "Destructive Distillation," by E. J. Mills (Gurney & Jackson); see also Acids and Alkalies.

ELECTRO-CHEMISTRY.—"Electro-chemistry, The Elements of," by M. Le Blanc (Macmillan, 6s.); "Electro-chemistry," by R. A. Lehfeldt (Longmans, Green & Co., 2 vols., 5s. each).

MANURES.—"A Treatise on Manures," by A. B. Griffiths (Whittaker & Co., 7s. 6d.); "Fertilisers," by E. B. Vorhees (Macmillan, 4s. 6d.); Bone Products and Manures," by T. Lambert (Scott, Greenwood & Son, 7s. 6d. net).

WASTE PRODUCTS.—"Waste Products, Utilisation of," by T. Koller (Scott, Greenwood, 7s. 6d. net); "Trades' Waste, Its Treatment and Utilisation," by W. Naylor (Charles Griffin & Co., 21s. net).

PETROLEUM, ETC.—"Lubricating Oils, Fats and Greases," by G. H. Hurst (Scott, Greenwood & Son, 10s. 6d. net); "Oil Fields of Russia, and the Russian Petroleum Industry," by A. B. Thompson, £3 3s. net); "Petroleum, Technology of," by H. Neuberger and H. Noalhat (Scott, Greenwood & Son, 21s. net); "Petroleum and its Products," by Sir B. Redwood (Charles Griffin, new edition in press. 45s. net); "Mineral Oils and their By-products," by I. I. Redwood (Spon, 15s.).

CELLULOSE AND PAPER-MAKING.—"Cellulose," by C. F. Cross, E. J. Bevan, and C. Beadle (Longmans, 12s.); "Researches on Cellulose" (Parts I. and II.), by C. F. Cross and E. J. Bevan (Longmans, 6s. each); "Practical Paper-making," by George Clapperton (Crosby Lockwood, 5s.); "Estimation of Moisture in Pulp," by Otto Winkler (Clayton, Beadle & Stevens, 2s.); "C. B. S. Units or Standard Paper Tests," by C. F. Cross, E. J. Bevan, Clayton Beadle and R. W. Sindall (Spon, 2s. 6d.); "Six Lectures on Paper Manufacture," by Clayton Beadle (Croxley Institute, 3s.); "The Sampling of Wood Pulp," by R. W. Sindall (Becker & Co., 2s.); "A Textbook on Paper-making," by C. F. Cross and E. J. Bevan (Spon, 12s. 6d.); "Leunig's Tables of Sizes of Papers," by F. Leunig, (Mardon, Son & Hall, 1s.); "Chapters on Paper-making" (Vols. I. to IV.), by Clayton Beadle (Crosby Lockwood & Co., 5s.); "Fibrous Constituents of Paper," by Clayton Beadle (George Newnes, Ltd., 15s.); "Paper Technology," by R. W. Sindall (Griffin & Co., 12s. 6d.); "The Paper Trade," by A. Dykes Spicer (Methuen, 12s. 6d.).

PHOTOGRAPHY.—"The Chemistry of Photography," by R. Meldola (Macmillan, 6s.); "Optics of Photography and Photographic Lenses," by J. T. Taylor (Whittaker & Co., 3s. 6d. net); "Photographic Optics, A Treatise on," by R. S. Cole (Sampson Low, 6s.).

HISTORY OF OUR OWN TIME

The Rebellion in Canada The Corn Laws. Some Great Statesmen. The Crimean War. The South African War. China and Japan

By JUSTIN McCARTHY

THE reign of Queen Victoria began on the morning of June 20th, 1837. The young queen, born on May 24th, 1819, was, at the time of her succession, little more than eighteen. The Queen's first Prime Minister, Lord Melbourne, was a man of great personal kindness, but with slight gift of statesmanship, and Queen Victoria was obliged from the first to exercise her own good sense in the direction of affairs.

Among the leading men in political life were Lord Brougham and Lord Lyndhurst in the House of Lords, and Sir Robert Peel, Lord John Russell, and Daniel O'Connell in the House of Commons. Among the earliest events of the reign were the development of the railway system throughout the country, the application of the electric current to conveying messages along the wires, and the use of steam for ocean navigation. The Melbourne Administration did not last long, and was succeeded by that of Sir Robert Peel. The Queen, in opening Parliament, on January 16th, 1840, had announced her intention of marrying her cousin, Prince Albert of Saxe-Coburg-Gotha, and the marriage, which took place on February 10th, proved a most happy union.

The Rebellion in Canada. The opening of the reign saw the great rebellion in Canada.

The Canadian Colonies had been divided by an Act called the Constitution of 1791 into Upper and Lower Canada. Upper Canada was inhabited chiefly by a British population and Lower Canada by a population of French or French descent. Each of the provinces had a governor and an Executive Council appointed by the Crown, a Legislative Council, also appointed by the Crown for life, and a Representative Assembly, the members of which were elected almost altogether through the influence of the ruling authorities.

The two provinces, at heart hostile to each other, agreed only in hatred of the absolute rule of a British sovereign and Government in far-off Westminster. The memory of the American Revolution was still fresh in Canada, and it stimulated French Canadians especially into an effort at armed rebellion. The arbitrary measures employed by the Canadian authorities to subdue the rebels only made their resistance more serious, and won the support of Upper Canada. The rebellion probably might have been crushed by the Canadian authorities, but such a result would only have sown the seeds of further risings. Fortunately there were statesmen then in the British Parliament able to see that Canada could not be made loyal by military force. Lord John Russell introduced a measure to suspend for a time the constitution of Lower Canada, and to send out from England a Governor-General and High Commissioner empowered to deal with the rebellion and to remodel the constitution of Upper and Lower Canada.

Lord Durham, who had been in more than one Administration and was known as an advanced reformer, was entrusted with this office. He invited the two provinces to join him in forming a new system of government, and framed a constitution which united the two provinces into one colonial system, representative and self-governing in colonial affairs, thus founding that principle on which all of England's great colonies have since been conducted. Lord Durham returned to England, and the measure, in substance, was passed in 1840.

The Opium Traffic in China. In the opening of the Queen's reign there were disturbances in China between the government of that country and some of the British trading companies, which led to the Opium War. These troubles had been going on before Victoria came to the throne, and were caused by the policy of preceding sovereigns. British traders, under the old East India Company in the first instance, had insisted on importing opium into China and selling it to the Chinese in defiance of the laws of the Chinese Empire, which made its sale a punishable offence. The Queen's Ministers were endeavouring to end this odious traffic, when the disputes between the Chinese authorities and the opium dealers led to the outbreak of war, causing much loss of life on both sides.

The British ships of war, and the British soldiers soon gained the ascendency, and the Chinese government had to give way. Peace was made on the conditions that the Island of Hong-Kong should be ceded to Britain, and that five ports, of which Canton was the most important, should be thrown open to British traders, and that an indemnity should be paid to England for losses incurred. The Government explained that England could not interfere for the purpose of enabling British subjects to violate the laws of China, and that any loss such persons might suffer from the execution of the Chinese laws must be borne by those who brought that loss upon themselves. This announcement had been made before the actual outbreak of the war, and the war was carried on to its end.

The Afghan War. The Afghan War cast a gloom over the opening of the reign. Afghanistan is inhabited by various tribes each ruled by its own chief, and all in frequent rivalry and conflict among themselves. The Government of Queen Victoria was brought into Afghan trouble through the medium of the East India Company, which became involved in one of the disputes among Afghan states and unwisely sustained the claims of one of the rivals who were contesting for sovereignty over the state of Cabul, and for something like supremacy over the other divisions of the country.

The greatest figure in the struggle was that of Dost Mahomed, a man of remarkable ability both in war and in peace, and who professed to be, and indeed appears to have been, a friend to England. The Governor-General of India, however, resolved to treat Dost Mahomed as an enemy, and the English Government was thus drawn into a policy which brought about his conquest and dethronement. His rival, Shah Soojah, entered Cabul, the capital city of the state, by the help of British officers. He was regarded there as a usurper, and when the British army afterwards withdrew, leaving only a small force behind it, Dost Mahomed renewed his efforts, and in November, 1840, opened a brilliant campaign. Knowing, however, that he could not withstand the power of England, he gave himself up

to the English commander, by whom he was treated with courtesy and honour and was sent to India under British protection. There was an immediate outbreak in Cabul, and in the tumult that arose a brilliant English soldier and traveller, Sir Alexander Burnes, was murdered. Akbar Khan, the favourite son of Dost Mahomed, became a leader of a movement against Shah Soojah. The English general, seeing that the situation was hopeless with the small force at his command, entered into a treaty, the effect of which was that the British troops should quit Afghanistan at once, and that Dost Mahomed should be brought back from India.

The Retreat from Cabul. During negotiations a fierce controversy broke out between the British commander, Sir W. Macnaghten, and Akbar Khan, in which the latter, who afterwards declared that he believed he was about to be captured by the British troops, shot Macnaghten dead. It was agreed that the British should leave the Afghan territory. Then began the disastrous retreat of the English through the mountain passes between Cabul and the Indian frontier, during which they were constantly assailed by fanatical native tribes, and the wives and children of the officers and soldiers suffered terrible privations. Few of the military force reached the Indian frontier alive. Under the rule of Lord Ellenborough, the new Governor-General of India, the losses which had been undergone by England were repaired, and on September 15th, 1842, Cabul was again occupied by the British troops. On October 1st, Lord Ellenborough issued a proclamation, revoking the policy of his predecessor, and declaring that to force a sovereign upon a reluctant people would be inconsistent with the principle of the British Government, and that the British arms would be withdrawn from Afghanistan. Dost Mahomed was soon after released from exile, and became once again the ruler of Cabul, and Shah Soojah, whom the policy of England, as directed by the East India Company, had set on the throne, was put to death shortly after the departure of the British troops by orders of the Afghan chiefs.

Sir Robert Peel's Government. The Administration of Sir Robert Peel was made remarkable by many reforms in social legislation. An Act of Parliament prohibiting the employment of women and girls in mines and collieries was carried, chiefly through the influence of Lord Ashley, afterwards the Earl of Shaftesbury. Many reforms were made in the conditions of factory labour, in which Lord Shaftesbury also bore a prominent part. Sir Robert Peel also passed the measure for removing the test by means of which Jews were excluded from some municipal and other public offices. The most famous of Peel's reforms was the Abolition of the Corn laws, which imposed heavy and indeed prohibitive duties on the importation of foreign grain into England. A great movement against these restrictive laws had been got up by the Free Trade party, which became very strong in Manchester and throughout the North of England.

The movement was for many years led by Charles Villiers, but its most powerful promoters were Richard Cobden and John Bright. Richard Cobden was one of the most convincing debaters the House of Commons has ever known, and John Bright must be ranked among the greatest of England's parliamentary orators. Sir Robert Peel had not yet become a convert to the principles of Free Trade. The Whig party, led by Lord John Russell, did not at the opening of the anti-corn law movement give it their full adherence, but they soon accepted the principle and Sir Robert Peel was gradually brought round to the same position. The outbreak of a potato famine in Ireland forced Peel's hand, as it became evident that without the most liberal introduction of foreign grain the peasantry of Ireland must die off. Peel could not force some of his colleagues to accept a Free Trade principle, and he resigned. Lord John Russell was sent for by the Queen to form a ministry, but even amongst his Whig friends he could not obtain sufficient support, and the Queen urged Sir Robert Peel to withdraw his resignation. The Free Trade movement had the full support of Daniel O'Connell, because of its bearing on the condition of Ireland.

Peel formed a new ministry, and Parliament met on January 22nd, 1846. On the 27th Peel brought in his measure for the gradual abolition of the protective duties on grain, which were to be abandoned altogether after three years. The Bill went through the House of Commons, passed its third reading on May 15th, and was then carried through the House of Lords mainly by the earnest advice of the Duke of Wellington, who saw that the change to Free Trade was inevitable.

The Irish Famine. A vast number of deaths from starvation greatly reduced the population of Ireland, and the dread of another famine and the unjustifiable enactments which secured to the landlords absolute power over their tenantry caused a rush of emigration to the United States, to Canada, and to other British colonies, which reduced the population still more. When the famine broke out the population of Ireland numbered some 8,000,000, but between that time and our own it became little more than 2,000,000.

Ireland was inevitably much disturbed by the famine, and the tardy movement of remedial measures caused much trouble among the Irish peasantry. Peel was prevailed upon by some of his colleagues and supporters to introduce a Coercion Bill, with the object of restoring order in Ireland. The Prime Minister thus put his Government into a most critical situation. The Coercion Bill would be met with unyielding opposition by O'Connell and his followers; the Whigs, when out of office, usually opposed coercion unless when accompanied by promises of concession and reform. The English Radical members, under the leadership of Cobden and Bright, would be sure to oppose coercion even more strongly: while the disappointed Protectionists were willing to vote for once with the Radicals, the Whigs, and the Irish Catholics, because the Government had turned against them on the Free Trade question. The division on the second reading of the Coercion Bill on Thursday, June 25th, 1846, left the Peel Ministry in a minority of 73. Within three days Peel resigned, and was succeeded by Lord John Russell as First Lord of the Treasury, with Lord Palmerston as Secretary for Foreign Affairs. Peel's career as a statesman ended with his great triumph in the repeal of the Corn Laws. He did not return to office, and on June 29th, 1850 he met with injuries which caused his death.

Famous English Statesmen. Lord John Russell, Lord Palmerston, and Mr. Disraeli were the most prominent among English statesmen during the immediate following years. Lord Palmerston devoted his attention mainly to foreign politics, and was a moderate Liberal in his views on home affairs. He was an admirable debater, although hardly an orator. Lord John Russell held more advanced views on home politics and was more cautious in his dealings with revolutionary and anti-revolutionary movements abroad. Disraeli was one

of the most brilliant figures in the House of Commons and was famous as the author of political novels before he entered Parliament. During some early attempts to obtain a seat in the House of Commons he declared himself a Radical and a supporter of O'Connell's Irish policy. When he succeeded in the object of his ambition and found a constituency to elect him he had become a strong Conservative.

Lord John Russell's Titles Bill was introduced in February, 1851, because of a Papal Bull authorising the establishment in England of a Hierarchy of Bishops deriving their titles from their own sees. The Pope had divided England into several districts, to which he appointed archbishops or bishops, with Cardinal Wiseman as Archbishop of Westminster. Lord John Russell denounced the action taken by the Pope as a pretension of supremacy over the realm of England, and brought in his Ecclesiastical Titles Bill accordingly. Parliament opened on February 4th, 1851, and soon after Russell introduced his measure to prohibit the use of all such titles by Catholics under penalty, and to render null and void all bequests made to or acts done by persons under such titles. The Bill passed through all its stages with some modifications, but the Roman Catholic archbishops and bishops still took their titles as before, and the Act was never put into force.

The Crimean War. The Crimean War was mainly the result of Russia's growing power in Europe and in the East, which was believed by many European statesmen to be a danger to Powers which, like England, had interests to guard in Asia as well as in Europe. The growth and the political ambition of Russia became a menace to Turkey especially, and, indeed, threatened the Ottoman Empire with ultimate destruction. The immediate cause of dispute between Russia and Turkey had to do with the manner in which Christians from Russia, Greece, and from other countries were treated by the Mohammedan ruler of Turkey. An alliance was formed between England and France, then under the rule of Napoleon III., with the object of compelling Russia to modify her policy of aggression against Turkey.

Austria and Prussia took a part at first with England in forming this alliance, but Prussia withdrew at an early stage of the arrangements, and Austria never became an active partner, although she continued to exert some influence. Sardinia, one of the small separate Italian states, eagerly grasped the opportunity of taking a part in European affairs by becoming a member of the Alliance. Turkey declared war against Russia, and then England, France, and Sardinia took the field. There was splendid fighting on both sides, many great battles like that of the Alma and of Balaclava, and the prolonged siege of Sebastopol. There was a want of generalship among English and French alike: no soldiers ever fought better than those of England and France, but there was a sudden and almost complete breakdown in the arrangements made for the food and clothing of the English troops. The services of the newspaper war correspondent created during this campaign an era in the history of warfare. They kept the world informed day by day of the events of the war, and compelled the attention of the authorities in England and France to the want of needful preparations for the health of the troops.

Another memorable event of the Crimean War was the splendid movement originated by Florence Nightingale in organising a little army of nurses to attend to the wounded in the field.

Sebastopol. The war came to an end by the capture of Sebastopol, which the Russians had set on fire before abandoning. The Emperor Napoleon was anxious to get out of the whole enterprise, and a congress was held at Paris on February 26th, 1856, and on March 30th the treaty of peace was signed. By this treaty Sebastopol and all other places taken by the Allies in the war were given back to Russia. The Sultan issued a decree to improve the condition of his Christian subjects, the Black Sea was neutralised, and the navigation of the Danube was thrown open. Two of the Sultan's Christian provinces, Moldavia and Wallachia, while continuing under the nominal rule of the Porte, were to be guaranteed the rights of citizenship, and out of these two provinces grew the kingdom of Roumania. The results of the war were hardly worth to England the blood and treasure it had cost. Sardinia gained the most, because the position she had taken as an ally enabled her to put herself forward as the representative of the whole Italian people. The Crimean War was still fresh in the memories of Englishmen everywhere when the great Indian Mutiny broke out, the story of which has been told in another place.

The close of 1861 brought with it the death of the Prince Consort, and after his death the Queen withdrew almost altogether from social life.

The year 1868 saw the conclusion of the celebrated British expedition into Abyssinia. This expedition was organised because of great alarms felt in this country as to the fate of a large number of British subjects held in captivity by Theodore, King of Abyssinia, who chose to consider that England had become unfriendly to him. All efforts failed to induce Theodore to surrender his prisoners, and at last the British Government made preparations for war. An expedition organised under the command of Sir Robert Napier was admirably planned and carried out from first to last. It had little danger to meet in the way of armed opposition, for there was no Abyssinian force which could hold out against the British troops. The expedition was a complete success, and reached the front of Magdala in the beginning of April, 1868. Theodore was ultimately compelled to restore all the prisoners in the hope of saving his capital and himself; but he would not surrender, and Sir Robert Napier felt that he could not leave other British residents at the mercy of such a monarch. Despite the immense difficulties of its position, Magdala was captured, and when the gate was forced open the dead body of Theodore was found inside. Napier destroyed the fortress of Magdala, and no attempt was made to interfere further with the internal affairs of Abyssinia.

Trouble in Egypt. The winter of 1881 saw the opening of new troubles for England in Egypt. At that time Egypt was under what was called the dual control of England and France, each of which states had done much fighting to secure its interests there, while the Ottoman Sultan still held a nominal control over the nominal sovereign or Khedive. Egypt was governed almost altogether by English and French officials, and the result was the formation of an Egyptian national party under the leadership of Arabi Pasha, a brilliant Egyptian officer.

He had been appointed War Minister under the Khedive, but soon became really master of the Egyptian Administration. It was evident that an Egyptian rebellion against the dual control was springing up, and the ironclads of England and France were ordered to Alexandria. The Khedive endeavoured to dismiss Arabi Pasha, but the leaders of the

army refused to obey his order. Arabi Pasha seemed as if he were already beginning preparations for war. Disturbances broke out in Alexandria, and some English and French subjects were killed, for which Arabi Pasha was undoubtedly indirectly responsible. As France did not seem disposed to interfere, the English authorities determined to act. An attack was made upon Alexandria by the British Fleet, and a bombardment began. Then Arabi Pasha hoisted a flag of truce, and without waiting for any negotiations withdrew his soldiers from the fortifications, and Alexandria was occupied by the British. There was still some fighting to be done, and Sir Garnet Wolseley was sent to command the operations. Arabi entrenched himself at Tel el Kebir, but the British advance was made so rapidly that the struggle was over almost as soon as it began. Arabi was made a prisoner and sentenced to death, but the sentence was commuted by the Khedive to a sentence of banishment. The dual control soon vanished after this, and England has since occupied Egypt.

The bombardment of Alexandria by the British forces led to the retirement of John Bright from the Gladstone Cabinet, because he could not agree with the policy of using force for the coercion of Egypt.

The Boxer Movement. Great troubles broke out in China in 1898 which compelled the active intervention of England. The increasing immigration of foreigners into China aroused a passionate clamour amongst the Chinese against the modern policy which allowed foreigners to hold property there. A powerful party of reactionary Chinese, called the Boxers, sprang up all over the country, which made it a first object to banish all foreigners from China. Many outrages were committed by the Boxers on Christian missionaries, and the American missionary buildings near Pekin were burned. The foreigners formed an allied squadron of vessels—English, German, French, Russian and Japanese—and these were compelled in self-defence to fire on the Chinese forts, which had opened fire on them, and to capture and hold the forts. Actual war had set in by this time between the Chinese and the foreign Powers, and its outbreak was precipitated by the murder of the German Minister, Baron von Ketteler, in the open street, by a civil officer of the Chinese Government. The foreign Powers were compelled to enter into an alliance, and an expedition was got under way from Tientsin on August 4th, 1900. The combined forces were British, French, Germans, Russians, Americans, Italians, and Japanese, numbering little more than 20,000 men. The allied troops had to fight their way to Pekin, the Chinese troops, who were well supplied with artillery, fighting from behind entrenchments. They reached Pekin, forced an entrance, and on August 26th the city was surrendered, and a detachment of the Allies marched through the capital to proclaim their victory. The Chinese Government were compelled to make peace with the Allies, and amongst the conditions was the infliction of severe punishment on Chinese even of high rank, convicted of having encouraged the attacks upon foreigners. It was also stipulated that some reform should be made in the methods of Chinese government concerning the admission and protection of foreign residents.

War With South Africa. The struggle for the suzerainty of the Transvaal Republic spread over more than twenty years of Queen Victoria's reign, and was only brought to a head in the reign of King Edward VII. The Transvaal Republic had been founded by Dutch Boers, or farmers, in 1848, and thus became a state in the neighbourhood of the great British settlement in South Africa extending to the Cape of Good Hope. The policy of the English Colonial governors in South Africa was directed towards the forming of a federation of all the states and of the Orange Free State, another colony also founded by Boers, to be held under the protection, and, in fact, the sovereignty of England. The Transvaal Republic resisted these proposals, and was afterwards joined by the Orange Free State, and war broke out, in which the Boers fought pertinaciously, and with many advantages on their side.

The Struggle in the Transvaal. The English had to conduct the invasion of the Transvaal, a region of vast extent, broken by great mountain ridges and vast swamps, in which the Boers could always choose their own points of defence and compel their adversaries to follow them. The English had an incalculable advantage in the number of their force, and in all the means of carrying on the war; but the difficulties in their way were so many and perplexing that at one time it seemed as if nothing less than the extirpation of the whole fighting population of the Boers could end the struggle. In December, 1880, the Boers proclaimed the Republic of South Africa with Paul Kruger as its President. During the night of February 26th, 1881, took place the engagement at Majuba Hill, in which the English troops, under General Colley, were defeated and their general killed. General Sir F. Roberts was then sent out to South Africa, but in the meantime the Boers had, with characteristic prudence, proposed an armistice, and afterwards expressed a willingness to enter into terms of peace. A treaty of peace was agreed upon early in August, the terms of which were that the Transvaal territory should be assigned to the Transvaal state, but that that state should be subject to the suzerainty of Queen Victoria, who was to be represented by a British Resident. This arrangement met with extreme disfavour among large numbers of influential Englishmen at home, who argued that England never should have consented to enter into terms of peace with an enemy after a defeat had been inflicted on the arms of England.

The Jameson Raid. The South African question was destined to be yet a source of trouble. The discovery of gold and diamond mines in the Transvaal region had brought a rush of settlers from all parts of the world, and from England in particular, and a large population had soon established itself in the Transvaal to whom was given the expressive name of Uitlanders, or Outlanders, who claimed votes and recognised citizenship in the Transvaal. President Kruger and his Government insisted on obtaining conditions of residence which, though not very severe in themselves, led to much agitation among the Outlanders. An invasion of the Transvaal by a number of the Outlanders was actually undertaken, under the leadership of Dr. Jameson, in 1895, but the invaders were met by a large force of Boers and compelled to surrender. Events now drifted rapidly towards a renewal of the war between England and the South African Boers, and in December, 1899, Lord Roberts, one of England's most famous generals, was sent out to take command. The war lasted for three years. The difficulties in the way of any rapid conquest were just the same as those which met the British commander and troops in the former Transvaal war.

The relief of Mafeking by the English troops

excited a tremendous enthusiasm through England. The Orange Free State was conquered and annexed, and then President Kruger, realising that all hope for the Transvaal was gone, fled from Pretoria, the capital, which was entered by Lord Roberts on June 5th, 1900. There were some further struggles and a long period of negotiations. The Dutch offered concessions from time to time which the British Government refused to accept, but it had become apparent to everyone that the actual war was over. A peace conference was held in May, 1902, in Pretoria. The British terms were unconditional surrender and the annexation of the Transvaal and the Orange Free State to the British Empire, but with the right of these states to local self-government, and the undertaking that no death penalty was to be inflicted on any of those who had fought in defence of the South African States. England has since allowed to the Transvaal its full power of local self-government, and it holds now a position like that of Canada or one of the Australasian colonies.

Some Great Reforms. The reign of Queen Victoria was essentially a period of reform. The system of transportation for convicts found guilty of any crime making them liable to a penalty short of capital punishment was abolished in 1857, and the system of penal servitude and tickets of leave, which had been extending its application became definitely set up in its place.

The reign was distinguished by reforms of all kinds—in constitutional and political arrangements, in jurisprudence and its workings, in the application of medical science, in financial systems, in universities and colleges and schools, in art and letters. We have already described the movement for the introduction of Free Trade in corn, and there had been more lately a commercial treaty with France accomplished mainly by the intelligence and the persuasive powers of Richard Cobden during the reign of Napoleon III.

The principle of religious equality was developed during the reign of Queen Victoria in a manner which makes the reign an era in England's history. Flogging in the army was abolished after years of agitation by a small and enlightened minority in the House of Commons. The Divorce Court has been set up and the old-fashioned, enormously expensive procedure through the House of Lords has become one of the curiosities of past history. In the political world we have had many great reforms, some of which have almost entirely cleared the air from the foul atmosphere of bribery and corruption which for many generations suffused our narrowly limited electoral system. Great political changes during Queen Victoria's reign were made by Conservative as well as by Liberal administrations. Disraeli having, as the leader of the Conservatives, defeated a very moderate Liberal measure of Parliamentary reform, introduced, when he became Prime Minister, another measure going much farther. Gladstone, at the head of a Liberal Ministry, introduced more lately the measure which set up the political system we have now in existence, practically establishing manhood suffrage.

Gladstone's Home Rule Bill. In 1886 Gladstone, once again in power, became convinced that the Irish Nationalist Party, the large majority of the Irish members of Parliament, were really the spokesmen of Ireland's demand for Home Rule. He brought in a measure for the creation of a statutory Parliament in Ireland, which was defeated on its second reading by the Conservative Opposition, with the help of many dissentient Liberals, and Mr. Gladstone, having appealed to the country, was defeated also at the General Election. But at the General Election of 1892 the Liberals, with the Irish Nationalists, secured a majority over the Unionists, and in 1893 Gladstone's second Home Rule measure passed through the Commons, but was thrown out by the House of Lords. Since that time the Irish National movement has been growing steadily in strength and in popular acceptation.

On January 22nd, 1901, Queen Victoria breathed her last. With her death the longest reign recorded in England's history came to an end. She was the first really constitutional sovereign who had ever occupied the English throne, and was succeeded by her eldest son, Albert Edward, known as Edward VII.

CHINA AND JAPAN

China and Japan were, in Queen Victoria's reign, beginning to break out upon the world in quite a new light. Europe was during many centuries brought into occasional intercourse with China, and England had especially been brought during many succeeding generations into conflict with the rulers of the Chinese Empire. But Japan had remained a state in absolute seclusion from the European world, just as she had been from the opening of her history. Suddenly, in 1867, a revolution broke out against the feudal system, which had hitherto ruled Japan, and with the success of that revolution the progressive party which came into power reversed all the traditional ways of the Japanese people. Japan seemed to have undergone a new birth. The passion of the Japanese now was for everything new, for everything belonging to modern Europe and to the United States: for the newest methods of political government, the newest developments of science and letters and art, the newest fashions and fantasies. The first railway in Japan was opened in June, 1872. Telegraph wires were soon conveying their flight of messages over the whole country and from the country abroad. The fine arts and the letters of Europe were studied everywhere with avidity.

A New Power in the Far East. But it was not only in the arts of peace that the Japanese began to take a sudden interest. Japan appeared to be inspired by a desire to become proficient in the knowledge and the practice of the modern warfare, and in these the Japanese showed themselves marvellously successful. Japan became entangled in a war with China for the over-rulership of Corea, and the Japanese unquestionably had the best of the struggle. From that time it began to be apparent to the whole world that Japan was determined to emerge once for all from her long seclusion and to become a conquering power. She adopted the principle of constitutional representation, and on July 1st, 1890, she opened her first national Parliament. But Russia at this time began to prove herself a determined opponent to the spread of Japanese influence in the Far East. Russia, although, strictly speaking, one of the European Powers, was, because of her vast Siberian territory, growing civilisation, and rapidly developing railways, making her influence widely felt throughout Asia. A power determined to rise like Japan was sure to come sooner or later into antagonism with Russia. This is what happened, and the result was a war which the whole world watched with keen anxiety. The outcome was a complete victory for Japan, and it then became evident that a new power had arisen in the Far East.

Concluded

SHOOTING AND FIXED STARS

Continued from page 6579

Atmospheric Bombardment. Nature and Constitution of the Stars. How Starlight takes Years to Reach the Earth. The Universe a Disc. Cosmical Evolution

By W. E. GARRETT FISHER

METEORITES, or shooting stars, have been known to mankind from the earliest times, though it is only of late years that their intimate association with comets has been discovered.

Aerolites. Shooting stars must be divided into two classes. There is the solitary *fire-ball* or *aerolite* [**40**], which sometimes assumes very respectable dimensions, like that which burst over Madrid a few years ago, or that which once strewed the plains of Arizona with vast masses of meteoric iron. These visitors can never be predicted, though few nights in the year pass without one or more of them being visible to the careful watcher of the skies. They are masses of rock, chiefly consisting of pure iron, which collide with the earth as it travels through space, but are fortunately prevented, as a rule, from dashing against its surface by the convenient buffer interposed by the atmosphere. The resistance of the air, which is practically experienced by cyclists struggling with a head wind, increases very rapidly with the velocity of a body moving through it. It is the most serious factor in the flight of a modern projectile, and a meteorite which enters the air with a velocity of many miles per second is promptly raised to such a temperature by the atmospheric resistance to its motion that it is rendered incandescent and dissipated into vapour or dust, unless its size is very great. In the latter case it breaks up into a number of small pieces, with a flash and a report which is sometimes heard on the surface of the earth, and these pieces may ultimately reach the ground.

Many specimens of such aerolites are to be seen in the Natural History Museum at South Kensington; the Sacred Black Stone of Mecca and the image of Diana, which was said to have fallen from heaven at Ephesus, are believed to be the remains of such meteorites. But, as a rule, visitors of this kind are entirely consumed in the upper regions of the air. The *luminous streak* which they leave behind them as we watch them on a clear night is composed of their disintegrated dust raised to incandescence by the friction of the air. This dust slowly settles down upon the surface of the earth, and is frequently met with in the ooze of the deep seas and among the sands of the deserts. It has been estimated that between 1,000,000 and 2,000,000 of these shooting stars are encountered by the earth in every twenty-four hours. If it were not for the atmosphere we should be bombarded by these projectiles in a fashion far more perilous than any known to Ladysmith or Port Arthur.

Star-showers. In addition to these solitary and mostly invisible aerolites, the earth encounters meteor swarms which are of periodical occurrence. The most conspicuous and famous of these are the November meteorites, known as the Leonids, which used to give rise to a wonderful display of celestial fireworks once every thirty-three years. From very early times men have recorded the fears produced by the contemplation of this wonderful and brilliant onset of stars shooting madly from their spheres. In 1833 the negroes of the Southern States were quite persuaded that the end of the world was at hand. The sky was said to be as full of shooting stars as it is of snowflakes in a winter storm [**41**]. They reappeared in 1866.

Something has recently gone wrong with these Leonid meteorites, and the display which was confidently expected about 1899 never took place. There are several hundred of these meteor-showers known to astronomers, and hardly a week in the year passes when one or more of them is not due. Each shower is recognisable by the fact that it seems to come from a particular place in the heavens, and it is usually named after the particular constellation from which it comes. Thus the two chief November star-showers are the Leonids, coming from the constellation of Leo, and the Andromedes, coming from the constellation of Andromeda. A star-shower due about the 10th of August, popularly known as the Tears of St. Lawrence, consists of the Perseid meteorites, coming from the constellation of Perseus. The point from which any particular star-shower appears to come is known as its *radiant*, and is found by tracing the path of each observed meteorite upon a star chart; the point in which all these paths meet—their vanishing point—is the *radiant point* [**42**].

Meteoritic Swarms. Many of these star-showers occur year after year on the same night, whilst others, like the November Leonids, occur on the same night at intervals of many years. There is only one plausible explanation of this fact.

The shooting stars which become visible by contact with our atmosphere on a particular night in the year must belong to a swarm of such bodies travelling round the sun in a definite orbit, which intersects the orbit of the earth at the point which our planet reaches on that night. At every meeting a considerable number of these minute bodies are sacrificed by contact with the earth, but their number is so great that there seems to be no appreciable diminution in it. If the meteoritic swarm be distributed with evenness along the whole of this orbit, there will be a display of shooting stars of pretty much the same brilliance every year.

In the case of meteorites like the Leonids, which only appear once in thirty-three years, the main body of the meteorites must be concentrated into a swarm which travels round its orbit at such a speed that it only passes the earth's orbit while the earth is in that neighbourhood once in thirty-three years. The explanation of the failure of the Leonids to appear when they were last due is that some external cause has changed their motion by perturbing their orbit so that now they just miss the earth. The orbits of a considerable number of these meteorite swarms have now been calculated—a wonderful achievement when we remember that they can only be studied in the brief instants in which they are burnt up by the contact with our atmosphere.

A Comet is a Meteoritic Swarm. Soon after the great shower of November meteorites in 1866, it was shown by an Italian astronomer, Schiaparelli, that the orbit which has been assigned to the Perseids or August meteorites was identical

with that of a comet which had been observed in 1862. Soon afterwards the orbit of the Leonids or November meteorites was also calculated, and it also turned out to be identical with that assigned to a comet which had been discovered by Tempel in 1866. Next the Andromeda meteorites, which meet the earth in the latter part of November, were found to move in the track of Biela's comet. Since then at least five other meteoritic swarms have been found moving in orbits coincident with those of comets.

It is impossible to suppose that all these coincidences are accidental. It is now believed that a comet is simply a meteoritic swarm, and that when it disintegrates—as more than one comet has been seen to do—it breaks up into a crowd of meteors, which tend to be scattered gradually more and more thinly along its orbit, until in the lapse of time there results an orbit covered from end to end with a thin ring of flying meteorites. These meteorites are mostly quite tiny bodies—mere specks of cosmic dust—though some are sufficiently large, as we have seen, to endure the intense heat which they undergo in passing through the atmosphere and still reach the earth as a solid mass. There is good evidence that at least once or twice many tons of solid iron have thus been precipitated to the earth; fortunately for our comfort, such evidences are rare, and are not known to have occurred in historic times.

The Fixed Stars. We have next to study the nature and constitution of the so-called *fixed stars*. Our sun is a body of the same kind as the stars, of which about 3,000 are visible to the naked eye in our hemisphere, and many of which are, in reality, far larger and brighter than our luminary. Yet their vast distances make them appear only sparkling points of light—for no telescope that man is ever likely to make can be expected to reveal the physical features of any of the fixed stars. The spectroscope, however, has told us nearly as much about their chemical construction as about that of the sun, while the telescope and spectroscope, with the gravitational theory, have revealed the most wonderful facts about their movements.

The fixed stars are arranged for convenience in certain groups or constellations, of which about eighty-six are recognised. Most of these constellations date from times when the heroes and totems

40. METEORITE FOUND IN OREGON IN 1902
(From "Knowledge")

of early civilisations were placed in the sky by a race living in the Euphrates Valley; many of them were afterwards modified to suit Greek mythology. The particular stars of each constellation are denoted by the Greek letters of the alphabet, Alpha, Beta, Gamma, etc., beginning with the brightest. Where it is necessary in telescopic work to deal with a greater variety of stars, they are given numbers or indicated by their place in some catalogue of stars. The brightest of the stars have also names of their own, like Sirius and Aldebaran.

The stars are classified according to their brightness in a series of *magnitudes*. On the original and rather rough scale, a star of any given magnitude is about two and a half times brighter than the average star of the magnitude immediately below it. There are twenty stars of the first magnitude, which differ greatly in brightness. Sirius is more than fourteen times as bright as Regulus, but both stars are called of the first magnitude. Stars of the sixth magnitude are the faintest normally visible to the naked eye. The more exact photometric methods of modern astronomers have led to more exact classification by tenths, and even hundredths of magnitudes, and in the case of the brightest star a negative magnitude has been introduced; thus Sirius, the most brilliant of the fixed stars, is said to be of magnitude $-1{\cdot}58$. A typical first magnitude star is Betelgeux, in Orion. The stellar magnitude of the sun, on this scale, would be about -26.

Parallax of the Stars. The prime fact about the fixed stars is that they are all situated at gigantic distances from the sun and from one another. For a long time the strongest objection to the theory of Copernicus was that if the earth really changed its place by an annual translation of more than 180,000,000 miles, the stars would have an altogether different appearance in perspective when the earth was at opposite ends of its orbit. The truth is that some of them do look differently to us at intervals of half a year, but the diameter of the earth's orbit is so tiny in comparison with the distance of the nearest star that any change in the apparent configuration of the stars caused by our motion from end to end of it is quite imperceptible to the naked eye, and can only be measured by the most accurate observations with powerful telescopes.

Some of the stars thus display an *annual parallax*, or show a slight difference in direction, according to which end of the earth's orbit we are looking from. The annual parallax of a star is, as already explained, equal to the angle which would be subtended at that star by twice the distance between the earth and the sun. But there is no star in whose case this parallax would amount to as much as a single second of arc. As Miss Clerke puts it, the annual shift of no known star amounts to as much as the width of a sixpence held up at Charing Cross and seen by an observer at Stanhope Gate or Millbank. The difficulty of measuring quantities of this nature is obvious. The most delicate instruments and the most refined handling are necessary for tackling the problem. Yet it has been successfully solved in the case of a fair number of stars.

The Unthinkable Distances of the Stars. Stellar distances, as will now be seen, are so gigantic that we are forced to measure them in terms of some different unit from that ordinarily used in computing distances. The nearest star is 275,000 times as far away as the earth is from the sun. Even this distance, if set forth in miles, would be quite unrealisable. To measure the distance of a star in terms of its parallax, though perfectly convenient for astronomers, has two objections for popular use, since the distance varies inversely as the parallax, and the latter has always to be expressed in small fractions of a second. Consequently, the unit which has been generally adopted for expressing the distances of the fixed stars is that known as the *light-year*. This is the distance over which light would travel in a year.

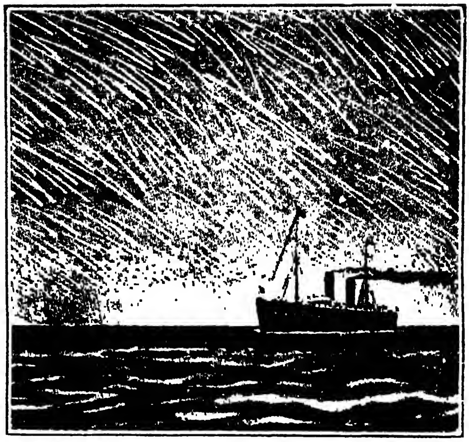
This distance can be computed in miles by multiplying the number of seconds in a year by the speed of light—186,330 miles per second. It is more useful to know that the light-year is 63,243 times the mean distance of the earth from the sun, over which light passes in 449 seconds. Thus the light-year is to the distance of the earth from the sun almost exactly as a mile is to an inch. A star with a parallax of one second is at a distance of 3·26 light-years from the earth. To find the distance of any star from its parallax we can use the simple formula $d = \frac{3 \cdot 26}{p}$, where d is the distance in light-years and p is the parallax in seconds. The nearest of all stars is the brightest star of the constellation of the Centaur, Alpha Centauri, which has a parallax of 0·76 seconds, and is consequently at a distance of 4·3 light-years from the sun.

The Scale of the Universe. Let us try to get a rough practical idea of what this means. Suppose we are making a model of the solar system and the stars. Let us start by taking a swan shot $\frac{1}{8}$ in. in diameter to represent the sun. The earth will be represented by a tiny speck of dust 1 ft. distant from this central globe. The superior planets come at distances varying from 5 ft. in the case of Jupiter to 30 ft. in the case of Neptune, the outermost planet. Some of the periodical comets travel out a good deal further into space—perhaps as much as 200ft. or 300 ft. But in order to get the nearest of the fixed stars into our model, we have to travel out for 50 miles before we reach its place on the same scale.

This will give the student some idea of the amazing isolation of our system. There is good reason to suppose that the average distance of the stars from one another is on pretty much the same scale. Some of the most conspicuous and brilliant stars, such as Canopus, Arcturus, and the bright star Rigel in Orion, have yielded no perceptible parallax, which means that their distance can be in no case less than 110 light-years. Among the nearest stars to the earth are Sirius (8·6 light-years), Procyon (10·9), Fomalhaut (23·3), and the Pole Star (44). The determination of stellar parallaxes is one of the most difficult tasks an astronomer can undertake. Photography has greatly helped in it, but as yet there are little more than 70 stars whose parallaxes are well determined. These, however, afford a scale for judging the size of the universe, and it has been estimated that the smallest stars visible in the most powerful modern telescope may some of them be at such a distance that their light would take more than 30,000 years to reach the earth —that is, in the model already described they would have to be placed farther away than the moon!

How History might be Lived Again. We may just remind the reader that this means, among other things, that if such a star were to be destroyed to-day by some catastrophe its light would continue to shine upon us for 30,000 years, and only at the end of that period would astronomers notice its disappearance. When we look at the star-strewn heavens, we are really gazing not only into the depths of space, but also into the dark backward abysm of time. We see the moon not as it is now, but as it was a little more than a second ago; the brilliant Dog Star shines on us with the radiance which lit it more than eight years before to-night.

Some of the other stars, and those among the brightest, we see not as they are now, but as they were at the time of the Spanish Armada or the Norman Conquest. A French astronomer has made a very interesting and perfectly sound deduction that a disembodied spirit which was able to move instantaneously through space to any distance from



41. METEORITIC SWARM

the earth, and was also able to see things clearly through any distance, could at will actually see any event which has taken place on the earth since the beginning of its history—at least, in the open air and under a clear sky—by simply travelling out to the distance to which the light rays carrying the picture of that scene have now advanced.

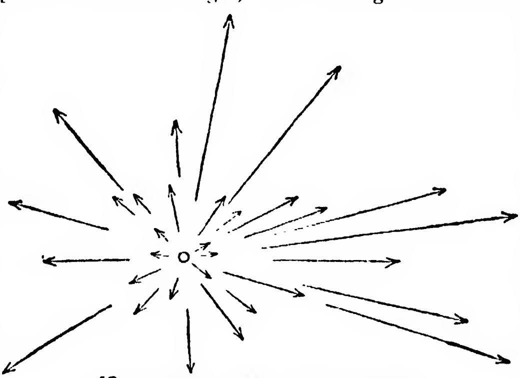
The Real Magnitude of the Stars. Having grasped the conception of the immense distances which separate us from the fixed stars, we are now in a position to see that these stars must in reality be gigantic suns. Wherever we can measure the distance of a bright star, we can make a rough calculation of its size by comparing its light with that given by the sun. We see at once that many stars must in reality be very much larger and brighter than our sun. Sirius, for instance, is at a distance of rather more than eight light-years; if the sun were removed to this distance, it would only give one-thirty-sixth as much light as Sirius gives, and we consequently infer that Sirius is thirty-six times as powerful a light giver as the sun. There are, of course, two factors in such a result. Sirius may either be very much bigger or very much brighter than the sun. We shall see directly that in many cases we are able to measure not only the brightness, but the mass of a star.

Some of the other stars are far larger still. Arcturus, which is about 126 light-years away, must be at least a thousand times as luminous as the sun. Canopus, the second brightest star in the sky—never visible in our latitudes—has shown no parallax at all, wherefore it must be well over 100 light-years away. At that distance our sun would shrink to a star of the tenth magnitude, absolutely invisible to the naked eye, and it can be calculated that Canopus is equal to at least 22,000 suns lumped together. No doubt many tiny telescopic stars, sunk in infinite space, are really still more brilliant and gigantic stars. Our own sun, in short, must be regarded as quite a second-rate member of the starry host.

The Motions of the Stars. Many stars not only show the annual shift of a fraction of a second which is due to parallax, but also change their position very slightly from year to year in consequence of their *proper motion*. There are two ways in which this motion can be measured. One is by the actual displacement of a star on the celestial sphere. About a hundred stars are now known which thus move a second or more per

annum. Such a displacement is perfectly measurable by modern instruments, though it only means that in about 2,000 years such a star would move over a distance equal to the diameter of the full moon. The star which has the greatest proper motion yet known moves over about eight seconds in the year. It is, unfortunately, invisible to the naked eye. If we know the approximate distance of such a star from the earth, we can, of course, calculate its actual velocity.

Runaway Stars. Thus, the extraordinary discovery has been made that the gigantic Arcturus is flying through space with a velocity of 257 miles per second—about 14 times that of the earth. What makes this so extraordinary is that the gravitational theory tells us that a star flying at such a speed cannot possibly be checked by the united gravitation of the whole known universe. It cannot be moving in an orbit, as almost all the heavenly bodies do, but seems to be engaged in a headlong rush through space, traversing the universe as an express train dashes through a wayside station. There are a few other stars of which the same thing has to be said. But, as a rule, the motion of the stars turns out to be similar in kind to that of the earth itself. Where their paths have been noted for a series of years, they generally prove to be not straight, but curved—parts of some vast orbit, which, in many cases, we are able to calculate, as will be shown when we come to speak of double stars.



42. RADIANT OF A STAR-SHOWER

There is a more modern way in which motions of the stars can be measured with even more accuracy. Of course it is not the case that all the stars which we see moving on the face of the heavens travel at right angles to our line of sight. Their paths lie in all possible directions, and all that we see of them is their fore-shortened projection on the imaginary sphere of the heavens. It will be apparent that a star which happens to be travelling straight towards the earth would not seem to be moving at all. But the spectroscope, among its numerous aids to astronomers, enables us to measure a star's motion in the line of sight with remarkable accuracy. This is in virtue of what is known as *Döppler's principle* [see page 3260], which may be briefly explained here.

Measuring the Stars' Velocities. We have already seen that the spectroscope breaks up the light given by any star into a series of lines, each of which has a defined place corresponding to the gas which gives birth to it. This is due to the fact that light of any particular wave-length is refracted to a definite extent. But suppose that the luminous object is travelling toward the spectroscope. The result will be that the light which it emits will reach the spectroscope with its own speed plus that of the moving body. Consequently, a greater number of light-waves will reach the prism in a second than would be the case if the luminous object were at rest. This causes a shift of all the lines in the spectrum through a distance which, though very minute, is capable of being measured with sufficient accuracy to reveal the stellar velocity in question.

The principle is exactly the same as that by which, when an express train dashes through a station, whistling all the time, the note of its whistle changes in pitch as it passes the observer. When the engine is approaching, a greater number of sounds reach the ear in every second, and the pitch of the whistle seems higher than it would be if the engine were at rest. When the engine has passed, the number of sound impulses in a second is diminished, and the pitch of the whistle drops noticeably. In the same way, the lines in the spectrum of any star shift towards one end or other, according as the star is travelling towards us or from us, and the amount of shift is proportional to the star's velocity in the line of sight. In this way, the speed of many stars towards or from the earth has been measured, and the combination of these two methods of measurement in many cases gives us, by composition, the actual speed and direction of the star's motion.

The chief result of such investigation is to show that there is no such thing as rest in the universe; every star that we can examine is in motion, and this, of course, is perfectly in accordance with the teaching of dynamics, which tells us that no such thing as a state of absolute rest can exist. All the stars which mutually attract one another are moving in vast orbits, with the exception of the few runaway stars like Arcturus, which seem to have come from the outer void of space and to be hastening back to it again.

Multiple Stars. One of the first discoveries of the telescope was that many of the stars which seem single to the naked eye really consist of two or more, very close together. The first double star discovered was the middle star in the tail of the Great Bear, which shows to great advantage, even in a small telescope. Another very fine double star, easily visible, is Castor, in the Twins. More than 12,000 of such pairs are now known. It is, of course, possible that a pair of stars, apparently so close together that they blend into one to the naked eye, may really be separated by a distance of many light-years, since they happen to lie in the same line of sight but at very different distances from the earth. But by far the greater number of double stars are physically connected pairs, which revolve in an orbit round a common centre of gravity.

Measurements made with the spectroscope show a double shift of the lines, which can only be due to the existence of two stars moving in opposite directions. In many cases this shifting of the lines has been observed to change periodically, so that the actual period in which the two stars complete their orbit can be accurately measured, though neither of them is ever visible separately. As an example of a typical double star, we may take Alpha Centauri, which consists of two stars nearly equal to our sun, which complete a very elliptical orbit about their common centre of gravity in about 81 years. Sirius, again, is the visible member of a double star, and has a companion of half its own mass, but 4,000 times less luminous, the pair completing their

orbit in about half a century. Not only double stars, but triple, and even higher, combinations exist in the heavens. In many cases these associated suns have strongly contrasting colours, which make them very beautiful objects in the telescope, and must create extraordinary conditions of vision for the possible inhabitants of a planet which happens to circle round one of them. Blue, green, red, and yellow stars are sometimes found, all associated together in a single system.

Colours of the Stars. Even with the naked eye we can see that the stars vary in colour. Some, like Aldebaran, Antares, and Betelgeux, are fiery red; others, like Vega, near the Pole, shine with a bluish lustre. Others, again, like Sirius, are white with a bluish tinge, while the majority shine with a yellowish-white light like that of our sun. There is good reason to suppose that these different colours indicate a different stage of stellar evolution, the bluish-white stars being th hottest, the red stars being comparatively old and cool, while the yellow stars, like our sun, hold a middle place. Telescopic stars often show much more brilliant colours than any which are visible to the naked eye, shining with sea-green and lilac, gold and azure, orange and emerald. These colours are usually found in compound stars, and not infrequently are found to vary from time to time.

43. PRÆSEPE STAR CLUSTER

Variable Stars. A great number of stars shine with a fluctuating or variable light. Observation has divided them into many classes. There are some in which the change is regular and recurrent. The best example of this type is Algol, the Demon Star, which falls from the second to the fourth magnitude once every three days, and is now known to be partially eclipsed by a vast dark satellite which revolves round it in that period. Another type is that of Mira, the Wonderful Star, whose light varies in a cycle of 333 days from below the ninth to nearly the second magnitude. At its weakest, it is quite invisible to the naked eye, while at its maximum it is quite a conspicuous star. Variability of this type is shown to be due to a periodical conflagration in the star. What causes this we do not know, but it is possible that this remarkable behaviour is somewhat analogous to the behaviour of the spots on our own sun, which is itself a very slightly variable star with an eleven-year period. There are several other classes of periodically variable stars which need not be described here. There are other stars which vary without regularity or warning, such as Eta Carinæ, which is normally invisible to the naked eye, but has been known on several occasions to burst out with a blaze which made it one of the most brilliant stars in the heavens.

Temporary Stars. There is no real distinction between irregularly variable and *temporary* stars. The latter, which create great interest among the public as well as among astronomers, are stars which once in history burst out into a sudden blaze, and then again shrink down to their former insignificance. The earliest recorded of these was seen by Tycho Brahé, in 1572, when a star which outshone even Venus and Jupiter suddenly blazed out in Cassiopeia. Within the last few years there have been well-known outbursts of the same kind in the constellations of Auriga and Perseus. Spectroscopic analysis has made it quite clear that in all these cases what we see is a veritable conflagration. Vast outbursts of incandescent gases suddenly well up from the interior of a quiescent and comparatively faint star, and raise it to a degree of luminosity which may rival that of vast and steady globes like Sirius or Vega. But such a star lacks the energy to keep up this output of light, and before very long dies away to its former faintness.

How the Earth might be Burnt Out. It has been supposed that the collision of two stars, or the falling of a vast planet into a tiny sun, might account for some of these sudden outbursts of light. Such an occurrence would certainly produce a blaze visible all over the heavens, but the collision of two stars is so improbable an event, in view of their vast distances apart, that we may eliminate it, and the falling of a planet into a sun has not as yet been known to occur. Probably it is bound to happen as systems grow old and decayed: it will certainly happen one day in our own system. But the behaviour of our own sun shows that the evolution of incandescent gas from a star's interior is quite a normal incident in stellar life. If the vast eruptions of glowing hydrogen which are daily emitted from the sun's surface were increased tenfold by some interior convulsion, the sun itself would blaze out as a temporary star—and, incidentally, life would be burnt off our planet. We can only say that the great majority of stars shine with fair regularity, and hope that the sun will continue to do the same.

44. A NEBULA

Clusters of Stars. A number of stars are arranged in clusters of groups, whilst others, like our own sun, are at vast distances from their nearest neighbours. Some of these clusters, of which the Pleiades afford the best example to the naked eye, can be resolved by a keen eye into separate stars: some, like Præsepe in Cancer [**43**], which only show to the naked eye as a hazy spot of light, break up in a good field-glass into clusters of stars; but the majority of stellar clusters require a powerful telescope for their resolution.

It was long ago noticed that the more powerful a telescope was, the greater was the number of these hazy spots of light which it would resolve into clusters of stars. Consequently the opinion was formed that all the hazy little clouds or *nebulæ* [**44** and **45**] which are so prevalent throughout a large part of the sky were simply clusters of stars, so far away that their light merged into a single impression on the eye. A great number of these nebulæ were only resolved by large telescopes, such as Lord Rosse's 6-foot reflector. But a great many of these nebulæ were found to be irresolvable by any telescope. It was simply concluded from this that they were still more distant than the clusters which had yielded to the resolving powers of the telescope, and it was further supposed that each of these clusters of stars might be a separate universe or galaxy, comparable in extent and importance with our own universe, bounded by the vast girdle of the Milky Way.

This grandiose conception of innumerable universes scattered throughout space was speedily destroyed by the spectroscope. As we have seen, the spectroscope distinguishes with entire certainty between the light sent to us from a solid star and that emitted by a gas. When it was turned upon the nebulæ which had been supposed in reality to be star clusters so distant that no telescope could resolve them, it showed unmistakably that these nebulæ were not star-groups, but simply masses of incandescent gas.

The Structure of the Universe. At the same time improvements in the methods of measuring parallax caused astronomers to revise their somewhat exaggerated notions as to the distance of the faintest visible stars. They have, in consequence, mostly given up the theory of innumerable universes in which the fancy of an earlier generation was pleased to run riot, and have formed a fairly coherent though still somewhat vague idea of the actual structure of the universe, of which a short account must now be given in conclusion.

The most casual inspection of the starry heavens shows that the visible stars are very irregularly distributed. Some regions are crowded with stars, whilst others show a very sparse distribution of orbs visible to the naked eye. The telescope, whilst vastly increasing the number of stars up to about 30,000,000 visible to the most powerful instruments, still emphasises the irregularity of their distribution.

The Galaxy. There is one region of the sky which is far more thickly strewn with stars than any other. This is the luminous belt which surrounds the whole sky nearly in a great circle, which is known as the Milky Way, or the Galaxy. To the naked eye it usually seems to be a luminous cloud, though on a very clear night it is possible for keen eyesight to make out here and there the brightest of the individual stars which compose it. The telescope and spectroscope agree in showing the Milky Way to be composed of innumerable stars, mostly of the eighth magnitude or smaller, and set so closely together that the whole belt of sky which they inhabit seems to be luminous [**46** and **47**].

The Milky Way contains very numerous clusters of stars, but very few gaseous nebulæ. The rest of the sky nowhere contains any such crowding of stars as is found in the Milky Way, though here and there we find a bright cluster, like Præsepe, where several thousands are condensed within a space much smaller than the full moon. The stars frequently seem to run into streams and groups, but on the whole their distribution is irregular and their number small in comparison with those of the Milky Way.

The Milky Way an Illusion. There is only one hypothesis which at present gives any reasonable explanation of this distribution of the stars. We cannot believe that the stars which form the Milky Way are really crowded together so closely as they look. The Milky Way is purely an effect of perspective. If we suppose the stellar universe to have the form of a vast flat disc, something like a crown piece, of which the diameter is much greater than the thickness, and our own sun to be situated somewhere near the centre of this disc, a little thought will show that we should get

45. THE GREAT NEBULA IN ANDROMEDA
(From "Knowledge," reproduced, by permission of Mrs. Roberts, from a photograph by the late Dr. Isaac Roberts, F.R.A.S.)

substantially the same appearance as has been described. When we look along the plane of this disc the line of sight travels through thirty or forty times as many stars as when we look up or down at right angles to the plane of the disc, provided that the stars are distributed in all directions with fair equality. Consequently to an observer near the centre of the disc there will appear to be a nearly circular belt thickly strewn with stars, whilst the rest of the sphere is much less thickly set with stellar orbs.

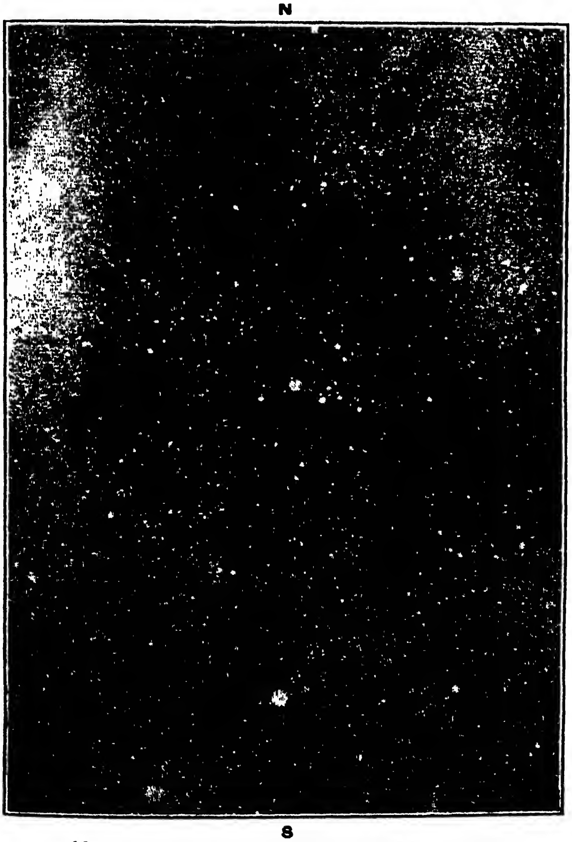
It is now generally held that this is roughly the arrangement of our stellar universe. There are many modifications in detail, based on the distribution of various kinds of stars and on the details which form the Milky Way, but these must be studied in more elaborate works, such as Miss Clerke's "System of the Stars." It is enough to say here that the probability is that our sun is near the centre of the stellar universe; that this universe consists of at least 100,000,000 stars comparable to our sun, but many of them vastly brighter and more massive; that these stars are arranged roughly in the shape of a circular disc of which the diameter is many times greater than the thickness; that the central part of this disc, near which our sun is situated, is much less thickly set with stars than the outer parts; and that its diameter is at least so great that it would take light 30,000 years to cross it.

The Nebular Theory of the Universe. It remains to add a few words as to the theory now accepted of the development of this universe and of systems like our own. We have seen that bright stars are divided into various types, according to their different spectra and colours. Some of them are undoubtedly hotter, and therefore younger, than others, and it is practically certain that there are many stars in the void of space which have grown cold and dark, so that we can never see them, though in some cases we are able to infer their existence from their gravitational influence on the neighbouring bright stars. Further, the universe contains a great number of *nebulæ* [**44** and **45**], which are merely clouds of incandescent gas. It was first suggested, by the great philosopher Kant, that these nebulæ might be the raw material of suns with their attendant planets. The physical conditions dominating the history of such nebulæ have been fully worked out by several generations of mathematicians.

The Birth of a Solar System. Suppose that we have a nebula or cloud of incandescent gas some 5,000,000,000 or 6,000,000,000 miles in diameter. This nebula must be subjected to two distinct causes of change. In the first place, all its material particles must attract one another by the law of gravitation, so that the nebula tends to condense towards the centre; and simultaneously, the incandescent particles which compose the nebula are constantly radiating heat out into space, so that the nebula must always be losing heat. On these two facts Laplace and his followers erected a complete theory of stellar evolution. Such a nebula cannot for a moment remain at rest, even if, which is exceedingly improbable, it was originally in such a condition. It would necessarily acquire a rotation about an axis, in addition to the movement through space which it would have under the influence of external gravitating bodies.

It has been shown mathematically that such a rotating nebula, losing heat at the same time and condensing inwards, would at regular intervals shed rings from its substance, and that these rings would tend to break up and coalesce into roughly spherical bodies or planets, which would revolve round the centre of the whole nebula and at the same time rotate on their own axes. Each of these rotating masses, if still hot enough to preserve the nebulous condition, would repeat the history of the original nebula, in turn shedding rings, which would coalesce into secondary spheres or satellites. Each of these derivative or secondary nebulæ, being much smaller than the parent nebula, would cool much more rapidly, and might become a solid body whilst the original nebula was still in the state of fiery gas.

This is believed to be the general history of the origin of the solar system, although further research has thrown doubt on some of Laplace's ideas. Once it was a vast cloud of fiery gas stretching beyond out the orbit of the farthest planet. As it contracted, it shed rings, which broke up into planet after planet, each with its own satellites. Neptune and Uranus came first; then Saturn, where the first anomaly appeared.

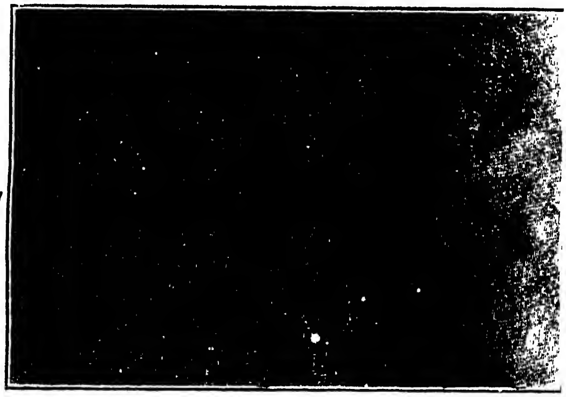


46. THE MILKY WAY ABOUT β CASSIOPEIÆ
(From a photograph by Dr. Max Wolf, from "Knowledge")

for one or more of the rings which Saturn shed in cooling did not coalesce into a spherical satellite, but remained as the wonderful arrangement called Saturn's Rings, which consist of a swarm of tiny meteorites or cosmic dust. Jupiter, the largest of the planets, was next formed. The next ring thrown off by the original nebula behaved like the rings shed by Saturn, and gave birth to the swarm of minor planets. Mars, Earth, Venus, and Mercury, were next born in the same order.

The vast luminous orb which we call the sun, and which we have seen to be still in an intensely hot gaseous condition, is merely the shrunk and dwindled remainder of this vast original nebula. This is a brief sketch of what is known as the Nebular Theory of planetary evolution.

The Beginning and End. It is highly probable that the gaseous nebulæ which exist in great numbers in the heavens are all in an early stage of such evolution, and that all the stars which bedeck the sky are the product of earlier nebulæ, and are surrounded by planets like the sun. But we are now approaching a region which borders on the realms of imagination rather than research. The span of our lives is so tiny in comparison with the vast ages that must go to the growth of even an inconsiderable system like our own, that man has as yet had no opportunity for verifying such a hypothesis. It may well be that the vast drama of stellar evolution passes through an unending and recurrent cycle. We can mathematically foresee the time when the inexorable operation of physical laws will bring back planet after planet to crash into the sun, and the result of such a series of collisions should be to reproduce the fiery nebula stretching far out beyond our own orbit. It cannot, indeed, be as vast as the nebula from which we were born, since the whole system is constantly losing energy in the form of light and heat radiated into space, from which (so far as we know) it never returns. From such a nebula there would be produced a new system with a smaller sun and fewer planets, again in the vast lapse of time to clash together, and to be expanded into yet another new nebula, still smaller and less potent.



47. THE MILKY WAY NEAR θ OPHUICHI
(From a photograph by Prof. E. E. Barnard, from "Knowledge")

A Cosmic Eternity. Thus we can dimly foresee the cosmic future as a kind of switchback, ever making smaller and smaller rushes up opposing hills, till ultimately the machine is brought to rest and the whole mass of material which now composes the solar system voyages through space in the form of one dark, solid, and lifeless globe. Possibly, two such globes may dash together after millions of æons, and again break up into one vast nebula, instinct with that energy which contains the possibilities of living worlds. All this is pure speculation, and yet (as far as we know) it is the only course which the history of our system can take. That history is probably typical of what is going on throughout the universe. Everywhere there is a vast recurrent cycle in operation. The energy derived from some unimaginable cataclysm, converted into heat and light, and gravitational forces, gives birth to a nebula, which in turn evolves a solar system, and perhaps produces some race of sentient beings such as man, as a casual and temporary accident in this evolution. We are, not unnaturally, apt to exaggerate the importance of this detail, but one of the advantages of even such a hasty survey of astronomical history as has been taken here is that it teaches us to estimate the place of man in the universe with a somewhat truer sense of proportion.

THE BEST BOOKS ON ASTRONOMY

"The Story of the Heavens" (Cassell. 10s. 6d.), "Primer of Astronomy" (Cambridge Publishing Co. 1s. 6d.), and other books by Sir Robert Ball.

"Popular History of Astronomy During the Nineteenth Century" (Black. 15s.), "The System of the Stars" (Black. 20s.), "Problems in Astrophysics" (Black. 20s.), "Concise Knowledge Astronomy" (Hutchinson. 5s.), by Agnes M. Clerke.

"Elementary Astronomy," "Manual of Astronomy," and "General Astronomy" (Ginn. 7s. 6d., 10s. 6d., and 12s. 6d. respectively), "The Sun" (Kegan Paul. 5s.), by C. A. Young.

"Myths and Marvels of Astronomy" (Longmans. 3s. 6d.), "Saturn and its System" (Chatto. 6s.), and many other books by R. A. Proctor.

"Astronomy Without a Telescope," by E. W. Maunder (Thacker. 5s.). "Celestial Objects for Common Telescopes," by J. W. Webb (Longmans. 12s. 6d.). "Astronomy with an Opera-glass," by Garrett P. Serviss (Appleton. 6s.).

"Popular Astronomy" (Macmillan. 18s.), "The Start" (Murray. 6s.), by Professor S. Newcomb.

"Handbook of Descriptive Astronomy," by G. F. Chambers (3 vols. Clarendon Press. £2 16s.).

"The Visible Universe" (Lockwood), "Studies in Astronomy" (Chatto. 6s.), by J. E. Gore.

"Meteoritic Hypothesis" (Macmillan. 11s.). "The Sun's Place in Nature" (Macmillan. 12s.). "Recent and Coming Eclipses" (Macmillan. 12s.), "Spectrum Analysis" (Kegan Paul. 5s.), by Sir J. N. Lockyer.

"The Moon," by W. H. Pickering (Murray. £2 2s.). "The Planet Earth," by R. A. Gregory (Macmillan. 2s.), "Jupiter and His System," by Ellen M. Clerke (Stanford. 1s.). "Remarkable Comets," by W. T. Lynn (Bagster. 6d.), and several other books.

ASTRONOMY *concluded*

A SHORT DICTIONARY OF ASTRONOMICAL TERMS

AEROLITE—A meteor which falls to the earth's surface.
Albireo—A double star in Cygnus.
Alcor—Star in Ursa Major.
Aldebaran—Brightest star in Taurus.
Algol—A variable star in Perseus.
Alphard—Brightest star in Hydra.
Altair—Brightest star in Aquila.
Altazimuth—Simplest telescope stand.
Altitude—Height of heavenly body from horizon in angular measurement.
Andromeda—A northern constellation.
Annular Eclipse—When eclipsed sun appears as a ring of light.
Ansa—The space between the ring and globe of Saturn.
Antares—Brightest star in Scorpio.
Aperture—Breadth of a telescope's object-glass, or principal mirror.
Aphelion—A planet's furthest distance from the sun.
Apogee—A planet's furthest distance from the earth.
Arc—A portion of a circumference.
Arcturus—Brightest star in Boötes.
Argo—A southern constellation.
Asteroid—See *planetoid*.
Auriga—A northern constellation.
Axis—The imaginary line on which a heavenly body rotates.
Azimuth—Angular distance of a heavenly body measured horizontally.

BELLATRIX—A star in Orion.
Betelgeuse—A variable star in Orion.
Bode's Law—An empirical arrangement of the planetary distances.
Bolide—A species of shooting star.
Boötes—A northern constellation.

CANIS MAJOR AND MINOR—Two southern constellations.
Canopus—Brightest star in Argo.
Capella—Brightest star in Auriga.
Cassiopeia—A northern constellation.
Castor—A bright binary star in Gemini.
Cepheus—A northern constellation.
Charles's Wain—Portion of Ursa Major.
Colure—Imaginary circle of the celestial sphere.
Comes (Comeez)—The small companion in a double star.
Comets—Gaseous bodies moving through the solar system.
Conjunction—Two or more heavenly bodies apparently near one another.
Constellation—An artificial grouping of stars by map-makers.
Co-ordinate—Elements which determine the position of a body.
Cor Caroli—Brightest star in Canes Venatici.
Corona—The sun's atmosphere.
Culmination—The meridian passage of a body.
Cusps—The extremities of a crescent, as the moon.
Cygnus—A northern constellation.

DEGREE (°)—A celestial measure, the 360th part of a circle.
Demos—One of the satellites of Mars.
Deneb—The brightest star in Cygnus.
Digit—The twelfth part of the sun or moon's diameter.
Draco—A northern constellation.

EARTHSHINE—Faint glow on unillumined part of crescent moon.
Eccentricity—The distance of a focus from the centre of an ellipse.
Eclipse—Obscuration of one heavenly body by another, or by its shadow.
Ecliptic—Sun's apparent annual path.
Egress—The passing of one body off the disc of another.
Ellipse—Shape of a planetary orbit.
Elongation—The angular distance of Mercury or Venus from the sun.
Emersion—The reappearance of a body after eclipse or occultation.
Enceladus—One of Saturn's satellites.
Epoch—Time to which calculations regarding heavenly bodies are referred.
Equation of Time—The difference between true and mean solar time.
Equator—Imaginary line running round the celestial sphere midway between the Poles.
Equinoxes—Those portions of the year when day and night are equal.
Eros—A minor planet between the earth and Mars.

FACULÆ—Bright markings on the solar disc.
Finder—Small telescope attached to larger to facilitate object finding.
Fomalhaut—The brightest star in the constellation Piscis Australis.
Fraunhofer Lines—Dark lines in the spectrum discovered by Fraunhofer.

GALAXY—The Milky Way.
Gegenschein—A luminous appearance resembling the zodiacal light.
Gibbous—A phase nearly approaching "full."
Gravity—Mutual attraction of bodies.
Gyroscope—An instrument for demonstrating the earth's rotation.

HELIACAL—Rising same time as the sun.
Heliometer—An instrument for measuring small angular distances.
Heliostat—Instrument for counteracting apparent motion of the sun.
Hercules—A northern constellation.
Hour Angle—Distance of heavenly body from meridian in hours, etc.
Hyperbola—Form of cometary orbit.

IAPETUS—One of Saturn's satellites.
Immersion—Disappearance of an object during eclipse or occultation.
Inclination—The angle made by an orbit to the ecliptic.
Inferior Conjunction—When an inferior planet approaches nearest to the sun on earth's side.
Inferior Planets—Mercury and Venus.
Ingress—The beginning of transit of one heavenly body across another.

JUNO—A minor planet.
Jupiter—The largest planet of the solar system.

KEPLER'S LAWS—The laws of planetary motions, enunciated by Kepler.

LATITUDE—The angular distance of a body from the ecliptic.
Leonids—Annual shower of shooting stars occurring about November 14.
Libration—An apparent oscillation of the moon.
Limb—Apparent edge of a heavenly body.
Longitude—Angular distance of a body from the first point of Aries.
Lyra—A northern constellation.

MAGELLANIC CLOUDS—Two nebulous objects in south hemisphere.
Markab—Brightest star in Pegasus.
Mars—Planet between the earth and Jupiter.
Mercury—The innermost planet of the solar system.
Meridian—A line drawn through the heavens from north to south.
Meteor—A shooting star.
Micrometer—An instrument for making celestial measurements.
Milky Way—A belt of minute stars spanning the heavens.
Mira—A variable star in Cetus.
Mizar—A star in Ursa Major.
Motion Direct—Advancing in the order of the zodiacal signs.
Motion Retrograde—Advancing contrary to order of zodiacal signs.

NADIR—The point opposite the zenith.
Nebula—A gaseous mass in the heavens.
Neptune—The outermost planet of the solar system.
Nodes—Points where an orbit crosses the ecliptic.
Nutation—An oscillation of the earth's axis.

OCCULTATION—The hiding of a star or planet by the moon.
Opposition—When a planet crosses the meridian at midnight.
Orion—A well-known constellation.

PALLAS—A minor planet.
Parabola—Form of cometary orbit.
Parallax—An apparent shift in the place of an object.
Penumbra—The dull edge of a shadow.
Pegasus—A northern constellation.
Perigee—Nearest the earth.
Perihelion—Nearest the sun.
Perseus—A northern constellation.
Perturbation—The influence of one body on the path of another.
Phobos—A satellite of Mars.
Photosphere—The sun's visible surface.
Planetoid—A minor planet revolving between Mars and Jupiter.
Pleiades—Star group in Taurus.
Pollux—Bright star in Gemini.
Præsepe—Star group in Cancer.
Precession—A slight retrograde motion of the equinoxes.
Procyon—Bright star in Canis Minor.
Prominences—Outbursts of incandescent vapour seen at the solar limb.

REGULUS—Brightest star in Leo.
Refractor—A telescope with an object-glass.
Reflector—A telescope with a mirror in lieu of object-glass.
Rigel—Bright star in Orion.
Rill—A cleft on the moon's surface.
Rotation—Period an object takes to turn on its axis.

SATELLITE—Attendant body; a moon.
Saturn—A planet between Jupiter and Uranus.
Selenography—The study of the moon's surface.
Sickle—The front portion of Leo.
Sirius—The brightest star in the sky, in Canis Major.
Solstices—Points where the sun is northernmost or southernmost.
Southern Cross—A brilliant star group near the South Pole.
Southing—Crossing the meridian.
Spectroscope—Instrument for analysing light.
Spectrum—Analysed light.
Spica—Brightest star in Virgo.
Sun—The centre of the solar system.
Superior Conjunction—When a body approaches nearest to the sun on opposite side from the earth.
Superior Planet—A planet remoter from the sun than the earth.
Synodic—The time which a planet takes to return to the same position with respect to the sun and earth.

TELESCOPE—An instrument for bringing distant objects apparently nearer.
Terminator—The line separating day and night on the moon or a planet.
Titan—Saturn's largest moon.
Transit—Passage of a body across the meridian or a larger body.

UMBRA—Earth's shadow in a lunar eclipse; centre of a sun-spot.
Uranus—A planet of the solar system between Saturn and Neptune.
Ursa Major—A northern constellation.

VARIABLE STARS—Stars whose light varies in intensity.
Vega—Bright star in Lyra.
Venus—Planet between Mercury and the earth.
Vesta—One of the minor planets.

ZENITH—The point exactly overhead.
Zodiac—That portion of the sky through which the sun and other bodies of the solar system move. The Signs of the Zodiac (not identical with the constellations of the same name) are:—Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libra, Scorpio, Sagittarius, Capricornus, Aquarius, Pisces.

STRINGED & WIND INSTRUMENTS

The Making of a Violin and other Stringed Instruments. The Pianoforte: Case, Soundboard and Strings. How an Organ is Built

By J. P. LORD

STRINGED INSTRUMENTS

The making of stringed instruments can best be learnt by studying the process of manufacture of the violin; firstly, because the violin is the only instrument which is generally the work of one man only (we speak of real violins, and not of the disgraceful articles which are turned out in factories by the hundred); and secondly, because the four most important stringed instruments—the violin, viola, violoncello, and double-bass—are all made in the same manner. The making of guitars and mandolines will be a simple matter to one who has mastered the method of building a violin, so with few alterations the one description will serve to give an insight into this branch of the trade. Moreover, we might point out that violin-making on a high-class scale is very frequently undertaken by amateurs, many of whom rank with the best of our English makers.

Selection of the Wood. If the selection of wood for the fashioning of a wind instrument is important, for the making of a violin it is doubly so. The wood of the violin makes or mars the tone. Fashion your instrument how you may, let it be the most scrupulously exact copy of a Strad, and if the wood is bad you will never get a good tone. Now, the essential in wood for violin making is that it should of itself possess a musical tone. If you hold up a piece of wood and rap it smartly with the fingers, it gives out a note, of a kind. If it is to be used for violin-making—and these remarks apply also to all other instruments of this class—the note must be a distinctly musical one, clear and ringing, although not necessarily powerful. Anything like a "woolly" sound indicates faulty wood.

The woods generally used are pine, sycamore, maple, and pear, the first being almost universally employed for the top plate or belly of the instrument, and one of the other three for the back.

The wood should be old, well seasoned, and free from all artificial seasoning agents. The beginner had better purchase from a dealer of repute, lest he waste his time making a worthless instrument.

As a further test of the musical quality of the wood, one corner of the slab may be gripped in a vice and the edge played on with a well resined bow, when a distinctly musical tone should be forthcoming.

How to Test Wood. The soundness and freedom from resin of a sonorous wood may be shown by the manner in which it burns. If it flames up rapidly, spurting out jets of fire, it is not properly seasoned, and contains resin: but if it burns clearly and smoothly and evenly, leaving a consistent ash, then it is sound and well dried.

For the back a handsome figured wood adds to the appearance of the violin, but not necessarily to its tone, and tone should never be sacrificed to beauty. As a word of warning to the beginner, we may add that wood with curly markings is difficult to work, and should only be used by experienced hands.

Violin wood comes into the market in two forms, known as "cut on the quarter" and "cut on the slab." Wood cut on the quarter is divided in wedges from the centre of the log to the bark; wood cut on the slab is sawn parallel with the diameter of the trunk.

The Age of the Wood. Much is said about wood being 250 years old, but in the opinion of competent makers great age is not necessary: if the wood is only well seasoned and matured, it will make as good a violin as wood which has lain in store for a century. Wood, however, should be cut from a well grown tree in its prime, before old age has begun to cause the cells to decay, and should be stored for at least seven years before being used for violin-making.

Wood for the belly of a violin should always be cut on the quarter, but for the back it does not matter whether it be on the quarter or on the slab. The belly is almost invariably made in two pieces, the portions joined being those nearest the bark of the two slabs cut on the quarter, because the wood there is stronger than that in the centre of the tree, and the centre line of the belly has to bear the greatest strain from the bridge. The back is made indiscriminately from one or two pieces.

Having carefully selected your wood, if it is in one piece and cut on the slab or quarter, you can at once cramp it to the bench, ready for outlining. If it be in two pieces cut on the quarter, you must first of all shoot the thick edges perfectly true and place them together, so that when the wood is lying with its flat surface on a true level there may be no gap at all between the thick edges, but the two pieces will lie together and form a ridge like the roof of a low-pitched house. When in this position and held up to the light, no ray should be seen between them. With some of the very purest and finest white glue these two edges are now joined firmly together and cramped in position till they are well set. Both pieces, now joined, are henceforth treated as one slab of wood, whether for making back or belly.

Having cramped your wood to your bench, you next plane the ridge, if of joined wood, sufficiently to enable you to rest the wood on when you turn it over, as you now do to plane the flat side perfectly level. In doing all planing, you will have to watch the wood very carefully, so as not to tear pieces out of it.

Drawing the Outline. When this surface is quite level, you proceed to draw your outline upon it, using a templet of veneer or stiff card, made exactly to represent one half of the outline of the violin you propose to make. This templet you must make yourself from any good pattern of violin, or you can construct one by means of compasses and ruler by following the method here given, which was originally devised by Wettengel, a German writer on violin construction, which has since been frequently followed by first-class makers.

On a large piece of paper, or thin wood, draw a perpendicular line down the centre of the exact length of the body, which is generally in the neighbourhood of $14\frac{1}{4}$ in. to $14\frac{1}{2}$ in. Divide this into 72 equal parts [see DRAWING, page 472]. Intersect this perpendicular line by twenty horizontal lines, exactly at right-angles to the centre line, at the points marked as follows, naming the lines as below [see also page 4623].

Line A	at point	8		Line L	at point	33
„ B	„ „	14		„ M	„ „	34
„ C	„ „	16		„ N	„ „	37
„ D	„ „	20		„ O	„ „	39
„ E	„ „	$21\frac{1}{4}$		„ P	„ „	40
„ F	„ „	22		„ Q	„ „	$44\frac{1}{4}$
„ G	„ „	23		„ R	„ „	48
„ H	„ „	27		„ S	„ „	55
„ I	„ „	28		„ T	„ „	56
„ K	„ „	31		„ V	„ „	65

Take your compasses and open them to an extent equal to 9 parts of the perpendicular, and from point *b* describe an arc *aa* on each side of the centre line, *b* being the top end of the perpendicular. With point 24 as centre, and radius *xr* to *b* draw curve *aba*, meeting *aa* at those two points [1]. Mark off points 2 parts distant from perpendicular, and on each side of it, on line C; call these *cc*. With centre *cx* and distance *ca* draw curves *ad* on each side, meeting line A at *d* and *d*. On B mark two points, *e*, *e*, one part distant on each side of centre line. With these as centres, and *ed* as distance, draw curves *df*, meeting line D at *f*. This practically finishes the upper portion of the violin body.

For the middle, or narrow portion, start by setting off on L two points *gg* $11\frac{1}{3}$ parts distant on each side of perpendicular, and then eleven points further distant from *g* mark two more points *hh*, and with *h* as centre and *hg* distance draw curve *gi*, meeting L and P at *g* and *i* respectively.

On line K set off $23\frac{3}{4}$ parts from perpendicular, on each side, to *kk*, and with *k* as centre and distance from there to point where curve *gi* cuts line M as distance, describe curve from that point to 1, meeting line H at 1. This gives the main curves of middle of body. Where there are tiny angularities between curves, they must be worked down by hand to a flowing sweep.

The lower part of the curves of the lower portion are obtained in this way: Take lower point of centre line, and call it *rr*. Open compasses *qq* parts, and with *rr* as centre describe arc *vv* on each side of middle line. With 35 as centre, and 35 to *rr* as distance, describe curve *v*, *rr*, *v*, cutting first arc at *v* and *v*. On line S mark two points *xx* 6 parts distant from centre line. With *x* as centre, and *xv* as distance, draw curves *vy*, meeting line V at *y*.

Set off two points at T, 4 parts distant from *rrb*. Call them *zz*, and with *z* as centre, and *zy* as radius draw curve *y*, *aa*, meeting R at *aa*. This completes the main curves of the lower body.

The Corners. For the upper corners, set off $24\frac{1}{2}$ parts on line G from perpendicular to *oo* on each side, and with *o* as centre, and *of* as distance, draw curve *fp*, meeting E at *p*. On line I set off two points *mm* on each side of *rr*, *b*, and distant from it $14\frac{2}{3}$ parts. With *m* as centre and distance to *l*, draw curve *ls*, above H. On line E set off 22 parts, giving *q*, and with *q* as centre and distance *qp* draw curve *ps*, determining point *s*. With 20 as centre, and $16\frac{1}{3}$ parts as radius, describe a short arc cutting *ps*, *ls* at *s*, giving two angles of corner.

For the lower corners, set off 24 parts on line O, from perpendicular to *bb*, and placing compasses on this point, open them to *cc* and draw curve *ccdd*. On line N set off $18\frac{1}{2}$ parts, from perpendicular to *t*, and with *t* as centre and *ti* as distance, draw curve *iu*, determining point *dd* of corner, as in the upper corners. With compasses on point 49, and distance equal to $19\frac{3}{4}$ parts, draw arc meeting *iudd*, and *aadd* at *dd*, giving angles of corner. The entire pattern is thus completed.

The corner, as indicated, will have to be rounded off, and the points at the angles of the corners neatly joined. To obtain the proper rise for the height of the back and belly, take a piece of hard wood and mark a point half way along it, and one quarter from its further edge. The wood must be slightly longer than the centre line of the body. With a piece of string, or very large compasses, with a radius equal to 216 parts of former scale, describe an arc meeting line perpendicular to edge of wood through A at A. This will give the curve of the rise, and if sawn out neatly will give a useful trying plate.

Of course, this pattern is not to be taken as a sample of the best man can devise—each maker constructs, to a great extent, his own pattern—but it will serve as a general guide for the beginner to work upon.

Having laid your templet, or pattern, flat on the planed side of the wood, mark carefully all round it with a pencil, and afterwards touch up your plan by hand. If your templet is a half one, having drawn one side, you must reverse the pattern and complete the other.

Cutting out the Pattern. That done, take a bow saw, or coarse fret saw, and cut out the marked pattern, keeping well outside the marking, lest a slip should ruin your work. Having done this, a very flat knife, especially made for violin-makers, is taken, and the wood pared down exactly to the outline.

Having got your outline right, with a gouge reduce the edges on the outer, or convex, side of the plank to about $\frac{3}{16}$ in. in thickness. That done, the wood must be further reduced by filing and rasping, or by gouging and planing, till it is about the right thickness at centre and edges, when measured with your pattern cut out of wood, keeping your work as smooth and even as possible.

Remember the shape of the outline of a violin and its general figure is its pattern; its model is the curvature of its back and belly. The body is divided roughly into three—the upper third to the upper corners is called the Upper Bout, from there to the lower corners is the Middle Bout, and thence to the tailpiece is the Lower Bout.

The reduction being right, and even all round, at this stage some makers advocate inserting the purfling, those strips of black-and-white wood which form the ornamental border round violins. This plan has much to recommend it, because if a slip be made it is not so injurious at this point as it would be later; while if the entire back be ruined, surely it is better to spoil an unfinished back than one on which you have spent days of labour.

A purfling tool is an arrangement for marking two or more fine lines at a regular distance from the edge of an object. This instrument is run round the edge, and when the lines are clearly scratched in, they must be deepened with a knife, and then the wood between removed with a fine, sharp gouge. The purfling instrument will mark a space of about an inch, where the button

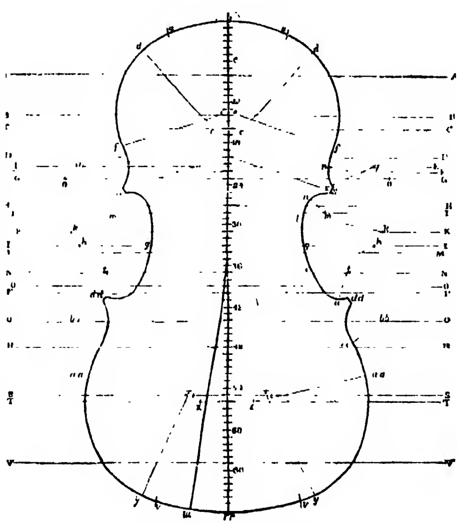
of the violin comes at the top of the upper bout, and this piece must be traced by hand.

When the groove has been cut out, the purfling, which consists of fine strips of black-and-white veneer, must be cut to approximate lengths, and then bent by passing it over a purfling iron—a hollow tube, heated by means of an iron which goes inside it.

The purfling must be gently handled, and passed over and round the iron till it assumes the proper curve, more by coaxing than by force. It is then ready for insertion. With a flat stick, or with the blade of an old knife, very hot glue is laid along in the grooves, and then the purfling gently forced into its place, some ingenuity being used to make the pieces join neatly, especially at the corners, where they should meet at an acute angle. The purfling being in its place, a little very hot glue is run in all round it to make all secure, and then the back is put away to dry.

While the back is drying the belly, or body of the instrument, can be got on with, its outline being traced and cut out exactly like the back. If you wish, you can also reduce it on the upper face at this stage, and purfle it, thus avoiding the use of much hot glue when you are nearly ready to polish it later on.

Cutting the Groove. When the purfling is dry, if it has been done, or when the outline is clear, if the purfling is postponed, the next thing to do is to cut a groove to the depth of an inch, and about $\frac{3}{4}$ in. broad, all round the back or belly, the edge of it being about $\frac{1}{32}$ in. from the inside edge of the purfling. This is best cut purely on the curve, avoiding the corners at first, and afterwards finishing them up with a gouge. Down to this groove the model is worked, using either plane or sandpaper folded over a cork rubber. Opinions differ as to the advisability of employing sandpaper, its opponents saying that it damages the fibre of the wood and injures the tone, while advocates of its use declare that planing is worse. The beginner will find sandpaper easier to work with, because it does its work more gradually, and there is less risk of catching on a fibre and ripping up a valuable piece of wood.



1. THE VIOLIN PATTERN

Finishing the Back. Working, then, with sandpaper or plane, the curvature of the back must be brought to fit exactly the model made, and the whole back must be finished off smooth. Between courses of papering or planing it will be found necessary to damp the wood, for that makes the soft parts swell up above the level, and proves that what appeared a perfectly level surface would have become rough on varnishing. The raised portions can easily be removed with paper or tool, and a perfectly smooth surface which will last thus produced.

The outsides of the back and belly being finished, and the model made correctly to pattern, the inside of the two tables, as they are called, are hollowed out.

Hollowing Out the Frame. The table is laid on a hollowed bed, protected by paper so as not to injure the smoothed surface of the outside, and on the inside is drawn the curved outline, which is like a guitar, the corners being only indicated by broad curves. This is drawn at a distance from the edge sufficient to leave a good flat rim for the ribs, or sides, to be eventually glued to.

A shallow cut is made along this line, and from that as a starting point the hollowing is worked. To graduate the hollowing nicely three grooves are cut across the inner side of the table of such a depth that the middle groove callipers a good $\frac{3}{16}$ in. in thickness of wood, the upper and lower callipering $\frac{1}{8}$ in. These fall away very little towards the edges at the outset. These grooves are best cut at the three nodal points, which correspond roughly to points 16, 37, and 55 on our centre line. From these the back can be hollowed all over gradually, the callipers being frequently employed to gauge the thickness all over, the taper being made very even and regular. Then with sandpaper, or spokeshaves, the reduction must be gradually carried on till the table varies from $\frac{5}{32}$ in. at the centre to between $\frac{1}{12}$ in. and $\frac{1}{16}$ in. at the edges. These measurements have been found to give an excellent tone for the back. The belly requires to be made only $\frac{1}{8}$ in. in thickness at the centre node, or breast, and to be reduced from that to a $\frac{1}{16}$ in. The reduction varies a little according to the resonance of the wood, very "active" pine requiring less to be taken off than would a

The Sound Holes. When the belly has been properly thinned down the time has arrived for cutting the four sound holes. These are of various patterns, some distinctive of certain schools of makers. Select good pattern, suitable for your violin, and trace it on the wood, or stencil it if you prefer to do so. Then, with a fine fret saw, cut it out, keeping well inside the line, finishing afterwards with a sharp knife. The F should lie on the belly from point $32\frac{1}{4}$ to point $46\frac{1}{4}$, and the centre of the upper round holes should be opposite point 31, and that of the lower opposite point $44\frac{1}{2}$. The outer notches fall opposite point $39\frac{1}{4}$.

The Bass Bar. The bass bar is a strip of wood glued to the inside of the belly under the G string of the violin. In length it should be 36 parts long, one part and one fifth in breadth, and 2 parts thick in the centre, sloping down to two-thirds of a part at the ends. Perhaps the best position for it is parallel to the centre line. It is one-third of a part from the upper round of the left F hole, and has its centre opposite 40.

The centre line of the belly may require strengthening, and if this is so small squares of veneer may be glued along it, the grain of the veneer running across the grain of the belly diagonally.

The Ribs. The ribs or sides are formed of strips of wood carefully bent by heat, in much the same manner as the purfling was done, till they assume the exact shape of the various sections of the outline. The pieces are six in number, corresponding to the right and left sides of the three bouts. In thickness they should be about $\frac{1}{16}$ in. and in depth they vary according to the proportions of the outline. The main point to be borne in mind is that the "box" of the body should contain a mass of air which when set in vibration will give a fixed note, and violin makers generally select C with 512 vibrations per second as their standard. A fairly general depth is $1\frac{1}{4}$ in. at the broad end and $1\frac{1}{8}$ in. at the narrow end of the violin, which corresponds to a body $14\frac{3}{8}$ in. long constructed on the plan given.

At the same time as the ribs are prepared the linings, which are thin tapering slips of pine wood, must be cut. There are two linings to each piece of the ribs, glued on the inside of the curve. The corner blocks should also be made ready. These are of such a shape as entirely to fill up the corners, reducing the inside contour of the violin to the guitar shape.

The ribs and linings having been carefully bent to the proper curves, the ribs are cramped in a beechwood mould exactly resembling the outline of half the violin, and when there the corner blocks are glued in, and the linings fastened on, the whole being cramped up to make all firm. When set the edges must be pared absolutely level and all is ready for attachment to the back, on which the end and the bottom blocks have been glued. The ribs are kept in place by a series of cramps, and extend up to the edge of the button, where the neck groove will be cut for the fixing of that portion of the instrument.

When properly dry and set, the groove is gouged out, and the belly glued on. Many makers drive two small pegs through the ends of the belly into the end blocks, just as they are about to cramp up the body.

The Neck. The neck of the instrument should be 26 parts in length, measuring from the body of the instrument to the nut, which is the little raised bar of ebony over which the strings pass on their way for the pegs. The neck and head is cut out of a block of wood, and really is a matter of wood-carving. Examination of the neck of a violin will show the shape to be aimed at better than pages of description. The fingerboard must be firmly attached to the neck by glue, and the neck must be set on the body in such a manner that the end of the fingerboard near the bridge is $\frac{13}{16}$ in. above the wood of the belly. Careful joinery is all that is needed to effect this. The peg for the attachment of the tailpiece is glued into a hole bored in the bottom block, and the tailpiece attached by means of loops of gut.

The Soundpost. The soundpost is the bugbear of beginners. It has to be cut so accurately that every portion of its upper and lower surfaces is in close contact with the wood of the belly and back respectively. It also must be of such a length that it just fits perpendicularly between the two when placed with its edge nearest the neck, just in a line with the back of the foot of the bridge under the E string. It must fit tight enough not to slip when the strings are slack, and yet not so tight as to strain or exert any appreciable pressure on the belly or back. Only patient chipping and scraping will ensure this result being attained. The post is inserted through the F hole nearest to it, and it is adjusted in position by means of a special iron instrument, known as a setter. The diameter of the soundpost and the breadth of each foot of the bridge must coincide with the breadth of the bass bar.

The Bridge. The bridge, which is made of maple or beech, must be set up so that exactly half of its thickness is on each side of a line drawn between the inner notches on the F holes, and passing through 40. The thickness of the upper edge of the bridge must be $\frac{4}{7}$ of a part, and of the soles of its feet $\frac{1}{5}$ of a part. Its extreme height depends on the length of the instrument, and is reckoned at $\frac{18}{103}$ of the body length of violins and violas, and $\frac{65}{452}$ of length of 'cellos and basses.

The soundpost being fitted, it is removed till the instrument is completed. If the purfling has not been done it is now added, and a piece of ebony let in where the tailpiece will rest.

Varnishing. A final polish is given to the violin, and then comes the varnishing. After the final polish has been given to the plain wood it is just run over with a damp sponge and allowed to dry. This throws up a microscopic roughness which holds the varnish well. The selected varnish, at first well diluted, is then applied in successive coats. Each coat must be permitted to dry thoroughly without artificial aid before its successor is applied. Each maker has his own recipe for varnish, and it is impossible to recommend one more than another, always provided that oil varnishes are better than spirit if properly applied, and have a more lasting effect.

The final varnishing and rubbing with the palm of the hand being completed, the pegs can be put in, the soundpost readjusted, the tailpiece looped on, and the strings attached. The senseless wood has become an instrument—whether musical or not depends upon the care which has been expended upon it.

The above instructions apply to the making of all instruments of the violin class, provided that the ribs of 'cellos and basses are made double as deep in proportion as those of violins and violas. This is done to obtain the proper volume of air inside the box, because the length of the body, if the ribs were of the former proportions, would be too long to be wieldy, so defective area in the base of the box has to be compensated for by increased height. For comparison we give these proportions for ribs:

Violin and viola, $6\frac{1}{4}$ parts at tail, tapering to 6 parts at neck.

'Cello and bass, 12 parts at tail, tapering to $11\frac{1}{4}$ parts at neck.

Miscellaneous Stringed Instruments. The making of guitars and mandolines is rarely undertaken in this country. Should, however, our readers wish to make either, the foregoing directions for violin-making will be of assistance. The wood of the belly of guitar or mandoline should be the best violin pine, old, and free from flaws, and should of itself be musical. It will not have to be hollowed out. A bass-bar may be placed under the lowest string, but a soundpost is not generally employed, though its use is commendable. The back of a guitar may be slightly hollowed, and with a model resembling rather a flat violin. The back of a mandoline is usually built up on a wooden frame, of strips of wood glued together. Harp-making is a "close trade," being in the hands of a few families who have made a speciality of this beautiful, but unfortunately almost forgotten, instrument.

Repairs. It is generally said that he who made can mend, but in the case of high-class stringed instruments this is not so. Strange as it may appear, the calling of a repairer of stringed instruments ranks higher than that of manufacturer of the same. The reason is not far to seek. The maker knows the exact proportions of the pattern he is engaged upon, has all the calculations before him, and, given good technical ability, produces a very even series of instruments. The repairer, on the other hand, has instruments of every conceivable pattern and model passing through his hands. He knows nothing about the defective instrument when it is sent to him, but he has to discover its normal and theoretical qualities for himself before endeavouring to restore the lost tone. He has to be scientist, artist, and craftsman in one.

Naturally the commonest form of repair to be executed is the mending of a crack. This is generally to be effected by careful gluing with clean glue, the liquid being worked into the crack by a very gentle bending backwards and forwards of the part which is cracked. Usually it is necessary to open the instrument to do this. The belly is easily removed with a flat-bladed knife, if great care is exercised and no undue forcing attempted. Worm-eaten pieces and badly smashed portions have often to be excised entirely, and a fresh bit of wood, matching the original as nearly as possible, inserted. Glued portions are separated by overlaying them for a time with wads of linen soaked in lukewarm water. Warped backs or bellies are brought into line again by damping, steaming, and drying in specially-cut cramps. The actual work is that of the most expert cabinet-maker and inlayer: the knowledge of what is to be done is only acquired by great experience, and a natural gift for the occupation must be present.

THE PIANOFORTE

One thing is bound to strike everyone who first makes an acquaintance with the manufacture of pianos—namely, the extraordinarily small amount of skilled labour requisite for their production. True, when once the piano has been put together, the greatest skill and the utmost refinement are necessary for the proper regulation and tuning of the finished instrument: but, prior to that stage being reached, only at one or two points in its progress does the piano in the making call for the exercise of great skill and experience. We speak of the daily work in the factory: the designing and calculating of improvements is quite another matter, and calls forth the powers of the engineer, musician, and draughtsman.

For purposes of convenience, let us divide the piano itself into three distinct parts. First there is the case, then we have the soundboard, with its frame and strings attached to it, and lastly we have the action, or mechanism, which transmits the blow from the finger to the string.

Making the Case. Case-making is a branch of high-class cabinet-making pure and simple. Certainly, the maker has to understand the conditions to which the cases are to be exposed, but for all that it is really a branch of carpentry. As such, we need not discuss it here, save to say it is essential that the wood be seasoned to perfection, and that the curved sides of grand pianos are formed of a great number of strips of thin wood, bent and glued together, huge moulds and cramps being employed in the process. A close study of the articles on CARPENTRY and CABINET-MAKING [page 6579] will put the student on the right road to learning his calling.

The case being made, it has to be polished, and again, the section on FRENCH POLISHING [page 6591] will give all needful instruction. We have, therefore, two main processes to study here, the first dealing with the material from which the sound is produced, and the other with the means by which that sound is evolved.

The Sound Mechanism. We will now take the portion of a piano devoted to the making of the sound. First there is the back, which must be strong, to support all the material which lies on it, or which is attached to it. At the same time it must be of such a form as not to spoil the resonance in any way, for on it lies the soundboard, which forms the second division of this part of the piano. On the soundboard in modern pianos we find the iron frame, which takes up the strain of the strings, over which we have the strings, attached to pegs, passing over certain bridges and between small pins. There we have the entire sound-making portion of our instrument.

The back, or underside, in a grand piano is built of well-seasoned wood, sometimes of best English oak, and occasionally, in cheaper instruments, of beech. It consists of a stout framework, carefully mortised together, with bars across at different points. In English upright pianos these bars are usually vertical, and seven in number; in German pianos the bars run diagonally, as they do in most grand pianos. The oblique bars are said to give a smoother singing tone to the instrument, but they are not conducive to great durability. The making of these bars is, it will be admitted, merely carpentry. The calculation of their thicknesses, and the selection of their positions with a view to the quality of sound desired, is the work of a practical and theoretical acoustician. To this back, or underside, is attached the soundboard.

The soundboard is constructed of lengths of the finest spruce fir, similar to that of which the bellies of violins are made. These lengths are glued together with the greatest care, just as the belly of the violin is joined, and the direction of the wood is so arranged that, where possible, the entire length of both the bridges over which the strings pass shall lie on a single plank. The selection of the wood for the soundboard is a matter of much judgment, for on its resonance depends the greater part of the tone of the piano. Need we say that the wood, like that of the violin, must have a tone of its own?

A moment's thought will show us that the strings must exert an enormous downward pressure on the bridges, and therefore we must fasten the belly-bars across the underside of the soundboard to resist this pressure. The grain of these bars must run in an opposite direction to that of the wood of the soundboard itself. The bars are also necessary from an acoustic as well as a mechanical point of view. Anything like proper vibrations in the soundboard itself would be exceedingly undesirable, and these bars serve to prevent such being established other than by the vibration of the string.

Modelling the Soundboard. The soundboard, when the lengths of pine have been glued together, is the object of the most scrupulous care of, perhaps, the most highly-trained man in the entire piano factory. Remember how we had to give a "model" to the belly of the violin. The soundboard of a good piano has to be modelled just as carefully. It is of a more or less convex shape, the rise being towards the strings, and it tapers gradually away in various directions, the thickness

being suited to the string which will lie over it. No fixed rule can be laid down for this tapering, nor for the thickness of the soundboard at any one part, each maker having his own private formula, preserved as a secret, which gives to his instruments their individuality.

After the soundboard adjuster has done his work, scraping, chiselling, and planing here and there till the wood gives out the right ring when he taps it, and till his callipers tell him his thickness all over is right, it is covered with several layers of varnish to prevent cracking and warping. The varnish used affects the ultimate tone, just like the varnish of the violin-maker, and differs with each firm of makers.

The "Wrest Plank." Above the top of the soundboard in cottage pianos, forming, as it were, a border to it, and at the lowest end of that of grands, separated from it by a small space, is a massive log of hard wood, generally made of layers of beech or oak, the grain of each successive layer running across those of the previous one to prevent splitting. This block is also very frequently further strengthened by a metal plate.

When we mention that the function of this plank is to hold the pegs by means of which the strings are tightened, the necessity for this care becomes evident. It is known as the *wrest plank*, and the pegs are called *wrest pins.*

The Bridges. Across the face of the soundboard are two bridges made of hard wood. It is through these that the vibrations of the strings are transmitted to the soundboard. The distance between them varies with the length of the string. The one furthest from the wrest plank is called the belly bridge, and is made in two parts, that taking the covered bass strings being separated from the bridge for the smaller strings. If the detached portion of the belly bridge is so placed that the bass strings have to lie over certain of the other strings, then the piano is spoken of as "overstrung." The second bridge, or wrest plank bridge, is placed close to the wrest plank, and in grand pianos the wires are pinned down to it, to prevent their being in any way shifted by the impact of the hammer, which in this class beats the string away from the soundboard, but in uprights drives it towards the belly. These bridges are firmly glued and screwed on to the soundboard.

The Iron Frame. Above all this is placed the massive iron frame, which has to withstand the enormous strain of the strings, a strain which, in large concert grands, approaches 30 tons. The iron frame is cast of the best hard metal, carefully finished by mechanics. It is attached to the wrest plank, soundboard, and back. At one end it bears the pins to which the fixed ends of the strings are attached.

Across the iron frame are bars, the direction of which differs in almost every make of piano. These are simply mechanical contrivances for enabling the frame to withstand the pressure upon it. The iron frame is bolted into its place by massive bolts and screws.

Stringing. When the piano has reached this stage it is taken to the stringer, who is often a youth destined later to become a tuner or regulator. He begins to put on the strings, placing the loop over the end pin and the free end through the hole in the wrest pin, which he then hammers into its hole and tightens up slightly.

The strings being all in place, the body of the piano passes to the "chipper up," who is an elementary tuner. This workman, or artist in embryo—for he is in the first stage of skilled work—starts to tighten up the strings into some sort of tune. To get the sound, he chips the strings with a piece of ivory, twanging them like the strings of a mandoline. He does not start at one end ot the piano and work right through, but, "setting" a scale in the centre, tunes roughly from that, as if tuning a proper piano. This prevents the strain from being put on one end suddenly, leaving the other loose, a proceeding which would damage the piano. [For PIANO TUNING, see page 6442].

Stretching the Strings. The instrument having been brought into some resemblance of tune, a piece of board, covered with leather, is taken and pressed with great force up and down the strings to stretch them and, as far as possible, remove all spring in them.

After this operation it will be found that the tune has vanished, and so the piano must be re-tuned, being brought almost up to pitch. It is then left for a few days, and then again tuned to pitch. Four or five such tunings will be necessary before the tune will stand, and only then is the piano ready to be tried with the action. This chipping up is generally done after the back, soundboard, and so forth, have been firmly screwed into the case which is to contain them.

The Action. Very few piano-makers in this country make their own actions; unfortunately, most of them depend on the Continent for the supply of very second-rate mechanism. A few firms, however—not half a dozen, alas!—prefer to manufacture their own, and the result is that their pianos contain sounder and better actions than any made abroad.

The bulk of the action for the best English makes of pianos is cut out of the finest and hardest French hornbeam, a wood with very little grain, and one which works as cleanly as metal. It is little affected by moisture, and consequently actions made of this material rarely stick, provided they have been properly made. Foreign actions, produced in a violent hurry and badly finished, manage to stick, even when made of hornbeam. Beech is used for a few parts, and English oak is used for the action rails running right across the piano, against which various portions rest, or to which portions are screwed.

Of actions there are many, but as examples we will take two typical actions for upright pianos—namely, the over-damper check action and the under-damper check action, with a tape. These are named according as the damper is over or under the hammer. Of actions for grands we shall not treat, because, until the beginner has mastered the fitting and regulating of upright pianos, he will not be entrusted with the more costly action of a grand. We will, however, indicate the principle upon which the grand action works.

The actual making of the component parts of an action is accomplished by machinery, the work being so subdivided that unskilled labour can be employed to an enormous extent. Thus, one operative will do nothing but pass wood into the sawmill; another will be solely engaged in boring holes in one particular part of the action: a third will give the correct bend to the various wires used, and so forth, each operation being performed on machines fixed to an exact gauge, so that error cannot possibly creep in. Only when all the individual parts are ready to be assembled does the skilled man step in.

Where, then, does the superiority of the English action come in? In attention to detail, and in the quality of the accessories which are indispensable

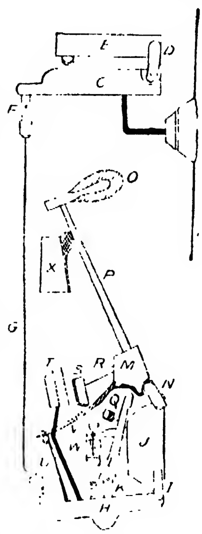
to the proper making of actions. We will indicate one small particular. The holes through which the tiny wires which act as hinges for the moving parts of the action should be lined, or "bushed" with cloth. In Continental actions this is never done so efficiently as in English actions, with the result that, after a time, the mechanism rattles, and rebushing becomes necessary if the piano is to work properly.

Over-damper Actions. The portions of an over-damper check action are best understood by reference to the accompanying diagram [2]. It will be seen that there are in reality two distinct motions, to be accomplished by two sets of levers operated initially by the primary action of the end of the key lever. The first motion is the withdrawal of the damper A from the string B, by the combined actions of the damper lever C, which is hinged on to the damper flange D, and checked in its turn by the damper rail E, to which also the flange is screwed. All flanges and parts screwed to fixed rails are fastened by one screw only, but, to prevent them from shifting, are provided with a groove across them, into which fits a raised bead on the rail. The damper lever is lifted by the damper lifter F, moved by the damper wire G, which passes through the base of the end of the jack rocker H. The wire is free in its hole, and has its button screwed upon it, on which the jack rocker presses to lift it. When the sustaining or loud pedal is pressed, by an arrangement not shown in the diagram, C is lifted, and so the dampers are moved away from the strings. The end of G, being loose in H, enables the jack rocker to move, when the key is struck, without affecting the damper at all. At the knob shown on the lower part of the jack rocker, a rod is fixed, which is pushed up or down by the direct action of the key.

The jack rocker may then be considered as the junction of the two systems of levers. It is hinged by means of the jack rocker flange I to the hammer flange rail J. Almost above the lower protuberance in the diagram is fixed the jack flange K, carrying the jack L, the upper end of which presses on the hammer butt M. The hammer butt is fixed to the hammer flange rail J by the hammer flange N, and on being pushed upwards by the jack, tilts the hammer O, carried by the shank P, against the string B. The little spring under the foot of the jack is to keep that part close against the hammer butt, and the jack is prevented from coming too far forward by the jack check rail Q, seen in section. The felt on this rail is adjustable by means of a screw. R, S, T, U, and V form the check system, and are named respectively the back check shank, the back check, the back catch on which the back check hitches when the hammer is far enough forward, and which regulates the rebound after a stroke—the stirrup wire, and the tape. The tape keeps the hammer from going too far forward, or from sticking close to the string after the key has been raised. W is the escapement rail, with screws and buttons for regulating, and X is the hammer rest, covered with padding against which the hammers lie.

Each of these distinct parts is made separately, and only assembled at the last minute. The curved and shaped pieces of hornbeam are first of all planed to shape with moulding planes, a whole strip some 6 ft. long being dealt with at a time. This is then cut up into sections by means of a revolving saw driven at very high speed. The sunk grooves, where the joints work, are then cut to a regular depth by another machine cutter, the depth being regulated by gauge. After this, the holes for the pins are bored, and then the holes are lined or bushed.

Lining the Holes. The bushing is done in this way. A strip of superfine cloth, known as "Mechanics' Cloth," and costing about 20s. a yard, is prepared of such a width that if forced into the hole its edges will just meet. These strips are cut by machines. The strip is rolled up spill-wise and the point drawn through a hole, and then through a second, and so on, till the strip of cloth is threaded through as many pieces of bored wood as will go upon it easily. Just as the cloth is drawn through the outside is slightly smeared with paste, to hold the bushing in the hole. When the strip is full, the various sections of wood are separated from one another by cutting the cloth with a sharp chisel, and when the edges are trimmed the holes are all neatly bushed. The bushing is then just opened for the pin by means of a needle. The shanks are made by drawing strips of wood through a revolving series of cutters, the strip emerging as a round stick, which is subsequently sawn up into lengths.



2. OVER-DAMPER ACTION
(For explanation, see text)

The base of the hammer butt, where the jack impinges, and the face of the back check are faced with very fine doe skin. This skin is far better than sheep skin, which is commonly used abroad. It must be shaved down to one regulation thickness before being cut into strips for the purpose of being glued into place. It is often advisable to fasten a piece of thick felt or cloth behind corners covered with this leather, as the shock is thereby softened, the action improved, and the life of the leather greatly prolonged. The felt for the hammer head is woven specially to a taper, and only requires bending and gluing into position, being pressed down with heated curved irons.

Fitting the Action into Position. When sufficient sections have been collected to make up an action a fitter builds them into position, by screwing the various flanges on to the rails attached to the action frame, which is made to fit the particular piano to be completed. Then he sees that each individual action works smoothly, and by means of the regulating screws gets all the levers to have about the right amount of play, leaving the final regulating to the expert later on.

In another part of the shop the keys have been sawn out, and the ivory or celluloid attached. Ivory, of course, cannot be bent, but celluloid can be bent by heat, and thus made to cover the top and ends of the keys. The holes for the pins and pivots are bored by machinery and the portions of the keys which play on the rod of the jack rocker burnished with black lead, or covered with felt or leather, according to the method employed by the particular maker. Then the keys have holes bored in them and lead weights inserted, of sufficient size, to nearly balance the entire key at the pivot when in contact with the action and the

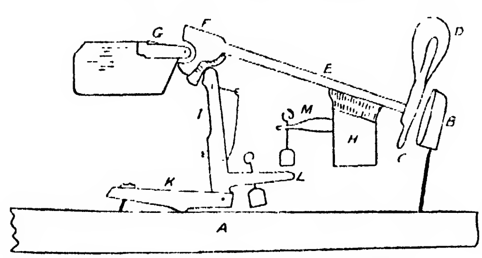
hammers lying back. The damper lever of over-damper pianos is also generally weighted, to ensure the damper falling forward on to the string as required. These weights are cast so as exactly to fit holes bored in the wood for their reception. The fitting must be done very neatly, lest a rattle should be set up.

All these adjustments having been made, and the keys placed on the key bed, and brought to a proper level by means of washers, or punches as they are sometimes called, placed under the keys round the pins, the action can be placed in position in the piano, and the instrument handed over to the regulator. At this stage the rail which is to lift the dampers is connected to the pedal levers which have been fitted inside the case, and the damping felt can be attached to the action, if the soft pedal is to be operated in that manner.

Under-damper Actions. The under-damper action, which we illustrate [3], is very similar to the over damper, save for the actual damping arrangements. The lettering of the hammer and check mechanism will, therefore, remain the same as in the previous illustration. The damper alone will claim our attention, together with the means of operating it.

In this action it will be noticed that the damper is inside the hammer mechanism, and the damper lever, which is in one piece, and marked A, is operated by a portion of the jack rocker on the opposite side of its hinge to the hammer mechanism. Did the end of the jack rocker touch the end of the damper lever, then, when the key was depressed, the end of the rocker would fall away from the lever. This would not work the damper. The damper lever is attached to the hammer flange rail by the damper flange C, and the lever has a small spring bearing against it, just sufficiently hard to press the damper firmly against the spring. The end of the lever, near the rocker, is covered with fine leather, and sticking upright in the end of the rocker, lying close to the end of the lever, is a small metal rod, flattened out into the shape of a spoon. This is marked Y.

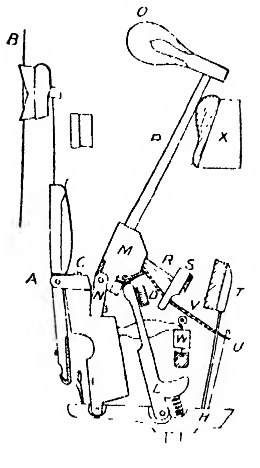
By means of a screw passing through the bottom of the lever the leather facing can be made exactly to graze the smooth surface of the spoon when the hammer is at rest. If, now, the jack



4. SQUARE AND GRAND ACTION
[For explanation, see text]

rocker be lifted by the depressing of a key, the end of the rocker beneath the lever will fall, but in so doing will thrust the spoon a little forward. The forward movement is not very great, but it is sufficient to enable the spoon to press against the leather-faced end of the lever, and so to lift the damper off the strings. On the key being released the spring returns the damper to the string. In this class of action the loud pedal mechanism may be of any kind which will press the entire set of dampers back from the strings a fraction, and may operate either above or below the damper flange.

Actions for Use in the Tropics. There is a new pattern action, which has recently been invented, for fitting to instruments intended for use in hot climates, which is excessively simple, while at the same time it is most efficient. In it the key acts directly on the jack rocker: the jack is very long indeed, and carries two projections on it at an interval of about 1½ in. distant. The lower one operates an over-damper action of the pattern shown in our former diagram. The inner and upper one carries the back catch, which in this case has the felt facing outwards. The hammer butt carries the back check, which is on a wire bent over the back catch, and with the leather facing turned inwards. The top of the jack acts direct on the hammer butt. By this means it will be seen that the friction, and consequent sticking points, are brought to a minimum, and there is much less padding for insects to destroy. The touch of these frictionless pianos is very delicate and they are fast becoming popular. In place of a tape, a small loop is attached to the hammer butt, and this hooks into a curved spring fixed in the upper part of the jack, the spring serving the double purpose of pulling the hammer back, and keeping the jack close up against the butt.



3. UNDER-DAMPER ACTION
[For explanation, see text]

Grand Piano Actions. The actions of grand pianos, as we have already said, are exceedingly complicated, but the principle which underlies their construction can be gathered from our diagram [4], which represents the action of an old square piano. It will be noticed that the key itself carries the back check, and the back catch is a prolongation of the hammer head in a downward direction. The jack rocker rests directly on the key lever, and the escapement lever, with its button and screw, also acts on the key, and, as well, on the set-off button attached to the escapement rail. The damper, which is above the string, may be raised by a wire fixed into the key lever at any point between the rocker and the back check. The parts are these:

A is key lever; B is back check; C is back catch; D is hammer head, and E hammer shank; F is hammer butt; G is hammer flange; H is hammer rail; I is jack, with spring and silk loop passing through jack or round it and attached to hammer butt; K is jack rocker; L is escapement lever and regulating button; and M is escapement rail with regulating button, or set-off button.

Regulating a Piano. The first thing the regulator does on having a piano handed over to him for adjustment, be it old or new, is to see that all the keys are perfectly level. If they are not, he places paper or cloth punchings, or wads on to the centre pin till all are exactly level. This will not,

as a rule, be necessary with a new piano, but it is mentioned because it frequently has to be done to old instruments. If the keys are too loose on the front holes the oval guide pins can be turned a little till they have free play, but are not able to shake. The depth of the touch is then tested. It should be about $\frac{3}{8}$ in. deep in the middle registers and about $\frac{1}{32}$ in. deeper or shallower in the bass and treble respectively. The correct depth can be arrived at by placing cloth or punchings under the middle rail to make the touch deeper, and under the back or front rail to make it shallower.

The Position of the Hammers. The regulator next sees that all the hammers are level and properly spaced, so that they strike the strings fairly. In a new piano, made with an English action, he will not find alteration necessary; but when a foreign action is fitted, he may have to shift one or two hammers a little. The jacks must next be adjusted close under the notch in the hammer butts, and this is done by turning the regulating screws; but the jack must not be raised too much or the note will fail to repeat in rapid passages. The proper position is immediately under the notch, just touching it lightly, so that the slightest touch on the key raises the hammer.

Next, the "set-off" must be seen to. The set-off of a note is the distance to which the hammer is raised by pressing down a key. In a properly regulated piano the hammer should advance to within a quarter of an inch from the string in the centre notes. In the bass it should be rather farther away, and in the extreme treble a little closer. Only experience can teach the exact ideal positions. The set-off is regulated by turning the regulating screw with a small hook till the hammer advances the proper distance.

That done, the back check and catch must be arranged by bending the wires till the check just catches the hammer and holds it for a second when the hammer rebounds from the string; this is to enable the jack to recover itself and get into the notch beneath the butt again. At the same time the check and catches must be adjusted so as to prevent the hammer from falling back too far from the string. About twice the distance of the set-off is correct, though some make the hammers fall back to $\frac{1}{2}$ in. all over the register. This must be properly adjusted or else the piano will not repeat with accuracy.

The damper action must next be seen to, and in an over-damper the wires should be adjusted by turning the buttons so that there is a play of about $\frac{1}{32}$ in. between the button and the end of the jack rocker. In under-damper actions the dampers do not often require touching, being adjusted in the shop. If, however, the dampers do not lift readily, or if they lift too much, the screw which passes through the lever end and presses the felt or leather out towards the spoon can be turned till the damper is correctly moved by the depression of a note. There should be a little space between the spoon and the lever tail when the action is at rest.

Next, the action of the pedals must be seen to, and any friction overcome by the use of a little blacklead. When all works smoothly, it is time to set about tuning the piano, be it old or new, in real earnest.

THE ORGAN

Organ building is a branch of the trade by itself. It is sometimes held to be the highest branch, but only on the grounds that the organ is the largest of instruments, for though the work in organ building must be accurate, the same exactitude in measurements is not necessary as that essential in making, say, a violin or an oboe. The organ builder, however, must add to his other qualifications that of an engineer and architect, for he has, as a rule, to build his instrument to fit some selected spot, and cannot make his instruments to any regulation shape or pattern. The trade is of such magnitude that we shall not attempt to do more than indicate the general principles followed, and we shall have to assume that the reader is a first-class carpenter to start with. Such he can become by studying the articles on that subject in this work [see CARPENTRY].

The organ builder, let us assume, has received a specification for an instrument to be constructed. The specification is a list of stops required, of mechanical accessories, and of methods of blowing, and so forth. The first thing to do is to plan out his organ, after taking measurements of the space which is at his disposal. Let us suppose that the space to contain the instrument is ample, so that he can build to suit himself to a large extent.

Now, an organ consists of bellows, a windchest, a soundboard, action for letting the wind into any particular pipe when the key is depressed, and mechanism for bringing various sets of pipes into use, and, lastly, the pipes themselves which give the notes.

The Question of Size. The size of the organ depends on the number of pipes to be used—that is, on the stops with which it is to be provided, and, if proper space is permitted, to avoid any makeshift arrangements, the general size of the organ will be regulated by the size of the soundboard, or soundboards, for the pipes stand on the soundboard. The organ may be entirely built on one very large soundboard, the great organ pipes being at the back and sides, the swell in the middle, covered by the swell box, and the choir, if there is one, in the centre and front; or each of these manuals, which are in reality separate organs, may have its own soundboard, as do the pedal pipes in most organs. So the organ builder, knowing the dimensions of the pipes of each stop, sets to work to make careful drawings of his soundboard, and so to arrive at the necessary measurements for it. Around this soundboard, or number of soundboards, the organ is built up.

The Pipes. The pipes of an organ are of two main classes—namely, wood and metal. The latter are divided into flue pipes and reeds, according as their tone is produced by a whistle-like mouthpiece or by a vibrating reed. The metal pipes are made by a special class of workmen, and are to be bought, or the organ builder makes his own from the sheet. They all have the familiar form, and differ only in length and voicing. The wooden pipes are also of two classes—namely, stopped and open. A stopped pipe gives the same note as an open pipe of double the length, and, as a rule, the stopped diapason is the most bulky of the stops placed on the main soundboards. This set of pipes, then, is first of all arranged for, and then the rest of the board divided up to suit the remainder of the instrument.

How a Wooden Pipe is Made. Making a wooden pipe is simply a matter of good carpentry. The parts are these: A foot, which is a conical, wooden tube, turned in a lathe and bored right through; a block, which closes the lower end of the pipe, and into which the foot conveys the wind to a channel cut across it; and a tube, formed of three pieces of board fastened to the back and two sides of the block, and a fourth with a bevelled edge attached to the edges of the two sides and coming just down to the top front edge of the block; and a

cap, which is a block of wood the size of the block, only broader by the thickness of the two boards. This has a wedge-shaped depression cut in it in such a manner that when applied with the hollow side inwards to the face of the block the thick end of the wedge may receive the wind from the channel and distribute it across the bevelled lip of the front pipe, producing a note. These are glued together, save in very large pipes, when the sides may be screwed to the block, and also the cap screwed on. In stopped pipes there is also a stopper which, when covered with leather, exactly fits the interior of the tube. This stopper has a handle which enables the tuner to pull it in or out at his pleasure.

With minute variations, all wooden pipes are constructed like this, though some have sides like inverted pyramids, and one or two rare stops have actual pyramidal pipes.

The Soundboard. The soundboard consists of a shallow box, divided internally into as many transverse grooves as there are notes on the keyboard, or pedal board, as the case may be. The pipes stand upon holes bored through the top of the box into these channels. The top of the box is made of two layers between which lie long strips of wood at right angles to the channels beneath, and directly under each set of pipes. The holes are bored right through the two layers and the strips, and thus it is clear that any wind in the channels can pass into the pipes above and make all sound. But if one or more of the layers be pulled out, or pushed in for an inch, a plain portion of the wood will intervene between the two bored layers, and the entire range of pipes standing above the layers thus shifted will be silenced. The drawing out or pushing in of these slips is controlled by the stops; when the stop is pulled the valves are opened, and closed when the stop is pushed back. In making this arrangement, the joinery must be perfect and the intercepting sliding parts accurately fitted lest the wind escape, and the tone of the organ suffer.

The upper table of the sound-box is conveniently made from sound boxwood, and the bars forming the sides of the grooves of good pine. The slips of wood which govern the admission of air to the ranges of pipes are cut from good pearwood, or other similar hard wood. They are termed sliders. Between each pair of sliders are strips of wood to prevent the air passing to a neighbouring set of pipes. These are termed *bearers*, and are glued between the two upper boards. It is needless to say that the upper boards need not be of the entire size of the soundboard proper, but may consist of a series of shallow boxes on the top of the soundboard, with the sliders and bearers enclosed within. This is a saving of wood. Also we need not point out that the upper board and sliders for small stops need not be as large as for heavy bass stops, such as those of 16 ft. pitch. The holes are bored through the boards, sliders, and soundboard with good centre-bits or *augers*.

To support the pipes a certain number of rack boards have to be prepared. These take the strain off the soundboard, and serve to maintain the pipe in an upright position. The holes in the rack boards have to be very much larger than those in the upper board, because they are eventually fixed on legs 5 in. above the upper boards, and so have to sustain the pipe, grasping it by the thick end of the conical mouth. Only the extreme tip enters the upper board. All holes are best scorched with a hot iron after being bored.

When the holes are bored, the interiors of the channels are well smeared with thin glue to close any flaw which may have been started in the process of boring. The sliders and boxes in which they work are best burnished with blacklead, and pins should be set in the slider cases to ensure the slider only moving its proper amount.

The Wind Chest. The wind chest is a shallow box, about 4 in. deep, or more, according to the size of the organ, attached to the under side of the soundboard. It is directly connected with the bellows by means of the wind trunk, a large wooden tube. This box contains the mechanism by which the wind is admitted to any of the channels in the soundboard, and thence to any pipe, for it will be remembered that there is one channel to each of the fifty-four notes of the keyboard, as well as one channel in the pedal soundboard for each of the pedal notes.

The width of the wind chest is governed by the length of the pallets which are to cover a great portion of the soundboard channels enclosed therein. The pallets are the wooden doors, with leather hinges which close the channels normally, and which are pulled downwards when a note is pressed. The back of the wind chest is usually made of a very stout bar of timber, called the wind bar, which helps to support the soundboard and enables it to bear the weight of the pipes.

The Pallets. To each channel is fitted a pallet, freely movable, but capable of firmly closing the portion it is destined to cover. It is kept closed normally by a wire spring, one end of which bears on a bar running the whole length of the wind chest, and the other on the surface of the pallet. The face of each pallet is covered with leather to ensure better closing of the aperture, and a ring or hook is attached to each which eventually is connected with the action of the organ. These rings are placed $1\frac{1}{2}$ in. from the end of each pallet.

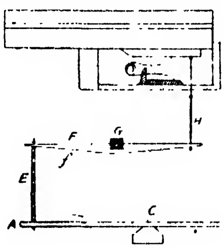
The bottom of the wind chest has to be bored at a number of spots exactly under the pallet rings and through the holes wires, known as *pull-downs*, have to pass to open the pallets, but at the same time the wind must not be allowed to escape through these borings. This is effected by fastening a piece of brass on the inside of the bottom board of the wind chest, with holes in it exactly of the size to take the pull-down wires; and along the edges of this brass slips of wood are glued to prevent any wind escaping beneath it. The pull-down wires are then passed through the board and the brass plate, and the ends attached to the pallet rings. The pull-downs must work very smoothly and never stick. All this being arranged, the open portions of the channels on the soundboard which are not covered by the pallets are covered in by gluing sheepskin or parchment over them, making an air-tight joint. The front board of the wind chest is made removable, to enable the pallets to be got at if necessary, but its joints must be made perfectly air-tight.

The bellows are not difficult to make. The form consists of three main boards for each bellows—the middle, top and feeder, as they are termed. There are also a number of thin plates of wood, known as ribs, to strengthen the sides. The whole are united by gussets of skin, and by leather hinges. The feeder must have ample room for play, according to the size of the organ, varying from 10 in. to nearly 2 ft. The upper part of the bellows, or reservoir, must also have the same amount of play, or possibly a little more. The middle board must be a little longer than the other two, so that its ends may rest upon the frame of the organ. It is the immovable base upon which the bellows work.

The middle board has a shallow box, some 4 in. deep, or more, affixed to its upper surface, or the same size as the top board. This is to enable the wind trunk to be attached to the reservoir, and is called the trunk band. In the reservoir there are sixteen ribs, and in the feeder only six, and of these last the long ribs are triangular in shape. The reservoir is made in two stages, the ribs being carried on a light frame the same size as the top board, and the folds are therefore double.

Valves. An opening is cut in the feeder board for the admission of external air, and in the middle board for the transfer of this air to the reservoir. Little bars are fixed across these openings, converting them into gratings, and valves, or " clacks " of white leather are attached thereto. The valves are best made of two thicknesses of leather glued together, and fastened at the edge by a slip of wood and a few brads, thus being firmly held down to the boards. They should fly open at the slightest pressure, and close quite flat. A valve 4 in. square should be made in the top board, opening inwards, and held closed by a stout spring to prevent over-blowing. This is opened by coming in contact with an iron rod when the reservoir is over-distended.

The wind trunks are rectangular wooden tubes, with the joints covered with leather to stop all leaks.



5. ORGAN ACTION
[For explanation, see text]

The Action. The essentials of an organ action can best be learnt from the accompanying diagram [5]; but it must be remembered that in nearly every organ various additions have to be made to these plain essentials on account of distance of sound-board from keys, and so forth, for it must be remembered that in an organ with more than one manual, however the pipes may be arranged, each manual *must* have its own perfect action mechanism.

AB is the keyboard, balanced on a pin rail near its centre, and has a pin, C, passing through a little mortise. Another pin keeps it in its place. E is a sticker, or light rod, which pushes, having wires at each end by which it is connected to AB at one end and to F, a backfall, or lever, at the other. F works on G, a backfall bridge. The other end of F, opposite to the sticker, is attached to H, the pull down, which is seen passing into the wind chest, and fixed to the pallet. This is the bare outline of the simplest possible action.

The necessary transference of motion in organ actions often necessitates the employment of rods which pull, which are then called *trackers*, and also of levers of angular form, turning between pins. These in their simplest form consist of rollers with arms projecting from them, and are called *rollers*, the frame in which they are fixed being known as the *roller board.*

The mechanism of the stops varies as much as that of the keys, and depends upon the position of the slider which has to be drawn. It resolves itself into a series of expedients for transferring the pull at the organ bench to a pull or push, as the case may be, at any given spot, and in this transference use is made of roller boards, trackers, and stickers. Only a little ingenuity is necessary to work out a scheme for any particular stop in any given position.

The pedal action is only a strong copy of the manual action and calls for no special comment.

Voicing and Tuning the Pipes. The voicing of pipes is the highest branch of the organ builder's craft, and cannot be taught save by practical instruction and by experience born of spoiling many valuable pipes. The slightest touch on the lips of a pipe may entirely alter its character. The tuning of organ pipes is difficult, but not so difficult as voicing. The tops of open pipes are cut down, a strip being taken out of the side till the right pitch is arrived at. Stopped pipes have their stoppers pushed in or pulled out till the desired result is attained, while reeds have the steel or brass rod which controls the reed knocked in or out to flatten or raise the pitch. It may be mentioned that two persons at least are necessary to tune an organ, one to manage the keys and the other the actual alteration of the pipes.

Reed Organs. Reed organs have bellows of two classes. In American organs the wind is drawn through the tongued reeds into the bellows and so discharged into the air; in harmoniums the wind is forced through the reeds from a wind chest filled by the bellows from a reservoir, as in the case of an organ. The making of the bellows in both only differs in the position of the valves, the one having the feeder with its valve to take air from the reservoir and deliver it outside, while the other has its valves in the reverse position. The spring which governs the reservoir is also reversed.

The reeds themselves in an American organ are in a frame from which they can be drawn by means of a hook. They are tuned by scraping them, at the point to raise the pitch and at the base to flatten it. Their voicing is accomplished by giving them a slight curvature. Harmonium reeds are fixed at the bottom of wind tubes leading from the wind chest, which rests on the top of the reservoir, to the pallets. They are screwed down. Their tuning is accomplished in the same manner as that of American organs, but they do not lend themselves to such varieties of voicing, the peculiar qualities of tone being obtained by variations in the wind tubes, which receive the vibrating column of air.

Miscellaneous Instruments

The accessories of the great family of orchestral instruments form a very small branch of the calling of musical instrument maker. The kettle-drums, which are really musical instruments, are built up from copper, or sometimes silver, sheets, into a form nearly hemispherical. The cubic capacity is accurately calculated for the note which the normal kettle-drum is to emit. Cymbals are beaten out of hard brass, and require much skill in tuning. The size of the central depression has to be accurately gauged or a pure tone will not result.

MUSICAL INSTRUMENT-MAKING *concluded; followed by* THE BUSINESS SIDE OF AMUSEMENT

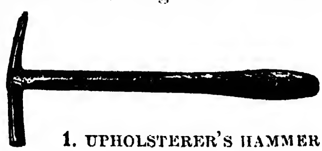
THE UPHOLSTERER'S WORK

The Tools and Materials of the Upholsterer. Stuffing Chairs and Couches. Making Mattresses and Bedding. Hangings, Carpets, and Linoleum

Following CABINET-MAKING from page 6591

THE work of upholstery may be divided into two classes—that which comprises the stuffing of chairs, sofas, and other articles of furniture, and that which concerns the arrangement of hangings. The former class demands chiefly the exercise of manual skill; the latter affords greater scope for the artistic faculties. We shall consider first the former class—that of furniture stuffing.

Upholsterer's Tools. The tools of the upholsterer are not numerous. The hammer used is light and of peculiar shape [1]. It usually has a claw at one end of the long head. A claw hammer of American or Canterbury shape [see page 3388] is also used. Then there is a special form of pincers used for stretching cloth [2] and sundry accessories such as upholsterer's needles, scissors, light or heavy according to the work in progress, a mallet, a bradawl, a ripping chisel, a screw driver, a pair of compasses, a rule, and perhaps a tape measure. The needles used by upholsterers are of special forms. The ordinary straight or bent packing needle is used for rough sewing. The proper upholsterers' needle is an instrument from 8 in. to 10 in. long, pointed at both ends, and with an eye near one end. For stitching up and mattress work a special needle bent to the shape of a semicircle or crescent shape is used. It has one sharp end only, the other end containing the head.



1. UPHOLSTERER'S HAMMER

The stud gauge is a small hand tool somewhat resembling a miniature daisy fork. The prongs, which are three in number and equidistant, are used to mark the places for the brass chair nails or studs put in round the edges. For ordinary studs—say $\frac{3}{8}$ in. in size—the prongs are usually $\frac{1}{2}$ in. apart. Web strainers, which are used to stretch the webbing tight before tacking it into place, are made in several forms, and one or other must be used if good work is to be done. The upholsterer's regulator is a pointed instrument slightly curved at one end and hafted at the other; it is used for working the stuffing into the corners during the stitching up. The stuffing stick, which is used for mattress making, may be made from a piece of hardwood about 30 in. long. One end is made fish-tail shape, and the remainder is rounded to make it convenient to hold in the hand.

A hair teaser is a machine which may be installed by the upholsterer. Its chief value is in repair and cleaning work, but it is used also to open out hair-stuffing from the rope in which it is bought. Flock and hair may also be teased by the use of hand carding combs, two flat boards thickly set with teeth and caused to move backwards and forwards with the material between, thereby teasing it out.

Upholsterer's Material. The materials used by the upholsterer are limited in number. Upholsterer's springs are used for the interior of chairs, etc. Their manufacture has been described on page 5173, but the upholsterer never makes them himself. The usual sizes used are 5 in. for the scrolls of couches, 6 in. for small chair seats, 7 in., 8 in., and 10 in. for couch and sofa seats and backs, and for easy-chairs. Chair webbing, or girth webbing as it is sometimes called, is used extensively. It is from $1\frac{1}{2}$ in. to 3 in. wide, and is an inextensible band of strong, closely-woven canvas. Then there is thick canvas for covering the springs, twine and scrim for covering the hair for first stuffing. Tacks and gimp pins—a small variety of tacks—are also used. Apart from these there are only the stuffing material and the covering material.

Stuffing Materials. The several materials used by the upholsterer for stuffing we shall describe briefly in catalogue order.

Horsehair is still an important filling material used by the upholsterer. It is supreme from the point of view of elasticity. The best qualities are used for filling mattresses, medium qualities for general work, and the cheapest varieties for rolls, or for inferior work. It is usual to lay between the hair and the covering material a layer of wadding, with its soft side towards the hair. This takes away the harsh feeling of the hair, and it also prevents the hair from working through the covering material. Hair is sold in rope form, and it must be teased out before being used as stuffing. Sometimes this is done by hand, as the machines used for the purpose are alleged to break the hairs, but machines are generally employed. The machine used by upholsterers in this country is a rotary machine consisting of a roller covered with spikes that tear the hair from the rope form. The machine employed on the Continent consists of a swinging quadrant furnished also with teeth, the thrust and pull working of the operator separating the hair as it is passed through.

Feathers are used as a filling material chiefly for mattresses. It is a mistake to use too cheap feathers, as they are not relatively so cheap as price would indicate; the better feathers are more elastic and fill more space, hence a smaller quantity suffices.

2. STRAINING PINCERS

Rabbit down is sometimes used as stuffing for very cheap work, but it is frequently verminous, and it is now seldom demanded. Flocks are common stuffing materials, and may be had in a wide range of qualities, and at prices from $1\frac{1}{2}$d. to 10d. per pound. They are the waste of the weaving factory, the best being waste from fine wool, and the lowest grades coming from the screening of cotton-cleaning machines. The best stuffing wool is white wool, which has a good curl, and is very elastic. It does not mat easily, and this is the factor of prime importance.

Flocks are sold in bags usually of 50 lb. or 56 lb. Their field is chiefly for cheap work, and only the washed varieties ought to be used. The upholsterer may save money by introducing cheap materials as stuffing, for the work is not open to inspection, but this is fatal to a good reputation and a permanent connection. Among the vegetable fibres used for filling—chiefly for cheap work—are cocoa fibre, Mexican fibre, Algerian fibre or Crin Végétal, and

alva, or alfa, a variety of sea weed which moths avoid. A superior material has recently come into use in kapok, a short-stapled vegetable wool which is of no use for wearing, but makes an excellent soft filling material. It comes from Java and India; its market price is about 7d. a pound, but under the name of "vegetable down" some dealers have made a little mystery about it and sold it at very much higher prices. The twine generally used for upholstery work are specially made. Stitching twine is thin and tufting twine is thicker. They are sold in ¼ lb. and ½ lb. balls.

Covering Materials. Important among the covering materials used by the upholsterer comes leather in several varieties. Morocco leather, or *levant*, as it is sometimes called, is the best, and owes its acceptance to its durability and its retention of its colour. It is the skin of the goat, and the sizes of the skins run from 25 in. to 35 in. wide. Roan, which is sheep skin, is much cheaper, and usually measures 30 in. to 38 in. wide. In appearance it is not easily distinguished from morocco leather, but it soon becomes shabby, and its chief sphere is for backs of chairs when the fronts are covered with morocco. Roan is elastic, and much easier to work than the more expensive morocco. Hair-cloth, the use of which is less common than formerly, is possible only for plain seats, as it cannot be plaited. The chair, or other article, is finished in holland or black canvas before the hair cloth is put on. Hair cloth is procurable in several widths from 16 in. to 30 in., but the price per superficial unit is much higher as the width increases, hence cloth work is commonly welted, thus making narrower widths workable. Hair cloth is generally black, and is made by weaving a horsehair weft—already dyed black—with a black linen warp. As a material it is very durable, and is not given to fade, but it is liable to retain a good deal of dust in its open texture.

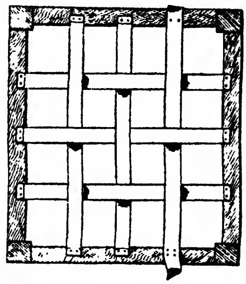
American leather cloth, or Crockett's leather, can be had in a wide variety of shades and surface markings. It has extended use in cheap work, and is valuable in being waterproof. The body is calico, and the surface is a waterproof composition. The usual width is 45 in.

Velvets—both genuine and imitation—are used in upholstery. The standard width is 24 in. Variation of the surface gives different kinds that are sold under specific names. Thus stamped velvet is passed through a rotary press and given a surface design. Utrecht velvet is made from mohair, and is heavy in pile and texture. Frieze velvet has a surface with small loops left uncut. Velveteen is a short-pile cotton velvet.

Plush is a variety of silk-pile velvet, and used to be much more frequently used in upholstery than it is to-day; plushette is a cotton imitation.

The covering materials used in upholstery are very numerous, and are constantly being added to. Fashion changes rapidly; one variety of expensive material may be adopted extensively by the highest-class trade, and will reign until manufacturing enterprise puts on the market an inferior and cheap imitation, and then fashion elects another queen.

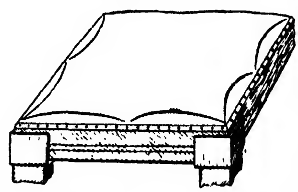
A Stuffed Chair. A chair is at once the most common and the easiest article of furniture to stuff, and it is therefore proper to consider it first. We shall take a small chair to be stuffed with hair and covered with leather. First take a roll of chair webbing, and having doubled over one end half an inch, drive some tacks through the doubled over part, thus tacking the end to the under side of the chair frame. Strain the webbing well and put two tacks into the other side of the chair frame, thus making a piece of webbing go right across the frame. Cut the webbing about 1 in. beyond the second tacks, then double this 1 in. over, and put some tacks through the double part. Use ⅝-in. tacks. Proceed until you have three lengths of webbing from front to back, and three from side to side [3]. Interlace the front to back pieces with the side to side pieces—that is, pass them over and under, as is done with the laths of a metallic bedstead. The spaces between ought to be of about equal size.



3. WEBBING OF CHAIR BOTTOM

Next, take five chair springs (6-in. size), and fix them with twine to the webbing. Let them be about equidistant from each other, and well towards the middle of the seat, not up to the edge of the chair frame. Then, to the top of each spring attach a piece of lashing twine, and tie the springs down so that they are not extended fully, but are compressed to, say, about 4½ in. high. In doing this, take care that the springs are quite upright. Take a piece of canvas and stretch it tightly across the top of the springs, securing it to the chair frame with ⅝-in. tacks. Then, using the bent needle, sew the top of each spring to the canvas, so that in use the springs will not be dislodged from their upright positions. In sewing, use about five or six stitches to each spring, and knot securely each stitch separately, so that if one stitch should come undone, it will not affect the others. So far, the work has been preparatory to stuffing. We now come to the stuffing proper. This is a double process, consisting of the first stuffing and the second stuffing.

The First Stuffing. For the first stuffing, run a string round, in long stitches, about 2 in. from the edge of the seat [4], and string on a fair quantity of hair. Avoid putting too much in the middle of the seat, especially if the seat has to be buttoned. Now, scrim—a variety of coarse muslin—is put over the hair and tacked into place temporarily.



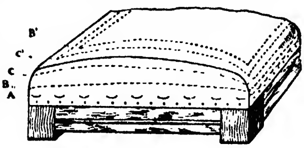
4. CHAIR READY FOR STUFFING

Stitch the scrim to the canvas, stretched over the springs and below the hair, using a double-pointed upholstery needle, and making the stitches about 3 in. long and about 4 in. from the edge of the chair all round. This leaves an outer edge right round, separated from the middle portion by the stitches. The temporary tacking round the edge must now be undone—a little bit at a time for preference—and the edge must be tightly packed with hair, using the regulator as an aid. Then having doubled over the edge of the scrim, tack it firmly all round.

We now stitch the edges of the seat. The purpose of the first stitches will be to secure the hair in the edges firmly, so that in use there will be no likelihood of it getting worked out of place into the centre of the chair. Thread the long, straight, double-pointed

needle with twine, and push it through from the front, just above the front rail, so that it will emerge from the top of the seat about 6 in. back. Pull the needle out a little, but not altogether, and changing its direction a little, send it back again to come out at the front, about 1 in. from where it entered. There is now quite a body of hair contained within the twine loop made in the inside. Pull the needle out at the front, and pull the twine very tight. Go on making stitches in this way right round the chair. Let the stitches be about 2 in. apart. They will be visible only in front [A in **5**], as the twine has not been carried out through the top of the seat. This form of stitching is called *blind* stitching. In sewing as described, try to get as much hair as possible, and to get as nearly uniform a quantity as possible into each stitch.

The second stitching is similar, but it is made to go right through the seat. Begin by entering the needle at the front, 1 in. higher than the first stitching [B in **5**], and draw it out at the top about 2 in. from the edge of the seat [B′]. After withdrawal, enter it again about 1 in. along, and at the same distance from the edge of the seat. Continue stitching in this way, making 1 in. stitches, and pulling them as tight as possible, until the front and the sides are all stitched. In a small chair, the back may be left with only the first stitching.



5. SEAT STITCHING

The final row of stitching may now be put in. It is similar to the second row, except that it takes in much less of the scrim and of the hair. Begin higher up in front than formerly [C], only $\frac{1}{2}$ in from the top, and come out on top only $\frac{1}{2}$ in. back from the edge [C′]. Having done this, the first stuffing is finished. If it has been properly done, it will be about 3 in. higher than the chair frame; it will overhang the frame a little, and will be packed to a uniform stiffness all round the edge.

The Second Stuffing. Now comes the second stuffing. If the seat is to be buttoned, draw a centre line on the scrim from front to back, and with this as a guide, mark places for ten buttons. The buttons will be in four rows, from side to side, alternating two and three buttons in the row. Thus, the front row will have three, the second row two, the third row three, and the back row two buttons. No button must be placed nearer than 3 in. from the edge of the seat. See that all the places for buttons are equidistant in the same row, and that the rows are at equal distances apart. With scissors, cut a small hole in the scrim where each button is to be, so that the place may be felt when the hair has been picked on.

We now take the skin with which the chair is to be covered. It must be marked for the buttons. Place it on the top of the scrim with the neck part towards the back of the chair, and mark and crease it into diamond-shaped squares. The extra size allowed for each diamond is usually $1\frac{1}{4}$ in. more than actual size, to allow for fulness in stuffing, but if the buttons be wanted very deep, as much as $2\frac{1}{2}$ in. may be allowed. If the skin has any flaw, it may be possible to make this go into the fold of a plait, thereby concealing it.

The skin having been marked and creased, the hair of the second stuffing is placed on the top of the scrim. A sheet of wadding, cloth side downwards, is laid on top, and upon the whole the skin is placed. The buttons are put into their places by means of string, with a slip knot. The hair is sloped away from under the buttons, which are pulled halfway down. The string is then tied, and the ends are cut off. Now, with the fingers, make the plaits lie regular and smooth, and make the stuffing even and uniform in thickness, so as to give symmetry of form to the seat. Pin the skin to the edge of the first stuffing, and cut off the skin to the exact size, leaving about $\frac{1}{2}$ in. all round for doubling in the edge.

Covering the Stuffing. The cuttings from the skin go to form the bordering all round the seat frame. For leather seats, the borders are usually attached with studs having heads covered with the same leather as the seat. If the studding be very close, border may not be necessary. The strips will not be sufficiently long to go round the sides and front of the chair frame, and there will probably be two joins. Let these be at the sides near the front corners, overlapping them about $\frac{3}{4}$ in. The border must be cut neatly with a sharp knife. Cut it about 1 in. wide, and double it back at both edges, so that the strip is $\frac{1}{2}$ in. wide, with the two edges touching, or almost touching, at the back. Thus, the exposed edges will be folded, and will not show the back of the leather. The joint should be made with glue that is not too hot, so that it will not penetrate and discolour the leather. The stud gauge will be used to mark the places where the studs or ornamental nails will be put in.

For the sake of clearness we have considered throughout a chair seat of horsehair, leather covered. Other stuffing is manipulated in the same way, and in any other variety of covering the same process is followed. American cloth ought to be warmed slightly, especially in cold weather, as otherwise the handling may cause it to crack. When the seat is to be plain and unbuttoned the instructions regarding the buttoning are, of course, not followed. When material other than leather is used for covering, the bordering used is gimp, a narrow, ornamental border of a colour to match the covering material. This is secured in position with gimp pins, a variety of small tacks. Now the underside of the seat may be covered with canvas tacked to the frame and hiding the springs.

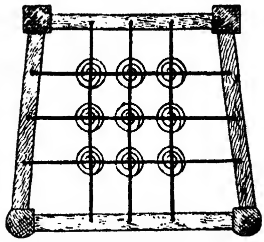
Upholstering a Chair Back. The back of a chair, if it is to be upholstered, is done much in the same way as the front, and as we have described. The interlaced webbing is attached and stretched to the frame, the springs are fixed—if springs are to be used—the stuffing is strung on, the layer of wadding is placed on top and the skin is attached as already described.

If the chair seat is buttoned, the back is both buttoned and tufted. The buttons are strung on, and the two ends of the string drawn through to the back of the chair, and tied over tufts, which are scalloped washers as used for mattresses.

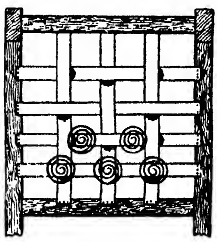
Stuffing an Easy Chair. An easy chair usually has a stuff-over frame—that is to say, the whole of the woodwork may be covered with upholstery except the legs. The frames are usually of beech or birch, the latter being the better, and the legs of mohogany or other superior wood.

The bottom is first webbed, say with six strands of webbing each way, then the back is webbed, the webbing for the back being attached to the front of the frame. Then the springs are attached. Four 6-in. springs are used for each arm, being attached with wire staples, or by any other convenient way, and no webbing being used. The seat will require 9 springs (8-in. size), and the back

5 springs (6-in. size). The seat and side springs are sewn to the webbing as described for the small chair, the side springs being in two rows, a lower row of three and an upper row of two. The seat springs are lashed with cord, that is to say, laid cords are tacked to the frame and passed round the top coil of each spring, there being a lashing cord for each row of springs from back tofront, and another lashing cord on each row from side to side, as seen in 6. The effect of this lashing is to compress the springs slightly, and to cause them to stand up about two-thirds of their natural height. If the work has been done properly, the springs will incline with their tops towards the front, so that when the seat is sat upon they will be vertical. We then give the back a little attention. We have already attached the five springs to the webbing [7]. From side to side we sew a piece of hessian to the horizontal strand of webbing just above the upper row of springs, then we pull the hessian tightly over the springs, compressing them a bit, and tack the hessian to the lower edge of the back frame, thereby retaining the springs in compression. Take another piece of hessian wide enough to cover the row of arm springs already in place. Tack this hessian to the inside of the arm rail, pass it over the top of the springs and pull it tight, compressing the arm springs in their turn, and tack the hessian to the outside of the arm rail. Treat the other arm similarly, and we are ready for the stuffing. Horsehair, flock, or alva may be used; if the first named, it may be of second quality. Put long loop stitches round the edges of the seat, and pull the loops fairly evenly with the stuffing. Cover the stuffing with scrim, which must be tacked to the edge, then put in more stuffing, using the stuffing stick, until there is all round the seat a roll similar to that we saw in stuffing a small chair. Then do the first and second stitching as described in our initial attempt and put the third row of stitches only in front, and up the sides as far as the arms, but not under the arms, and not along the back of the seat.



6. SPRINGS LASHED DOWN



7. EASY CHAIR BACK WITH SPRINGS

Easy Chair Arms and Backs. The back of the chair is sewn with long loops of twine, and stuffing is strung on under the loops. The swell at the bottom should have a much larger quantity of stuffing than higher up if the seat is to be comfortable, as this part goes into the hollow of the back of the person using the chair. Cover the back stuffing with scrim, and the first stuffing of the back is complete. We now stuff the arm bolsters—that is, the portions under the arm rails. These should be well and firmly stuffed. Sew on loops of twine as elsewhere and when the stuffing has been put on, cover with scrim. An equal quantity of stuffing must be put into each bolster or the result will not be uniform, and this caution applies particularly to the arm rail stuffing. The arm rail or bolster head, as it is called, may now be negotiated. Tack the end of a piece of scrim to the under side of the rail, and having stuffed it well, bring the scrim right round over the top of the roll and tack the other end down to the under side of the rail. In stuffing the arm rails, let the front parts be more firmly stuffed than the back parts, as the front requires to have greater resistance in use. Tack the scrim down at the back, and sew the front of the rail roll with two rows of stitches similar to those in the first stuffing of the small chair.

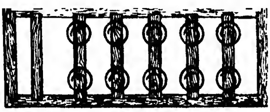
The second stuffing of the seat is done in the same way as we have described for the small chair. The material is strung on to the scrum within the rows of stitching and is made higher in the centre of the seat. Then the layer of wadding is placed over this, and the covering is put on top. In good work, a covering of calico, well stitched and made free from wrinkles, is placed below the leather or other covering, and tacked to the frame. After putting on this calico, the seat should be sat upon to see if it is all right. It will be found whether or not it shows sufficient firmness; if too yielding and slack, more stuffing should be put in, which means undoing the calico for the purpose. The other parts of the chair—the back, the arm bolsters, and the arm rails—are treated in similar fashion. Then the covering material—leather, velvet or other material—is fitted and attached, and the arm-chair ought to be a thing of symmetry and comfort.

Saddlebags. Saddlebags are properly of Persian carpet, and are very expensive. The name is now usually applied to squares of Wilton carpet pile which are used extensively by the upholsterer. They are square, and are put on the market in two sizes, 18 in. and 22 in. By sewing them to velvet surrounds, they have the appearance of panels, and thus used are widely employed for easy chairs such as we have just considered. Such a chair requires four saddlebags—two 22 in. for the seat and back, and two 18 in. for the arms. There is room for skill and ingenuity in cutting out the surrounding cloth so as to avoid waste, and with plain surrounds this is not very difficult, but with figured velvets it is much more difficult, because the pattern of the surface must be made to match, thereby limiting the freedom of action. Before cutting and sewing the surround to the saddlebags, sizes must be taken carefully. The width of the seat and sides between the bottoms of the stuffing rails at both sides must be measured exactly. Add 1 in.—an allowance for seams—and subtract the width of the saddlebags. By halving the result we have the width that the surround at each side must be. Similarly measure the chair from front to back, make the 1 in. allowance, deduct the width of the saddlebag, and halve the result; this gives us the width which the surround at front and back must be. The surround should be cut from the piece straight across the cloth; both strength and appearances require this. Now place the surrounds on a table with the saddlebag in the centre, and when they have been adjusted to their proper position, sew them together. This having been done, the seat is covered. Care must be taken to have the saddlebag right in the middle of the seat, and the cover is then tacked on. No wrinkles must be allowed to appear, and there must be no undue straining at any part or the balance will be upset, and the result will be uneven. The back and bolster arms are treated in the same way, care being taken to do the work evenly; more stuffing may be inserted or some stuffing may be taken out if it will conduce to this result. The back of the chair behind is usually covered with plain cloth

similar to that used for the surrounds of the saddle-bags, or a cheaper material of the same colour may be used. The bordering for the seat will be of a suitable nature and colour for the covering; sometimes a deep fringed bordering is used. The ends of the arms and head are often finished with tassels and cords, the colour matching the covering. The bottom of the chair underneath should be covered with cloth—usually black linen—put on over the webbing, and attached to the frame with tacks.

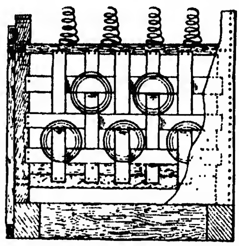
Couches and Sofas. We now come to the consideration of sofas, couches, and ottomans. A sofa, of course, is a long seat, with a back and two ends or arms. Remove one end and slope the back at one side, and we have a couch. Now take away the back, leaving the seat with only one head or arm, and we have an ottoman. A sofa has the back upholstered like the back of an upholstered chair, but a couch often has the back open with merely an upholstered top rail. Couches are commonly left-handed, which means that a person reclining on one and facing the front would have his left arm free and be reclining on his right side. The old English style of sofa has very steep ends, so that a pillow is necessary to comfort, but the present fashion is towards the German style of arm, which slopes away at a more obtuse angle, and is at once more comfortable and more graceful. The practical effect of the construction of the latter type is that the pillow of the English style is introduced into the upholstery itself, rendering the extraneous article unnecessary.

Upholstering a Couch Seat. Let us upholster a spring seat couch with a serpentine back—that is, a back which in profile is like a camel's two humps, that further from the head much lower than the other. The seat is the first part to which we give our attention, and before we upholster it we must remove the back from the frame, which will not be difficult, as it will be found to be attached by screws. We shall not use webbing, as we did with the small chair and the easy-chair, but rails of wood attached to the front and back of the seat frame by their ends. There will be six of these cross rails, arranged so that the daylight spaces are equal. We do not put springs on the rail at the head end, but on every one of the others we put two springs [8]—one towards the back and one towards the front—and fix them with staples. Tack a length of hessian to the front of the frame, strain it over the springs, compressing them to two-thirds of their natural height, and tack the hessian at the back of the frame so as to keep the springs compressed. Sew the top coil of each spring to the hessian, seeing that their final positions are vertical. With the curved needle put long loops of twine along the front edge, along the bottom edge, and along the back at its edges. Pack under these loops stuffing to the thickness of 3 in.—fibre or rag flock, not the mattress varieties of flock. We have now a border of stuffing all round except at the head. Fill up the middle part with flock, making it higher in the centre than elsewhere. Tack a piece of scrim all along the front, fold it right over to the back, and tack it to the back rail in the centre of its length. Then tack down the whole to the back rail, working from the centre. Do not pull up the scrim too tightly when doing this, but let it be stretched evenly, and see that the stuffing is fairly uniform as the work proceeds, remedying any shortcomings in this direction with the stuffing stick or regulator, and withdrawing or adding flock if necessary. The front, back, and bottom end may now be stitched—in a manner similar to that followed in the case of the easy-chair—with first, second, and third stitches.



8. COUCH BOTTOM WITH SPRINGS

The Couch Head and Back. The frame of the head consists of covered scrolls at each side, connected with cross rails, probably four in number. Tack webbing to the face of the cross rails—say three lengths, straining it as already seen. Then interlace cross webbing and tack it to the side scrolls. Attach the springs in the usual way, using five in all, a lower row of three and an upper row of two. Then attach four springs to the top rail at right angles to the other springs, all as illustrated in **9**. Cover now with hessian, attaching it to the side scrolls, and string on twine loops, filling the loops with stuffing. Cover the whole with another piece of hessian, tacked to the bottom cross rail and at each side to the side scrolls, pack the stuffing uniformly, and not too firmly into the bag thus formed, and sew the whole up complete.



9. SPRINGS FOR HEAD OF COUCH

The couch back will probably have upright rails. Web it horizontally, and interlace intermediate webbing vertically. Attach twelve 4-in. springs, cover with hessian, loop up, pick on the stuffing, and cover with hessian again as for the other parts of the couch, finally sewing right around the curved edge with first and second stitching. The covering remains to be attached.

Covering for Couches. If skins are used for covering couches, they must be sewn together because one is not large enough. Three skins are always required, and sometimes part of another as well. If the couch seat is not to be buttoned, cut the skins quite straight so that the seam will be at right angles to the line of the front rail, and sew them neatly together with a small welt. The sewn skins must be cut to shape upon the couch itself. Tack the cover on at the front rail first, then beginning in the centre, strain the covering back and attach to the back rail. Work along from the centre until the whole couch is done. If the seat is to be buttoned, the skin must be marked for the buttons as already seen for the small chair. The front row of buttons should be 3½ in. to 4 in. from the front of the seat, and the diamonds of the buttoning should be marked 7½ in. from side to side and 9 in. from front to back: this, with the allowance necessary for fulness, giving diamonds 7 in. from back to front and 5 in. from side to side. If the depth of the couch from front to back is greater than the width of one skin, another skin must be sewn to the first, so as to give the necessary width. The edges to be sewn should be cut to a diamond, pointed zig-zag shape so that each point will fit into a corresponding angle. To mark the buttons for the head of a couch is a complex task, and can be done properly only by the experienced man whom practice has instructed. The allowance for fulness in the diamonds must be increased the further up the head the work is carried on. This increase is usually 1 in. more for each diamond than for the diamond immediately

below it, and is caused by the curve of the head demanding an allowance in addition to the of the individual diamonds.

Bedding Manufacture. The manufacture of bedding falls within the scope of upholstery in the widest sense of the term. The stuffing of a mattress is hidden just as is the stuffing of a piece of furniture, and there is even more imperative call that absolutely clean materials should be used. Vegetable fibres such as cotton flocks and alva do not attract moths; hence they are generally healthier than feathers and wool. Horse-hair is considered the healthiest material, however, as it is a better heat conductor than other materials and does not retain the body heat of the sleeper. Horse-hair for mattresses should be short and curly, and if suspicion be entertained that it has been adulterated with vegetable fibre—rather a common practice—it may be tested by burning it, as horse-hair burns to a black ash and vegetable fibres to a grey ash. If wool be used for mattress stuffing, white wool is the best, but it is also the dearest. The temptation of the upholsterer to use inferior stuffing is very great in these days where such a large share of the trade depends upon competition in price. Sometimes both hair and wool enter into mattress filling, the hair being in the centre with a layer of wool below and above, also at the sides and ends, the object being to secure the springiness of the hair combined with the softness of the wool. Such mattresses are known as "cased" or "French." The hard, straw-stuffed mattresses used under the hair or wool mattress are called *palliasses*. Their purpose is to protect the mattress proper from the hard wear which would come by placing them direct contact with the bed laths.

An ordinary mattress of 6 ft. by 4 ft. size contains 48 lb. of best hair, 54 lb. of medium quality hair, or 54 lb. of good wool stuffing. Mattresses should be opened and have the stuffing material thoroughly cleaned and teased at periodical intervals, say, every two years at least. This is a detail regarding which the majority of English people are too indifferent; in some other countries householders are much more alive to its importance. In France, for instance, a common feature of the household spring-cleaning is that bedding cleaners visit the house and open, clean, tease, and refill the bedding.

Stuffed Mattresses. The most common variety of mattress is the stuffed mattress, and we shall consider the manufacture of one of the size mentioned above—to wit, 6 ft. by 4 ft, which is the size sold in largest numbers. The covering is ticking, a strong material which may be had in various colours and patterns. It is usually cotton, and is mixed in the cheaper qualities. Linen and jute cloths are also used, chiefly for hair mattresses. Coloured ticking is known as fancy Belgian. Drill is a variety of ticking, and sateen is another variety with a lustre caused by the methods adopted in finishing. To bind the mattress together, mattress ribbons, which are to be had in patterns and colours to match the coverings, are used. Then mattress buttons are to be had in any colour to match the covering material. Mattress tufts are stamped circular pieces of leather, leather, or woollen cloth.

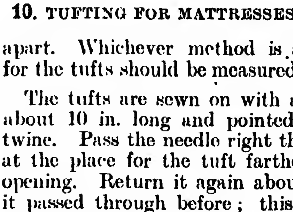
The cutting-out is the first operation. The tying down of a mattress uses up some cloth, so in cutting the cloth we must allow for this. The usual allowance for a hair mattress is 1 in. for every foot of length and ¾ in. for every foot of width, so that the upper and under surfaces of a 6 ft. by 4 ft. mattress will be 6 ft. 6 in. by 4 ft. 3 in. If wool is the stuffing material, the allowance is not quite so great. Having cut the main pieces, cut out the borders, or sides. They must be cut from across the piece so that the stripes will run up and down in the direction opposite to the stripes on the face of the mattress. Make them 6 in. wide and 6 ft. 4 in. long, the odd 4 in. being allowance for sewing. The border for the ends will be similar—4 ft. 4 in. long by 6 in. wide.

Sewing the Mattress. Now, with the sewing machine sew the large top piece to the four borders all round it—the seam being ¼ in. from the edge of the material—so that the edges come to the outside of the corners of the mattress. Take a roll of mattress ribbon—an entire roll contains 144 yds.—and sew it over this seam with the sewing machine, and through the double thickness of the ticking. The corners are not sewn up to a sharp angle, but are slightly rounded.

The bottom piece is now sewn to the side pieces—at the free sides of the latter—leaving, however, about 20 in. unsewn at one end to be used for filling the case. The ribbon is sewn over the seams round the bottom piece in the manner already described, and the corners of the borders—where the side pieces join the end pieces—are sewn from the inside with a needle and thread.

The stuffing material is now put into the case, through the opening left for the purpose. Put in a small quantity to begin with—say 10 lb.—and with the help of the stuffing stick push it well into the corners, but do not press it too firmly. Add more stuffing, distributing it evenly over the whole space, and see that the mattress comes up square, with the sides in their correct relation with the top and bottom surfaces. In this way fill about three-quarters of the mattress case.

We now tuft the mattress, that is, sew it through and through with stitches held by a tuft at each side. The tufts may be in rows parallel with the sides and ends of the mattress, which gives the appearance of squares, or they may be arranged as in the buttoning of an easy chair, in which event they will give a diamond-shaped appearance [10]. The latter looks better, but the former makes the mattress more easily rolled up for storing and transit. The tufts are usually 6 in. apart. Whichever method is adopted the places for the tufts should be measured out properly.



10. TUFTING FOR MATTRESSES

The tufts are sewn on with a mattress needle—about 10 in. long and pointed at each end—and twine. Pass the needle right through the mattress at the place for the tuft farthest from the filling opening. Return it again about 1 in. from where it passed through before; this will show a stitch about 1 in. long. Place a tuft under this stitch, make a slip knot at the other side and insert a tuft here. Now pull up the string tight until the tufts are drawn together and sink quite an inch into the stuffing, then tie it firmly and cut it off. Proceed with the other tufts in the same manner, until almost as much of the mattress as is filled has been tufted. Fill the remainder of the mattress, sew up the opening that is left, and finish the

tufting. The mattress is now finished; it should be firm and its appearance regular.

For hair mattresses a stronger ticking is necessary than that used for wool; it is usual to employ linen ticking, as this prevents the hairs, which are comparatively sharp and penetrating, from making their way through the cloth.

Feather Beds. Feather beds are mattresses filled with feathers instead of hair or flock, and are not tufted. The feather bed, if of good quality, will be bordered and welted, as we have described in the manufacture of mattresses; but many are made without border, the case, in that event, being merely a large sack of ticking. Feathers have the power of penetrating the cloth, and this tendency cannot be entirely eliminated, but it may be minimised by waxing the inside of the ticking, the waxed surface offering a smoothness which the feather stem finds difficulty in piercing. A feather bed 6 ft. long by 4 ft. wide requires about 48 lb. of feathers, and one 6 ft. 6 in. long, demands about 52 lb. of feathers.

Upholstered Spring Mattresses. The box spring mattress, or upholstered spring mattress, is a mattress consisting of a wooden frame with a bottom of wooden laths or webbing, upon which are mounted spiral springs, surmounted by a stuffed superstructure. For a box spring mattress of ordinary size the wooden laths usually number six, and are placed across the frame. To each lath six 10-in. springs are attached by wire staples, or, if the laths be replaced by webbing, by sewing. These springs are lashed down by having twine strung across their tops. Over the top is placed a piece of hessian, and all round the side, but not at the top; the hessian is formed into a roll about 8 in. wide, which is stuffed with cocoa fibre or other coarse stuffing material. This roll is securely stitched, and when finished forms a semicircular pad close to the edge of the mattress frame all round the sides and bottom. Now cut the top cover, which will be 2 in. larger than the wooden frame and 1½ in. wider. Put stuffing all over the hessian which covers the springs, and over this put the top cover; tack it into position all round, and tie it down, tufting it in the way already described. Short pieces of webbing may be nailed to the seams of the frame near each end so as to form handles by which the mattress may be lifted. Now cover the entire bottom with a piece of hessian.

Certain precautions should be observed in making a box-spring mattress. There is a temptation to make the centre too high, as is customary in stuffing chairs, but a top that is perfectly flat is far preferable.

Webbed Box-spring Mattresses. Another style of box spring mattress is made without bottom laths, but with webbing above and below the springs. A box frame, consisting of sides only, would be rather weak, and two cross stretchers must be used to impart strength. The webbing is put on in the usual way, 3 in. spaces being allowed between the lengths. It should be strained well. The springs—of which there will be 30 to 36 in a mattress of 6 ft. by 4 ft.—are 8 in. high, and of No. 10 wire gauge. Care must be taken to have them upright before being attached to the upper webbing, which is put on tightly so as to compress the springs. We have now got a wooden frame with interlaced webbing on both upper and under sides, the space between the webbing being occupied by springs. Place over the top webbing one piece of hessian to cover the entire surface, and tack it to the wooden frame. We now cut two side pieces and two end pieces the exact length of the sides and ends of the frames, all being 6 in. wide. Sew these pieces to the hessian 4 in. from its edge; then we shall have a loose flap all round the hessian. Tack the unattached edge of this hessian to the wooden frame all round, thus forming long channels all round the four sides of the mattress. These channels must now be filled with stuffing—fibre or flock—and will form a thick roll all round. String on stuffing about 3 in. thick to the top surface within the rolls just formed. Cover this with hessian, which tack to the side frames all around just beneath the edge of the rolls. Now make a top cover of sateen ticking, giving it a 6-in. deep border for sides and ends, and sewing it up and binding it with mattress ribbon, as already described in making the ordinary stuffed mattress. Having made the cover to fit the frame, pull it on and tack it beneath the wooden frame. The whole is now tufted in the usual way; and after having had the under surface covered with hessian, the box spring mattress is complete.

Spring-framed Mattresses. A spring-framed mattress is another variety which resembles somewhat the box spring mattress, but its manufacture is work for the carpenter rather than the upholsterer. Also it is being discarded in favour of less cumbrous arrangements. Two rectangular wooden frames are made and are lathed with wooden straps. Turned conical guide blocks are nailed at each crossing of the laths. The guide blocks in the lower half look upwards and those on the upper half look downwards. Mattress springs are put over the guide blocks, the cones keeping the springs in the proper positions, and wire staples are used to retain them, four staples being driven in around each bottom coil. The whole may be covered with mattress ticking, or the sides may be left open. In use, this type of mattress has always an overlay mattress on top, but the wire-woven spring mattress has displaced it, and will no doubt eventually oust it altogether.

Palliasses. The palliasse, or straw-filled mattress, is used underneath the ordinary or overlay mattress. Its object is to protect the mattress proper from contact with the metal laths of a bedstead, but the introduction of the wire mattress affected the extent to which palliasses were used, and they are now becoming less common. Palliasses are usually made in two parts, divided right across the length, so that a palliasse for a 6 ft. by 4 ft. bed consists of two halves, each 3 ft. by 4 ft. The case is usually of canvas, with a border of ticking on three sides, that side which butts against the other half being of canvas. The case is bound right round. The border is not so wide as for an overlay mattress, being only 4 in. Straw is the best material for filling. It is frequently used as it comes from the bale, but ought to be twisted up and broken before being used. Straw that has been used for packing goods makes, if clean, excellent filling, as it is usually well broken. The case is made by sewing the tick border to the hessian cover with strong linen thread, well waxed. After being filled and sewn up, it should be beaten well with a heavy stick to make it quite flat. It is now sewn right through, as in tufting, but tufts are not generally used. The top and bottom edges may be blind stitched—that is, sewn with the first stitching we saw in upholstering a chair, but this is not always done. When many palliasses are made, a palliasse frame—that is, a box the exact size of the half palliasse internally, and serving the purpose of a templet, may be used. It conduces to rapid work, making individual measurements unnecessary.

Making Pillows and Bolsters. The usual size of pillow is 27 in. by 18 in., and in cutting the ticking for it the size of the two pieces is 28 in. by 19 in., the extra inch being the allowance for curvature. Feathers and down are the best materials; with the latter the covering is usually swansdown, the woolly side being left inwards. The amount of filling used depends upon the filling properties of the feathers selected for the work. Down requires only 1½ lb. for a pillow, and feathers run from 2½ lb. for white goose feathers to 3 lb. for poultry feathers.

The length of a bolster is decided by the width of the mattress, and the cloth required to go round the girth of the bolster is from 36 in. to 40 in. The bolster ends are either oval or oblong, with rounded corners. These ends, if oval, are cut about 11 in. by 7 in., the finished size of the oval being 10 in. by 6 in., the odd inch each way being taken up by the seam. The oblong ends are cut about 14 in. by 6 in., which are, of course, smaller when finished. The ends may be sewn to the body with a welt, the ends of the cylinder body being drawn into the welt for this purpose. The welting is not universal, however. The bolster takes rather more than twice as much stuffing as the pillow. Some bolsters are wedge shaped, tapering to the front. But this kind is found uncomfortable by most people; it is used more frequently in Continental countries than it is here.

Draperies and Hangings. In addition to the stuffing of furniture, the upholsterer is called upon to undertake the arrangement of curtains and hangings, and these may therefore be considered within the scope of upholstery. But success in this department cannot be obtained by precise instruction regarding procedure. It is a matter for the artistic eye rather than the skilled workman, and the best work can be done only by the possessor of an eye for grace of form, line, proportion, and colour. The ability to judge effect can be cultivated by careful study of the designs of the masters of the craft. But with the knowledge that instruction must be limited to the minor and mechanical part of the business, we can proceed to say what can be said with advantage.

The specific uses of hanging draperies are for window curtains, bed curtains, portières or door curtains, fireplace hangings, and curtains for pictures and mirrors. For window and door curtains the material should be heavy and pliable, so that the weight will give natural folds, and that the hang may not be made unnatural by any inherent stiffness in the material. Thus jute tapestries, Utrecht velvets, serges, and heavy printed crepes are suitable for such work. Window curtains should be cut to a length so that when hanging loose they will be about 3 in. longer than just sufficient to touch the floor. The hook from which the curtain chain is suspended should be from 4 ft. to 4 ft. 6 in. from the floor, and when the chain has been drawn up with the curtain within it, the bottom of the curtain will just about touch the floor. If there is to be a valance above the curtain, it may be cut straight or stepped, or with just enough of edge cutting to relieve the stiffness of absolute plainness. For a room of reasonable height, the valance is usually about 24 in. deep. If the material of a valance be tapestry, it should be panelled with plush or Utrecht velvet, the edges of the velvet being finished with gimp. The curtain should have a width of the same velvet right across its width, about a foot from the bottom.

Draping a Mantelshelf. The simplest form of household upholstering is the surround for a mantelpiece shelf. This may be made with side hangings; but the most elementary form is merely a valance along the front, and returned down each side. The shelf itself should be covered with cloth or baize, returned over the front edge and tacked to the under side. This cloth must be put on tightly, and with the weave of the cloth parallel to the line of the shelf. Wrinkles should be avoided; but if they appear, they may be dispelled by being damped and ironed. Now a strip of buckram may be tacked to the front edge, or to the front of the under side, and made to hang down in front and at the sides, but must not be so long that it will show under the valance. The valance looks best when of velvet or plush. The fringe of the valance, usually a ball fringe, must be sewn on before the valance is attached to the shelf, and the valance may be lined if desired. In fixing, tack it first in the centre, and then work along to the ends, making it tight, but not straining it, or the corners will not hang down square. The festoons are now put on. They must be of a material that is very soft, as any stiffness in these would ruin the appearance of the drapery. They must be uniform in size, and to make them so a pattern or templet, easily made out of card, may be used with advantage. A pinking iron, or mushing iron, as it is sometimes called, is a sort of steel chisel of crescent shape with a scalloped edge, and is used to shape the edges. It is used by placing its edge on top of the cloth on a block of lead and hammering it on to the cloth. It is possible to hang the festoons in one piece, drawing it up into festoons; but it is better to make individual festoons, tacking the upper edges to the shelf edge on top of the valance, and afterwards drawing the sides together and fixing them up with a tack. After this has been done, the points where the ends of the festoons join are fitted with rosetts, cords and tassels, or by fancy brass nails.

Wall Upholstery. A new class of work is falling to the lot of the upholsterer with a high-class trade. Silk, or other fabric, is stretched across walls from end to end, taking the place of wallpaper. The walls contain, or have fixed to them, battens all round, and first "bump"—a species of heavy cotton cloth—is stretched and nailed to the battens. Then the fabric, which has been sewn into one piece, is stretched over the bump and tacked. The work must be evenly done. Then gimp or braid is glued round the edge. The same treatment is applied to decorated skins, such as those for which the seventeenth century Spaniards were noted.

Carpet Laying. The planning and laying of carpets are operations which fall within the sphere of the upholsterer. A plan of the room is first made on paper, and great care is necessary to see that the sizes are correctly recorded, because to find that a carpet is a misfit after it has been sewn up is an expensive matter. When a room is of rectangular or square shape—and most rooms are—it is necessary to measure the distance between the opposite corners, and if the two diagonals are not of exactly the same length, it is obvious that the room is not truly rectangular or square, and the trouble must be found and noted, the carpet being made accordingly. When a wall recess or a window space is of circular form, a base line must be drawn from the two extremities, and parallel lines drawn every twelve or six inches from the base line to the arc, the size of each one of these parallel lines being recorded on the plan.

Plan of the Carpet. When cutting a carpet, the plan of the carpet—full size—should be drawn

upon the floor with chalk. The long, straight lines can best be made by a chalk line, that is, a length of cord which, in use, is rubbed with chalk, then held tightly at each end, lifted up in the middle and let go, when it makes a straight line upon the floor. Having made the plan of the carpet on the cutting floor, the border must first be cut. The corners of the border must be mitred. This is not difficult when the corner is square, because then each mitred end is half of a square, and the extreme points are cut to angles of 45°; but if the corner is not square, care and skill are necessary to secure a good and regular mitre. The carpet proper is now cut to fit the space within the border. Kidderminster carpets are 1 yd. wide, and other varieties are ¾ yd. wide. Difficulty may be found in matching the pattern at the seams where the lengths of carpet join, but it is imperative that this be done if the completed carpet is to be a symmetrical whole. The carpet is sewn either by hand or by machine. The selvedges of the carpet are sewn quite close to each other, and are, of course, sewn from the back. If the carpet has a plain woven selvedge, this is doubled back after sewing at the inner edge of the selvedge. If there is no such selvedge, each edge is turned in half an inch, so that, in planning and in cutting out, an inch has to be allowed in the width of each length for seaming. The ends of the various lengths must be doubled over and overstitched, so that they will not fray. Another method of treating the ends is to sew a piece of webbing across the end underneath, right up to the edge, and to overstitch the webbing and carpet together. The extra thickness is not appreciable from the upper side.

Stretching the Carpet. After the carpet has been sewn together, it should be stretched and have any wrinkles and creases taken out. The carpet-stretcher is used for this operation. This is an instrument with a handle resembling a broom handle, but the end is something like a flat shovel, with the point of the blade cut into prongs or teeth. By standing on the carpet and pushing it away with some force by means of the carpet-stretcher, the stretching is effected. Working from the centre, stretch it section by section until it fits the chalk plan made on the cutting floor. As one part is stretched, put drugget pins—that is, brass-headed studs—into it, so as to retain it in its stretched condition. Any loose or creased part may be made right by being damped by the application of a wet cloth and ironing.

The carpet may now be considered ready to be laid in its proper place. The floor upon which it is to be put should be smooth, all projecting nails and spikes should be withdrawn, and all projecting knots planed down. Felt may be put on before the carpet, thus thickening the floor covering. Care must be taken not to have the carpet and underlay so thick that doors opening inwards into the room will rub against the carpet. It may be necessary to unhinge and cut the door in such an event. The actual putting down of the carpet is a simple matter, the only precaution necessary being to make it quite straight.

Much trouble and time may be saved by using carpet squares instead of planning and sewing carpets. Carpet squares are rectangular carpets made in one piece, including the border. The room in such an event has a polished or stained floor around the carpet square.

Laying Stair Carpets. The laying of a carpet on a straight stair is a matter of extreme simplicity. It is simply tacked at the top or bottom, and put at each step under the stair rod and tacked at the other end. The stair-rod eyes should be screwed or driven in in a perfect straight line right from top to bottom of the stair, and their distance apart should be half an inch more than the width of the carpet, thus giving a quarter inch of clearance at each side. The distances at each side of the carpet between the wall and the balusters should be uniform. Stout pads or underfelt are usually put on each tread under the carpet: they give a softer tread, and prolong the life of the carpet. Stair pads should be about 1½ in. shorter than the carpet is wide, and, while stopping short of going right to the back of the tread, where they would interfere with the stair rod, they come down over the nosing or rounded front of the tread, where the greatest wear is. In America stair rods are practically unknown. Instead, stair carpets are tacked, or are held by stamped brass corners with short prongs, which are pressed into the angle made by the tread and the riser.

Carpets for Spiral Stairs. The laying of a carpet on a circular or spiral stair presents greater difficulties. If laid properly, it should look, when laid, as if it were unbroken from end to end. The best way, but the most expensive on account of the waste that it causes, is to cut the carpet across at the bottom of each riser, and to sew it together there. The more usual method is by folding triangular sections under the face at each riser, so as to absorb the unnecessary cloth caused by the circle. Whichever method be adopted, it is a good rule that the narrow carpet edge on every step should be some distance from the balusters. It will not be possible in some cases, where all the treads are not at the same angle.

Laying Linoleum. The practice of having linoleum made in bordered squares is lessening the need for fitting linoleum, although fitting is still the more common method. The standard width of body cloth, as the body of the linoleum is termed, is 2 yd. In cutting up there is room for skill in devising methods of saving waste. Patterns of geometrical design are more likely to be economically laid than floral carpet patterns, because the former can be reversed, and sometimes even turned sidewise, and still preserve the pattern, while the latter must be kept running one way.

The customary knife used for cutting linoleum and floorcloth is of the billhook variety, and must be kept sharp. Many workmen rub the knife edge through their hair every few minutes as they proceed, this perhaps imparting to the edge a lubricant that makes cutting easier. The chalk line is used for making straight lines. Some linoleums are uncertain, and may expand considerably after laying. The variety known as cork carpet is particularly liable to this defect. For this reason linoleum is sometimes not tacked into place for a week or more after it has been laid, so that if stretching takes place, sufficient may be cut off the edge to make a perfect fit. The edges of linoleum are tacked to the floor with thin brads, these being placed as close to the join as possible, and being put at the same spot on opposite sides of the join. Linoleum bordering is mitred in the same way as carpet bordering.

Designing for Wallpapers and Printed Fabrics. Block and Machine Printing. "Sanitary" Papers. Stencilling. Designing, Cutting and Printing Stencils

Continued from page 6598

By H. NAPPER

THE covering of walls presents to the designer the largest field for the use of repeating pattern. There is very little technical difficulty to contend with compared with designing for carpets or woven fabrics.

Block-printing Wallpapers. This is the simplest and most artistic way of getting a repeated pattern. It is also the most expensive, not in the actual preparation, but in the time taken (by the printer) in producing the finished paper. It is necessary before starting the design to decide whether it is intended to use it for printing in transparent or solid colour—that is, whether the pattern is to be printed light on dark, or the reverse. Whichever is chosen, paint the design the way in which it will be printed—that is, do not paint in the ground if the pattern is to be printed, but paint solid the part that should represent the part of block which carries the colour on to the paper. The designer will then not be so likely to make dots or enclosed spaces, which would fill up when the block is placed on the colour pad and spread into a solid mass when applied to the paper [30].

The design, when bought, will be handed over to the block-cutter, who will trace and transfer the drawing on to a wooden block the size of the repeat—that is, if it is not larger than 21 in. by 24 in. (21 in. by 21 in. is the most convenient size). If the design be smaller than this, endeavour to repeat it twice in height, so that two repeats can be produced by the same impression. To draw designs for, say, 14 in. or 15 in. in height too large when doubled for the printer to handle conveniently, would mean a third more time and labour than in printing a piece of 12 yd. He will then, after colouring with a strong colour the shapes transferred to the block, cut away the ground, leaving the design raised. The same process will follow for every colour used, be it outline or mass. Small points will be left at the corners of the block, raised a little above the ornament, to enable the block to register and keep it firm on the printing table.

A Primitive Method. The blocks will be handed to the printer, who sits with a table in front of him, colour pad at the side. The block is then attached at the centre of the back to a lever, which is balanced so that he can easily place the block on the pad (which is coloured for every impression by his boy), and when charged with colour, place in the right position on the paper. With his foot pressed on a lever he brings sufficient weight down on the block to get a clear impression.

Only one colour is printed at a time. The paper, passing up to the ceiling on rods, is allowed to dry before other colours are added.

Two colours can be printed from one block if necessary by arranging, say, groups of flowers, so that they are well away from each other to allow different colours to be easily applied to the surface of block or on the colour-pad.

The effect of colour printed from the wooden surface is richer, fuller, and softer than when printed by machine. Especially is this the case when transparent colour is used; the texture or grain is very beautiful, and would not repeat itself in the next impression. Only the best quality of paper is suitable for block, owing to the lightness of handling compared with machine; it has not the tendency to destroy the surface or original texture.

Machine Printing. The method of printing by machine is entirely different from block. The design is traced and transferred to rollers, the circumference of which corresponds to the height of the repeat. An outline is then punched into the roller with strips of brass in varying thicknesses to give the variety of outline. The process is repeated with the rollers representing masses of colour, an outline first being made with brass, then filled in and felt added to the printing surface. It will be seen that this is a costly and difficult process—in some cases ten or twelve rollers are necessary. The rollers, when finished, are made to register—that is, to fit exactly into the proper place for printing. The method is much cheaper than block printing, for the machine produces miles of paper printed with the finished design.

The plain paper passes round a large drum, attached to which are the smaller rollers with the pattern; revolving against it, printing and at the same time re-charging with colour for the next repeat.

The whole pattern is, of course, wet, the rollers following so quickly that, although the rooms are heated, great care must be taken that too much of one colour does not fall upon another. Two colours that in block could be printed one over the other, must, in machine, be made to fit even so that a slight running together will result. Should a light outline be required, the filling-in colours must be about $\frac{1}{16}$ in. from it. There is not so much difficulty with a dark one, owing to the medium being thicker.

Engraved Rollers. This is the process commonly called "sanitary." This name was a great mistake from the artistic point of view, for it is capable of most beautiful results—in fact, almost anything can be represented in the matter of gradation and colour. The rollers are of copper, upon the surface of which the pattern is engraved by a series of punctured dots, giving, by their scarcity or density, the depth of colour required.

If two or more rollers are used, more than two or three different colours can be obtained. The colour being transparent, one can print over the other, and give various tones of the mixture.

Thus, blue roller printed over yellow would give a series of greens; blue over red, purples, etc. Care should be taken not to depend too much on the mixtures, for. owing to the great pressure of the rollers, the colour is liable to become muddy. The whole surface of the roller receives the colour, but before meeting the paper a scraper cleans the smooth parts and leaves the colour only in the punctured surface. Large surfaces of dark colour across the design should be avoided, as these parts would tend to wear away owing to the action of the scraper. The sizes of rollers vary both in surface and engraved printing. Those in ordinary use vary from 15 in. to 21 in. in circumference. In engraved work small patterns which repeat often in the width of 21 in. are engraved mechanically, saving tedious labour.

Hints for Wallpaper Design. In preparing designs for wallpapers use strong paper so that it will bear the rough handling of the cutter and printer. Use solid colour for block and machine, and keep the work on the hard side, leaving nothing to chance. This will enable the cutter to interpret the work better. For engraving use water-colour, but let the gradations have distinct tones so that the engraver can easily trace them.

In **27** and **28** there is given a small piece of a design showing the difference between a block and machine print. The outline of a block is inclined to spread and give a fat look, but with machine it is inclined to shrink and give a thin look, the speed of printing, of course, tending to give this effect. Part of the same design [**29**] for engraving shows the graduated effect with one roller.

Printed Fabrics. The printing of patterns on fabrics—velvets, cretonnes, silks, muslins, etc.—is in some way similar to the printing of papers. There are two distinct methods, block and machine. The same qualities of richness are produced by the hand block and the beauty of the original material is preserved to a far greater extent than in papers. It is impossible to produce by machine the velvety depth or flooding of colour which is the characteristic of block printing, owing to the material having to be of a smoother and harder nature so as to pass through the machine in an even manner. The breadth of rollers for machine is generally 30 in. for piece-goods (printed curtains run to much larger widths), but with block-printing a greater variety of widths can be used, thus making it of greater value for commercial purposes.

Block Fabric Printing. Block work is, of course, more expensive than machine owing to the time taken in printing and to the better material used, but its lasting powers are far greater, and for hangings nothing can be better. The material is generally pasted or strained on large tables, and the repeat set out as shown in illustration [**35**]. It will be seen that there is a different method of handling the blocks compared with paper printing. There is no way of reducing the weight of block, the entire weight being lifted by the printer and placed in position. This limits the size of the pattern, 10 in. by 15 or 18 in. to 15 in. by 15 in. being quite large enough for the printer to handle comfortably. If larger repeats are required, say 15 in. by 30 in., two sets of blocks must be used, thus doubling the cost of cutting and adding to the time of printing.

Varieties of Design for Block Printing. Care should be taken not to make the work too fine, and also as to the number of colours used; over-printing is sometimes an advantage, but should be used sparingly, as it tends to limit the range of schemes—the extra colours made are called "supers." If possible try to arrange the pattern so that it will look complete without the ground—that is, arranging for the principal part to be printed, say, in four colours, reserving two for extra effects. Use these to get darker effects by the addition of a pattern on ground which enables the manufacturer to produce two changes in appearance by the same design. Should the same blocks be used for velvet, requiring a dark ground, a still richer effect can be obtained by adding another block.

Another use made of block is in the printing of patterns for bed-spreads, table-covers, hangings, and other fabrics. in which a large surface of colour is required with borders, etc., in light colour [see illustration **34** to discharge or resist printing]. By the use of, say, two blocks, one for corner and the other for repeating patterns, an endless pattern can be made to work on any size material. The light part is left up on the blocks and is printed on to the raw material with chemicals which resist the action of colour. When printed the whole piece is dyed, leaving the pattern in the untouched ground colour of the material.

Machine Printing on Cretonne. The method used for this fabric is somewhat similar to the engraved process for wallpapers. The pattern is made on copper rollers, several tones of the same colour being obtained from each roller by means of lines or dots called "stippling." The illustration [**33**] suggests how the tones are worked by the engraver. It is not necessary to work the design in this manner. The exact shapes required can be painted in in water-colour, for although it will be made with dots and lines, the result will be a flat tone when printed, owing to the necessity of having always underneath a first roller to soften the material.

The design can be made to repeat in full width of rollers or any equal division, but the height or circumference of rollers in general use should be 15 in., unless otherwise stated. In making a design for ordinary or all-over patterns, the best method is to plan it on the diamond or lozenge, 30 in. by 15 in., to give greater freedom [**36**]. In 15 in. this becomes a drop, but for conventional work it is better to plan the drop in squares [**37**]. Reversible cretonnes are made by machine—that is, with a clear print on both sides of the material.

Stencilling. For the young designer, decorator, painter, or any other craftsman there are few crafts as interesting and instructive as

33. MACHINE PRINTING CRETONNE

37. DESIGN IN SQUARE STEP OR DROP

PRINTED FABRICS

stencilling. In all the other branches of decorating by means of pattern, the designer, as a rule, has no control over its production; but with stencilling he can be designer, cutter, and printer. The production of the plates is so simple and inexpensive that the decoration can be planned and completed in the room or house in which it is required. Take the stencilling of a frieze [40] as an example. The interesting or the largest part of the design can be arranged in the centre of the wall, and the motive altered in colour or simplified in design, so that when the corners are reached, the effect of overcrowding can be saved, and the decoration given the appearance of having been produced specially for the room [38]. The same plates can sometimes be used for door panels or screens, giving quite a different effect. It is quite easy to stencil on almost every kind of plain fabric, such as muslin, arras cloth, linen, or velvet.

Designing for Stencilling. As an example of preparing a design for use in pure stencilling a frieze may be taken which is to be worked with three plates. By a little arrangement one or both of these plates can be made to give two distinct colours. The best method is to decide on some simple arrangement and plan out roughly the masses of colour without much thought regarding the drawing. Keep them as large as possible so that there is plenty of scope for graduating the colour, the great charm of stencilling being the accidental effects.

For the first plate, flower and leaf can be arranged together, reserving the second and third plates for the background [39]. Now take a solid white, and begin to give the shape you require to the flower, etc., by painting an outline on the masses of colour. This serves two purposes, giving shape to the pattern and strength to the plate. Break up the mass as little as possible, and see that the full amount of expression is obtained for every line. These lines are called ties. Do not be afraid of them or paint them out afterwards, for this is a sign of the incompetent craftsman. Treat the background plates in the same way, but give them an entirely different effect, either giving a lot of even detail or making them almost plain.

Cutting the Plates for Stencilling. Take a piece of tracing-paper (fairly strong, for it must stand a good deal of rubbing), and make a careful tracing, outlining each side of the ties. This is very essential in order to save the trouble of thinking of the part to be cut. Then take four pieces of cartridge paper (thick), being certain that they are much larger than the design. In one of them put two drawing-pins, point up, at top and bottom of paper—this is for the registration of plates to ensure their fitting exactly—then place the other piece on the top and press the pins through. Do the same with the tracing, and it will save much unnecessary trouble. Now rub the tracing on to the three plates, taking care that the tracing is exactly in the same holes. Start by cutting the flower-and-leaf stencil-plate first. In doing so, place the paper on a piece of thick glass, and with an ordinary knife cut out the parts enclosed by a line. Care should be taken to cut away from the corners in every case, so that slipping across the ties is avoided [42].

When the cutting of the first stencil is complete, lay it on to the background plate, and stencil through the cut parts to verify its fitting exactly; proceed with the second plate in the same way. Afterwards give the plates a coat of knotting or varnish on both sides, and allow them to dry thoroughly.

Practical Stencilling. Almost any medium can be used in stencilling—water-colour, oil, tempera, etc. For small work water-colour is the best. When once the difficulty of preventing the colour from running too freely from the brush has been mastered, always use large brushes [41], even for the finest work: they cover the ground more quickly, and give the colour a better texture. Never by any chance allow the brush to go directly into the colour. Mix the colour rather thick, place it in a saucer, on the top of which put a piece of clean flannel, and charge the brush by rubbing it on the top of the flannel. By this means the colour will be taken up evenly, and too much moisture, which would have the tendency of running underneath the ties, will be prevented. Cut on the plates a small piece more than is required [see petal of flower in 39A], so that if the design runs along it can be seen at once whether it fits into the right place.

THE WORLD'S MINERALS

A List of the Important Minerals and Mineralogical Synonyms, Giving Their Chemical Composition, Physical Properties, Products, Uses, and Other Particulars

By S. G. STUBBS

THE purpose of this article is to give in convenient form a comprehensive account of the characters and uses (if any) of all the important minerals. The 1,300 names and synonyms given in the pages following are not equal to more than one-third of the minerals dealt with in Dana's wonderful "System of Mineralogy," but the two-thirds here omitted are not important economically or mineralogically. Rocks are not dealt with here. They are mixtures of simple minerals, and particulars of them will be found in other pages or in any good work on petrology or petrography.

Important synonyms of the minerals dealt with are included in the tables and are indicated by the italic *s* (synonym); for particulars of these, reference is to be made to the name given. Where a mineral is a more or less closely related variety of a more important mineral, this fact is noted, the italic *v* (variety) being used.

In the second column the chemical formula or chemical composition is indicated by means of the ordinary symbols and formulæ of chemistry, which are fully explained in the course on CHEMISTRY. Where possible the structural formulæ are given. Where it is not possible to assign a definite formula the constituent compounds or elements are given. Elements enclosed in brackets and separated by commas can, and do, replace one another without altering the crystalline form of the mineral.

Physical Properties. All minerals vary greatly in colour, generally on account of accidental impurities derived from the rock or other environment in which they occur, and the colours given here are those which are most usual. In the fourth column are stated the approximate specific gravities of the minerals. Where the limits are somewhat wide they are noted. For methods of determining gravities of minerals see Precious Stones, page 5853; much of the information appearing there as to the physical properties of stones applies equally to other minerals.

The figures denoting the hardness of the minerals are those of Mohs' scale, which comprises ten degrees of hardness, the following being the typical minerals:

1. Talc	6. Felspar
2. Rock salt, or gypsum	7. Rock crystal (quartz)
3. Calcite	8. Topaz
4. Fluorspar	9. Corundum
5. Apatite, or glass	10. Diamond

This scale is entirely arbitrary, and the value of the degrees varies greatly, the difference between 10 and 9, for instance, is much greater than that between 9 and 8 [see also page 5852].

Crystalline Systems. The system of crystallisation to which the mineral belongs is indicated by the Roman numeral in the sixth column. The six systems are:

I. Isometric (Cubic, or Regular);
II. Tetragonal (Pyramidal);
III. Hexagonal (Rhombohedral);
IV. Orthorhombic (Rhombic, Trimetric);
V. Monoclinic (Monosymmetric, Oblique);
VI. Triclinic (Asymmetric, Anorthic).

Although crystals occur in very many geometrical forms, it was early seen that many of these were merely modifications of simpler forms, and ultimately, as the result of the birth and decease of many ingenious theories, it was shown that all these modifications might be referred to the six simple systems given above, and, moreover, that, as the result of the mathematical laws of symmetry, no more than six simple systems are possible.

The Principles of Crystal Systems. These systems are based on the relations of the axes of the crystals—imaginary lines connecting opposite points, such as opposite corners or the centres of opposite faces. In the first system, the Isometric, or Cubic, the axes are all equal, and cut one another at right angles. This is the simplest and most regular system, and examples of it are common salt and fluorspar, which crystallise in the form of a cube. In the Tetragonal system only two of the axes are equal, but all intersect at right angles. The precious stone zircon is an illustration of this system. Other systems are considered to have only three axes, but the Hexagonal, or Rhombohedral, has three axes intersecting at 60°, and a fourth cutting these at right angles. In the Orthorhombic or Rhombic system none of the axes are equal though they cut one another at right angles. The majority of minerals fall into this class, of which barytes and topaz are representatives. Monoclinic or Monosymmetric minerals have all their axes unequal and only two of the axes intersecting at right angles. Quartz takes this form. The sixth system, the Triclinic, or Anorthic, is, as its second name indicates, entirely irregular. None of the axes are equal and none intersect at right angles.

Abbreviations Used in the Tables. Some minerals are not found crystalline. These are indicated by the abbreviations Am., Amorphous; Mc., Micro-crystalline; Mass., Massive. In the seventh column are a set of abbreviations indicating the appearances of the minerals. These are:

A	Adamant	S	Silky
B	Brilliant	Sa	Sub-adamant
D	Dull	Sm	Sub-metallic
E	Earthy	Sp	Splendent
F	Fibrous	Sv	Sub-vitreous
G	Greasy	Tc	Translucent
Gl	Glinting	Tp	Transparent
O	Opaque	U	Unctuous
M	Metallic	V	Vitreous
P	Pearly	W	Waxy
R	Resinous		

In the eighth column are given very briefly the products, uses, or other particulars of the minerals. The products are given first, and are followed either by the uses or other particulars.

For a chemical classification of the minerals and for a short account of the principles of mineralogy and crystallography reference should be made to the course on GEOLOGY, page 765.

Arkansite *v.* Brookite	TiO_2	Red, brown, etc.	4·2	5·5	IV.	A.	Titanium; from Arkansas
Arksutite, *s.* Chiolite							
Arnimite *v.* Herrengrundite	CuO,SO_3,H_2O	Green	3·1	2·5	V.	—	From Plauitz
Arquerite *v.* Amalgam	$Ag_{12}Hg$	White	10·8	3	I.	M.	From Chili and Brit. Columbia
Arsenic	As	Grey	5·7	3·5	III.	M.	For uses see index
Arseniosiderite *s.* Löllingite							
Arsenolite	As_2O_3	White	3·7	3	I.	A.	Commercial "white arsenic"
Arsenopyrite, *s.* Mispickel	$FeAsS$	Greyish-black	6	5·5	IV.	M.	Arsenic (46 per cent.)
Asbestos (Hornblende group)	$(CaMgFe)SiO_3$	White to brown	3·2	5·5	V.	F.	*See* Chrysolite
Asbolite, Asbolan, *v.* Wad	$Co(Fe,Cu)O$	Bluish-black	3·5	2·25	Am.	R.	Cobalt
Asmanite	SiO_2	Colourless	2·3	7	IV.	V.	
Asparagus-stone, *s.* Apatite							
Aspasiolite	Si,Al,Fe,Mg oxides	Greyish	2·7	7	—	—	A pseudomorph of Iolite
Asphaltum	$C_{14}H_{18}O$	Black to brown	1·5	1·25–2	Amor.	R.	Paving, covering, etc.
Astrakanite, *s.* Blödite							
Astrophyllite	$R,R_2Ti(SO_4)_4$	Yellow to gold	3·3	3	IV.	P.	R is H, Na, K; R_2, Fe, Mn, Ca, Zr
Atacamite	$Cu_2ClH_3O_3$	Emerald green	4·1	3·5	IV.	V.	Copper (59 per cent.)
Atelestite	$H_2Bi_3AsO_8$	Yellow	6·4	3–4·5	V.	Te.	
Atopite	$Ca_2Sb_2O_7$	Yellow	5·0	5·5–6	I.	G.	
Augite (Augite group)	$AlO_3.MgAlSiO_3$	Greyish	3·3	6	V.	V.	Resembles hornblende, pp. 768, 1009
Aurichalcite	$(Zn,Cu)(OH)_2CO_3$	Greenish-blue	3·7	2	V.	S.	
Autunite, Calcouranite	$(UO_2)_2Ca(PO_4)_2.8H_2O$	Citron yellow	3·1	2	IV.	P.	Uranium
Avanturine felspar, *v.* Oligoclase	Al_3,Na,Ca,Si_5O_{16}	Greyish-white	2·56	6	VI.	V.	In jewellery as Sunstone
Axinite	$H_2Ca,Fe,Mn,BO,(SiO_4)_5$	Brown, grey	3·3	7	VI.	V.	
Azurite, Chessylite	$(CuOH)_2Cu(CO_3)_2$	Blue	3·7	3·75	V.	P., V.	Copper, p. 4127
BABINGTONITE	$(Ca,Fl,Mn)SiO_3$	Greenish-black	3·36	5·5	VI.	Sp.	Cornish iron ore
Baltimorite, *s.* Serpentine							
Barcenite	Sb,S,Hg,Ca,H_2O	Dark grey	5·3	5·5	—	D.	
Barsowite, *v.* Anorthite	$CaAl_2.Si_2O_8$	White	2·58	5·5–6	IV or V	P.	Corundum gangue
Barylite	$Ba_4Al_4Si_7O_{24}$	Colourless	4·03	7	—	G.	
Barytes (Heavy-spar)	$BaSO_4$	Varies	4·3	3	IV.	V.	White-lead substitute; pigments; paper-making
Barytocalcite	$(Ca,Ba)CO_3$	White, yellow	3·6	4	V.	V.	

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Basaltic hornblende	$(Mg,Fe)_2,Al_2O_3,SiO_3$	Black	3·1	5·5	V.	—	
Basanite, *s.* Lydian stone							
Bastnäsite	$[(Ce,La,Di)F]CO_3$	Yellowish-grey	4·9	4·5	III.(?)	V.	Ce, La, Di; from emerald mines
Bauxite	$Al_2O_3.2H_2O$	Whitish, etc.	2·5	3(?)	Oolitic	E.	Aluminium: alum mfr.; fire-bricks, crucibles
Beauxite, *s.* Bauxite							
Beegerite	$Pb_6Bi_2S_9$	Grey	7·2	—	I.	M.	
Bell-metal ore, *s.* Stannite							
Bernstein, *s.* Amber ..							
Berthierite	$FeSb_2S_4$	Greyish-black	4·1	3	Pr.	M.	
Bertrandite	$4BeO.2SiO_2.H_2O$	Colourless	2·6	6·5	IV.	V.	
Beryl (Emerald)	$Al_2Be_3(SiO_3)_6$	Green, blue, etc.	2·7	7·5	III.	V.	Flawless, as precious stone. *See* p. 5855
Beryllonite	$BeNaPO_4$	Colourless	2·84	5·75	IV.	V.	From U.S.; precious stone
Berzeliite, Kühnite, Pyrrharsenite	$(Ca,Mg,Mn,Na_2)_3(AsO_4)_3$	White to yellow	4·0	5	I.	R.	
Berzelite, *s.* Mendipite ..	$Pb_3O_2Cl_2$	White to yellow	7·1	3	IV.	A.	
Bieberite	$CoSO_4.7H_2O$	Rose-red	1·9	2·5	V.	S.	An efflorescence
Biharite *s.* Agalmatolite							
Bindheimite	$Pb_3Sb_2O_8.4H_2O$	White, grey, etc.	4·7	4	Am.	R.	Cu often replaced by Ag to 14 per cent.
Binnite, *s.* Tennantite	$Cu_6As_4S_9$	Dark grey	4·47	2·75	I.	M.	
Biotite	$(Mg_{12},Fe)_2(K_3,H)_2(Al_7,Fe)_2(SiO_4)_3$	Black, brown	2·9	2·5	V.	P.	Stained with FeO; commercial mica; electrical apparatus
Bismite (Bismuth ochre)	Bi_2O_3	Greenish-yellow	4·3	–	IV.	A.	Naturally non-crystalline
Bismuth	Bi	Silver-white	9·7	2·25	III.	M.	Alloying metal
Bismuth blende, *s.* Eulytite							
Bismuth glance, *s.* Bismuthite							
Bismuthinite	Bi_2S_3	Steel-grey	6·4	2·5	IV.	M.	Bismuth ore
Bismuthite	$Bi_2O_3.CO_2.H_2O$	Grey, yellow, green	6·9	4	Am.	D.Gl.	Bismuth ore
Bismutosphærite	Bi_2CO_5	Yellow to grey	7·3	3-3·5	Sph.	—	Fibrous structure
Bitterspar, *s.* Dolomite							
Bitumen, *s.* Asphaltum							
Black copper, *s.* Melaconite							
Black-jack, *s.* Blende							
Blende	ZnS	Yellow, red, green	4	4	I.	A.	Most important zinc ore, 60 per cent.
Blödite	$MgSO_4.Na_2SO_4$	Colourless	2·2	2·5	V.	V.	
Bloodstone, *v.* Quartz ..	SiO_2 and FeO	Green	2·7	7	Mc.	—	Has blood-like spots of red
Blue-stone, Blue vitriol, *s.* Chalcanthite							
Boart, imperfectly crystallised *v.* Diamond		Black	–	10	I.	—	Diamond-cutting powder
Bog iron ore, impure *v.* Limonite	Fe_2O_3,H_2O	Brown to yellow			Am.		Contains organic substances; foundry pig iron
Bog-manganese, *s.* Wad							
Bole	$Al_2H_4Si_2O_9.Aq.$	White, yellow, red	2·5	2	Am.	R.	Gold-leaf adhesive
Boltonite, *v.* Forsterite ..	Mg_2SiO_4	Red	3·2	6·7	IV.	V.	
Bone-turquoise, *s.* Odontolite							
Boracite	$Mg_7Cl_2B_{16}O_{30}$	White-grey	3	7	I., IV.	V.	
Borax	$Na_2B_4O_7.10H_2O$	White, part grey	1·7	2·25	V.	R.	General flux; in medicine
Bornine, Bornite, *s.* Erubescite *and* Tetradymite							
Borocalcite, *s.* Ulexite							
Bostonite, *s.* Chrysotile							
Botryogen	$MgO.FeO.Fe_2O_3.4SO_3$	Hyacinth red	2·04	2-2·5	V.	V.	
Botryolite, *s.* Datolite							
Boulangerite	$Pb_3Sb_2S_6$	Lead-grey	5·6	2·75	IV.	M.	
Bournonite	$Pb_2Cu_2Sb_2S_6$	Grey to black	5·8	2·75	IV.	M.	Old Cornish copper ore
Boussingaultite	$(NH_4)_2SO_4.MgSO_4$	White	1·68	—	V.	—	
Bowenite, *v.* Serpentine ..	$(MgFe)_3H_4Si_2O_9$	White	2·6	5·5–6	IV.	V.	
Bragite, *s.* Fergusonite							
Brandtite	$Ca_2MnAs_2O_8.2H_2O$	Colourless to white	3·6	5-5·5	VI.	V.	
Braunite	Mn_2O_3	Black	4·7	6·25	II.	M.	Manganese (63 per cent.)
Bredbergite, *v.* Andradite ..	$Fe_2Mg,Ca_3(SiO_4)_3$	—	3·74	7	I.	V.	A common garnet
Breithauptite, *v.* Niccolite ..	NiSb	Copper-red	7·5	5·5	III.	M.	Nickel ore
Breunnerite	$(Mg:Fe)CO_3$	Yellowish-white	4	4	III.	V.	
Brewsterite	$H_4(Sr,Ba.Ca)Al_2(SiO_3)_6$	White	2·45	5	V.	V.	
Brittle silver, *s.* Stephanite							
Brochantite	$(CuOH)_4SO_4$	Emerald green	3·8	3·5	IV.	V.	
Bromargyrite	AgBr	Bright yellow	5·9	2·3	I.	A.	Chilian silver ore 57 per cent.
Bromlite	$(Ca,Ba)CO_3$	White	3·7	4	IV.	V.	
Bromyrite, *s.* Bromargyrite							
Bronzit, *s.* Enstatite							
Bronzite, *s.* Seybertite							
Brookite	TiO_2	Brown to black	3·8	5·5-6	IV.	A.	Titanium
Brown Hæmatite, *s.* Limonite							
Brucite	$Mg(OH)_2$	White	2·3	2	III.	P.	
Brushite	$HCaPO_4.2H_2O$	Colourless	2·2	2–2·25	V.	V.	Occurs on rock-guano
Bunsenine, Bunsenite ..	NiO	Green	6·39	5·5	I.	Tc.	Occurs with nickel ores

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
CABRERITE	$(Ni,Mg)_3As_2O_8.H_2O$	Apple-green	2·9	2	V.	P.	Spanish nickel ore
Cacoxenite, Cacoxene ..	$(Fe_2(OH)_3PO_4)_2.9H_2O$	Yellow	3·4	3·5	V. or VI.	S.	
Cadmium ochre, *s.* Greenockite							
Cairngorm, *v.* Quartz	SiO_2	Smoky-yellow	2·6	7	III.	V.	Scotch precious [stone
Calaite, *s.* Turquoise							
Calamine	$(Zn.OH)_2SiO_3$	White, yellow	3·1-3·9	5	IV.	V., P.	Important zinc ore
Calamite, *s.* Tremolite							
Calaverite	$(Au,Ag)Te_2$	Yellowish-grey	9·04	2·5	—	M.	Au : Ag :: 6 : 1
Calcite	$CaCO_3$	All colours	2·6	3	III.	V., D.	Furnace flux; includes limestones [and marbles
Calcouranite, *s.* Autunite							
Calcspar, *s.* Calcite							
Caledonite	$(Pb,Cu)_2SO_4{\cdot}CO_3$	Green	6·4	3	V.	R.	Allied to Leadhillite
Callainite, Callait, *s.* Variscite							
Callais, Callaite, *s.* Turquoise							[artificially prepared
Calomel	Hg_2Cl_2	White, grey	6·5	1·5	II.	A.	Valuable medicine,
Cancrinite	$(Na_2,Ca)_4H_6(NaCO_3)_2Al_8Si_9O_{36}$	Colorless	2·45	5·5	V.		Altered Nephelite
Cannel Coal	—	Brown or black	—	—	—	E.	Gas manufacture
Capillary pyrites, *s.* Millerite							
Carbonado, *s.* Boart							
Carbuncle, *s.* Almandine							
Carnallite	$MgCl_2.KCl.6H_2O$	Red, white	1·6	3	IV.	V.	Magnesium. *See* p. 5756
Carnelian, *v.* Chalcedony ..	SiO_2	Bright red	2·7	7	Mc.	O.	Ringstone
Carpholite	$MnAl_2(OH)_4(SiO_3)_2$	Straw-yellow	2·9	5	V.	S.	
Cassiterite	$(SnO_2)_2$	Black-brown	6·8	6·5	II.	A.	Important tin ore [p. 6161
Castor, *s.* Petalite							
Cat's eye, *v.* Quartz	—	—	—	—	—	—	*See* p. 5855
Celadonite	Fe,Al,K,Mg,SiO	Olive-green	2·85	1·5	Am.	D.	
Celestite, Celestine	$SrSO_4$	Colourless, etc.	3·9	3–3·5	IV.	V.	Strontium nitrate; fireworks
Cerite, Cererite	$(Ce,Al,La,Di)_2CeO(Ca,Fe)(SiO_3)_3$	Grey	4·9	5	IV.	R.	Ce, La, or Di
Cerargyrite, *s.* Chlorargyrite							
Cerussite	$PbCO_3$	White, grey	6·4	3·5	IV.	A.	Lead (83·5 per cent.)
Cervantite	Sb_2O_4	Yellow, white	4·08	4·5	IV.	P.	Antimony (80 per [cent.)
Chabazite, Chabasie	Al,Ca, and SiO_3	White	2·1	4·5	III.	V.	
Chalcanthite	$CuSO_4.5H_2O$	Blue	2·2	2·5	IV.	V.	Fertiliser
Chalcedony, *v.* Quartz ..	SiO_2	All colours	2·7	7	Mc.	Gl.	Precious stone
Chalcocite, *s.* Copper glance	Cu_2S	Blackish	5·5	2·5–3	IV.	M.	Copper (79·8 per cent.)
Chalcodite, *s.* Stilpnomelane							
Chalcophyllite	$CuOH,AsO_4,7H_2O$	Emerald green	2·5	2·5	III.	P.	Called Copper Mica
Chalcopyrites, *s.* Copper-pyrites							
Chalcosine, *s.* Copper glance							
Chalybite	$FeCO_3$	Yellowish	3·4	5·7	Am.	D.	Iron ore (48 per [cent.)
Chamosite	$Fe_2(Fe,Mg)_3H_6Si_2O_{13}$	Black	3·3	2·5	III.	V.	
Chelmsfordite, *s.* Scapolite							
Chessylite, *s.* Azurite							
Chiastolite, *v.* Andalusite ..	$Al_2O.SiO_4$	Red, grey, brown	3·1	7	IV.	R.	
Childrenite	$Al(OH)_2(Fe,Mn,Ca)PO_4.H_2O$	Colourless	3·2	4·5	IV.	V.	[gunpowder, nitric acid
Chile saltpetre..	$NaNO_3$	White, etc.	2·1	1·75	III.	V.	Nitre; fertilisers,
Chiolite	$(AlF_3)_3.(NaF)_5$	Snow-white	2·86	3·75	II.	V.	
Chloanthite, *v.* Smaltite ..	$(CoFeNi)As_2$	Tin-white	6·8	5	I.	M.	Cobalt
Chlorargyrite	AgCl	Pearl-grey	5·5	1–1·5	I.	R.	Silver (75 per cent.)
Chlorite group	Al,Fe,Cr,Mg, Fe, and SiO_3	Various	1–6	1·85	V.	P.	
Chlorite-spar, Chloritoid ..	$Al_2(Fe,Mg)H_2SiO_7$	Green to grey	3·5	6	V.	V.	
Chloropal	$(Fe,Al)_2(SiO_3)_3.5H_2O$	Brown and green	1·7 – 1·8	1–1·75	Am.	R.	Similar to Nontronite
Chondrodite	$(Mg.OH)_2(MgF)_4(Mg,Fe)_{13}(SiO_4)_8$	Yellow-brown	3·1	6·5	V.	V.	
Christianite, *s.* Phillipsite							
Chrome-yellow, *s.* Crocoite							[chrome steel
Chromite	$FeCr_2O_4$	Iron-black	4·3	6	I.	Sm.	Chief chromium ore;
Chrysoberyl	$Be(AlO_2)_2$	Green, yellow	3·7	8	IV.	V.	Precious stone, p. 5855
Chrysocolla	$CuSiO_3.2H_2O$	Blue to green	2·2	2·4	Amor.	V.	Copper (36 p'r cent.)
Chrysolite, *v.* Olivine	$(Mg,Fe)_2SiO_4$	Green, yellow	3·4	7	IV.	V.	Precious stone, p. 5855
Chrysotile, *v.* Asbestos ..	—	—	—	—	—	—	Commercial asbestos
Cinnabar	HgS	Red	8·9	2–2·5	III.	A.	Mercury (85 per cent.); vermilion
Cinnamon stone, *v.* Garnet ..	$3SiO_2.Al_2O_3.CaO$	Honey-yellow	3·6	7–7·5	I.	V.	*See* p. 5855
Citrine, *v.* Quartz	SiO_2	Yellow	2·6	7	III.	V.	Is false topaz
Clarite, *s.* Enargite							
Clausthalite	PbSe	Lead-grey	7·6-8·8	2·5	I.	M.	Selenium
Clay, *s.* Kaolinite, Halloysite, etc.	—	—	—	—	—	—	Fire-bricks, paper-glazing, alum

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Clay ironstone, *s.* Chalybite ..	$FeCO_3$	Yellowish	3·4	3–7	Am.	D.	Variety of Siderite
Cleavelandite, *s.* Albite							
Clingmanite, *s.* Margarite							
Clinochlore	$H_8(Al,Fe,Cr)_2 (Mg,Fe)_5Si_3O_{18}$	Greenish-white	2·7	2·25	V.	P.	Chlorite group
Clinoclase, Clinoclasite ..	$(CuOH)_3AsO_4$	Bluish-green	4·2	2·75	V.	P.	
Clintonite, *s.* Seybertite							
Coal	C,H,O and ash	Black	1·4-1·6	2·5	Am.	R.–V.	Most common fuel
Cobalt bloom, *s.* Erythrite ..	$Co_3O_8As_2.8H_2O$	Crimson	2·9	2	V.	P.	Cobalt (29·5 per cent.)
Cobalt glance, *s.* Cobaltite							
Cobalt-ochre, *s.* Asbolite							
Cobalt pyrites, *s.* Linnæite ..	$(CoNi)_3S_4$	Steel-grey	4·9	5·5	I.	M.	Cobalt (57·9 per cent.), nickel
Cobaltite, Cobaltine	$CoAsS$	Silver-white	6	5·5	I.	M.	Cobalt (35·5 per cent.)
Cockscomb pyrites, *s.* Marcasite	FeS_2	Pale yellow	4·8	6–6·5	IV.	M.	Iron (46·6 per cent.) in jewellery
Colemanite	$Ca_2B_6O_{11}.5H_2O$	Colourless	2·4	4·25	V.	V.	
Coloradoite	$HgTe$	Greyish-black	8·6	3	Am.	M.	Mercury (61·5 per cent.), tellurium
Columbite (Niobite)	$Fe[(Nb,Ta)O_3]_2$	Black	6	6	IV.	M., A.	Niobium, tantalum
Comptonite, *s.* Thomsonite							
Connarite	$H_4Ni_2Si_3O_{10}$	Yellowish, etc.	2·5	2	III.(?)	P.	
Copalite, Copaline	$C_{12}H_{18}O$	Yellow, brown	1·01	2	Am.	R.	A fossil resin
Copiapite	$(FeOH)_2Fe_2(SO_4)_5.18H_2O$	Sulphur-yellow	2·1	2	V.	E.	
Copper	Cu	Red	8·9	2·75	I.	M.	Crystalline near igneous rocks
Copper froth, *s.* Tyrolite							
Copper glance	Cu_2S	Blackish	5·5	2·5–3	IV.	—	Copper (79·8 per cent.)
Copper green, *s.* Chrysocolla							
Copper mica, *s.* Chalcophyllite							
Copper pyrites	$CuFeS_2$	Brass-yellow	4·2	3·5–4	II.	M.	Copper, 34·5 per cent.
Copper vitriol, *s.* Chalcanthite							
Copperas, *s.* Melanterite							
Coquimbite	$(Fe,Al)_2(SO_4)_3.9H_2O$	Whitish, etc.	2·09	2·25	III.	—	Is White copperas
Cordierite (Iolite)	$(Al,Fe)_6Mg_3Si_8O_{28}$	Blue, green, grey	2·6	7	IV.	V.(?)	Highly dichroic
Corundellite, *s.* Margarite							
Corundum	Al_2O_3	Blue, red, etc.	4	9	III.	V.	Emery; sub-varieties are ruby, sapphire, etc.
Cotunnite	$PbCl_2$	Colourless	5·25	2	IV.	A.	Found in Vesuvian lava
Covellite, Covelline	CuS	Dark-blue	4	1·5–2	III.	Sm.	
Crispite, *s.* Rutile							
Crocidolite (Hornblende group)	$(Fe,Na)_2.(SiO_3)_4 FeSiO_3$	Blue to green	3·25	4	F.	S.	
Crocoite, Crocoisite	PbO_4Cr	Yellow	6	2·5–3	V.	Te.	Chrome-yellow
Cronstedtite	$Fe_2(Fe,Mg)_3.H_6Si_2O_{13}$	Black	3·3	2·5	III.	V.	
Cryolite	$Al_2F_6.6NaF$	White, etc.	3	2·5	V.	V.	Aluminium (12 per cent.); alums, glass, soda, page 5989
Cryptolite, *s.* Monazite							
Cube Ore, *s.* Pharmacosiderite							
Cupreine, *s.* Copperglance							
Cuprite	Cu_2O	Red	6	3·5–4	I.	Sm.	Copper (88 per cent.)
Cupro-uranite, *s.* Torberite							
Cyanite	$(AlO)_2SiO_3$	Blue, etc.	3·2	5·5	VI.	V.	
Cyprite, *s.* Copperglance							
DANAITE, *v.* Mispickel ..	$(FeCo)AsS$	White, grey	2·35	3	V.	P.	Cobalt ore
Danburite	$CaB_2(SiO_4)_2$	Yellow	3	7·25	IV.	V.	
Datolite, Datholite	$Ca(B.OH)SiO_4$	White	2·9	5	V.	V.	
Delawarite, *s.* Orthoclase							
Delvauxite, *s.* Dufrenite							
Demantoid, *v.* Andradite ..	- -	Green	3·83	6	I.	V.	*See* p. 5855
Descloizite	$(Pb,Zn)VO_4 (Pb.OH)$	Black to brown	5·8	3·5	IV.	V.	Discovered by Descloizeau
Desmine, *s.* Stilbite							
Deweylite	$Mg_4H_4Si_3O_{12}$	Yellow	2	2·5	Am.	R.	
Diaclasite, Diaclase, altered Enstatite							
Diadochite	Fe_2O_3,SO_3,P_2O_5 and H_2O	Yellowish	2	3	V.	R.	
Dialogite, *s.* Rhodochrosite ..	$MnCO_3$	Red, etc.	3·5	4	III.	V.	Manganese (47 per cent.)
Diamond	C	Colourless to black	3·5	10	I.	A.	Precious stone; glass and gem cutting
Diaphorite	$(PbAg_2)_5Sb_4S_{11}$	Steel-grey	5·9	2·5–3	IV.	M.	Similar to Freieslebenite
Diaspore	$AlO.OH$	White	3·4	6	IV.	V.	Aluminium; similar to Bauxite
Diatomite, *s.* Tripolite							
Dichroite, *s.* Cordierite							
Dickinsonite	$(Mn,Ca,Fe,Na_2)_{12}(PO_4)_8 3H_2O$	Grey	3·3	3·5	V.	V.	
Dicksbergite, *s.* Rutile							
Dihydrite, *s.* Phosphorochalcite							
Dillenburgite, *s.* Chrysocolla							
Diopside (Augite group) ..	$Mg,Fe,Ca(SiO_3)_4$	Green, white	3·3	6	V.	V.	Feebly translucent
Dioptase	CuH_2SiO_4	Emerald-green	3·2	4·75	III.	V.	

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Diphanite, *s.* Margarite							[building-stone ;
Disthene, *s.* Cyanite							[basic steel
Dolomite	$(CaMg)CO_3$	White, grey, etc.	2·8	3·5–4	III.	V.	Lime ; marble,
Domeykite	Cu_3As	Tin-white	7·5	3·25	Mass.	M.	Chilian copper ore
Dufrenite	$Fe_2(OH_3)PO_4$	Leek-green	3·3	3·25	IV.	V.	
Dufrenoysite	$Pb_2As_2S_5$	Lead-grey	5·5	3	IV.	M.	
Dumortierite	$Al_2(AlO)_6(SiO_4)_3$	Bright blue	3·2	7	IV.	V.	Strongly pleochroic
Durangite	$Na(AlF)AsO_4$	Orange-red	4	5	V.	V.	
Dysanalyte	$Na_2(CaFe)_8.Ce(NbO_3)_3Ti_{10}O_{29}$	Iron-black	4·1	5·5	I.	Sm.	In limestone
Dyscrasite	Ag_3Sb	Silver-white	9·5	3·5	IV.	M.	Silver
EARTHY COBALT, *s.* Asbolan	$MnO_2CoO, CuOH_2O$	—	—	—	—	—	Alteration product varies greatly
Edelite, *s.* Prehnite							
Edwardsite, *s.* Monazite							
Eggonite, *s.* Barytes							
Ehlite, *v.* Phosphorochalcite ..	$Cu(CuOH)_4(PO_4)_2.H_2O$	Emerald-green	4	2	—	P.	Similar to Pseudo-malachite
Ekebergite, *v.* Scapolite ..	$Al_2(AlO)Ca_4(Si_2AlO_8)_3$	White	2·7	5·5	II.	V.	
Elæolite, *v.* Nephelite ..	$Al_8(Na_2,K_2$ or $Ca)_4Si_9O_{34}$	Reddish, greenish	2·6	6	III.	G.	
Electro-silicon, *s.* Tripolite							
Electrum, *v.* Gold	xAu + yAg	Yellowish-white	12·5–15·5	2·5	I.	M.	A natural alloy used by ancients
Embolite	$Ag_2(ClBr)$	Grey-green	5·9	1–1·5	I.	A.	Silver (about 64 per cent.)
Emerald, *v.* Beryl	$Be_3Al_2(SiO_3)_6$	Green	2·6-2·8	7·5	III.	V.	Precious stone ; p. 5855
Emerald, Oriental, *v.* Sapphire	Al_2O_3	Green	4	9	III.	V.	An emerald-coloured sapphire
Emerald nickel, *s.* Zaratite ..	$3NiO.CO_2.6H_2O$	Emerald-green	2·6	3	Am.	V.	Nickel (46 per cent.)
Emery, *v.* Corundum	Al_2O_3	Black	4	9	III.	V.	Coloured by Magnetite; abrasive
Empholite, *s.* Diaspore							
Emplectite	$Cu_2(Bi,S_2)_2$	Tin-white to grey	5·15	2·5	IV.	M.	
Enargite	Cu_3AsS_4	Iron-black	4·4	3	IV.	M.	
Enceladite, *s.* Warwickite							
Endlichite	$Pb[(As,V)O_4]_3Cl$	Red, brownish	7	3	III.	R.	Perhaps *v.* of Va-[nadinite
Enstatite	$(MgFe)SiO_3$	Brown, green	3·2	5–5·5	IV.	P.	
Eosphorite, *v.* Childrenite ..	$(Mn,Fe)H_2O.AlPO_4$	Pink, yellowish, etc.	3·13	5	IV.	V.	
Epidote	$Al_2(Al.OH)Ca_2(SiO_4)_3$	Green, etc.	3·5	6·5	V.	V.	Common rock constituent
Epsom salt, *s.* Epsomite							
Epsomite	$MgSO_4.7H_2O$	White, yellow, red	1·7	2·25	IV.	V.	Artificial salt used in medicine
Eremite, *s.* Monazite							
Erinite	$Cu_3As_2O_8.2Cu(OH)_2$	Emerald-green	4·04	4·5–5	Mc.	D.	From Cornwall
Erubescite	Cu_3FeS_3	Reddish-yellow	5	3·5	I.	M.	Copper (55 per [cent.)
Erythrite, Erythrine	$Co_3O_8As_2.8H_2O$	Crimson	2·9	2	V.	P.	Cobalt (29 per cent.)
Euchroite	$((CuOH)CuAsO_4.3H_2O$	Emerald-green	3·4	3	IV.	V.	Copper
Euclase	$(AlOH)BeSiO_4$	Colourless	3·1	7·5	V.	V.	Very brittle
Eudialyte	$(Na,K,H)_{13}(Ca,Fe)(Zr,Si)_{20}O_{52}$	Rose, etc.	2·92	5·25	III.	V.	
Eudnophite, *s.* Analcite							
Eulytite, Eulytine	$Bi(SiO_4)_3$	Brown, yellow	6	5	I.	A.	Similar to Agricolite
Euxenite	$R(NbO_3)_2R_2(TiO_3)_3,H_2O$	Brownish-black	4·6	6·5	IV.	M., V.	R is Y, Er, Ce, U ; possibly Ge
FAHLERZ, *s.* Tennantite *and* Tetrahedrite							
Faröelite, *v.* Thomsonite ..	$2Al_2(Ca,Na_2)(SiO_4)_3,H_2O$	White	2·3	5·5	IV.	V.	From Hebrides, Faroe Is.
Fassaite, *v.* Augite	$MgCa(SiO_3)_2$	Green	3·3	5	V.	V.	Also called Pyrgom
Fayalite (Olivine group) ..	Fe_2SiO_4	Light yellow	4	6·5	IV.	—	Metalloidal lustre
Felspar group	$Al_2SiO_3(K,Na,$ Mg or $Ca)SiO_3$	Various	2·5	6	V.	V., P.	Pottery glaze. Varieties : Orthoclase, Oligoclase, Albite
Fergusonite	$Y(Nb,Ta)O_4$	Brownish-black	5·8	5·75	II.	D.	
Feltbol, *s.* Chloropal							
Fibroferrite	$Fe_6(OH)_8(SiO_4)_5,H_2O$	Honey-yellow	1·84	3·25	V.(?)	P.	
Fibrolite	$Al(AlO)SiO_4$	Grey, brown	3·2	6·5	IV.	R.	Dimorphic with [Cyanite
Figure Stone, *s.* Agalmatolite							
Fiorite, *v.* Opal	H_2O,SiO_2		2	5	Am.	W.	A volcanic sinter, Fiora, Tuscany
Fireblende, *s.* Pyrostilpnite							
Flint, *v.* Quartz	SiO_2	White, grey, etc.	2·7	7	Mc.	Gl.	Gun-flints ; building-stone, road metal, pottery
Flos ferri, *v.* Aragonite							
Fluor, Fluorite (Fluorspar) ..	CaF_2	All colours	3·2	4	I.	V.	Metallurgical flux, glass-making, HF, paints
Foresite, *s.* Stilbite							
Forsterite (Olivine group) ..	Mg_2SiO_4	White	3·2	6–7	IV.	V.	In volcanic ejections, etc.

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Fowlerite, *s.* Rhodonite							
Franklinite	$(FeZnMn)(Fe_2Mn_2)O_4$	Iron-black	5·15	6	I.	M.	Zinc (10 per cent.); [spiegeleisen
Freibergite, *s.* Tetrahedrite							
Freieslebenite	$(Pb,Ag_2)_5Sb_4S_{11}$	Grey	6·2	2·5	V.	M.	Lead (30 per cent.), silver (to 27 per cent.)
Frenzelite	$Bi_2(Se,S)_3$	Bluish-grey	6·4	3	IV.	M.	Selenium
Fullers' earth, *s.* Smectite	—	—	—	—	—	—	Grease absorbent for woollen fabrics
GADOLINITE	$Fe[Be(YO)SiO_4]_2$	Black, brown	4–4·5	6·75	V.	V.	
Gahnite (Spinel group)	$(Zn,Fe)(AlO_2)_2$	Greyish, green	4·3	7·75	I.	V.	A zinc spinel
Galena, Galenite	PbS	Lead-grey	7·5	2·5	I.	Sp.	Lead (86 per cent.); stoneware glaze, [p. 5985
Galmei, *s.* Calamine							
Garnet group	$R_2R_3(SiO_4)_3$	All except blue	3·1-4·3	7	I.	V.	Very many varieties; R_2 may be Al, Fe, Cr; R_3, Ca, Fe, Mn
Garnierite	$(Ni,Mg)H_2SiO_4$	Pale green	2·5	2·5	Am.	D.	Nickel (7 to 10 per cent.), p. 5982
Gaylussite	$(Na_2.Ca)(CO_3)_2 5H_2O$	White	1·94	2·5	V.	V.	
Gehlenite	$(AlO)_2(Ca,Mg,Fe)_3(SiO_4)_2$	Green, brown	3	5·5	II.	G.	
Genthite	$(Mg,Ni)_2H_4Si_3O_{10}$	Green	2·4	2	Am.	R.	Garnierite is impure variety of this
Gersdorffite	$Ni(Fe)SAs$	White, grey	6	5	I.	M.	Nickel-glance; nickel (35 per cent.)
Gibbsite	$AlPO_4(H_2O)_4$	White, etc.	2·35	3	V.	P.	
Gilsonite, *s.* Uintahite							
Girasol, *v.* Opal	SiO_2,H_2O	Hyacinth-red	2	5	Am.	V.	Called Fire opal; from Mexico
Gismondite, Gismondine	$CaAl_2(SiO_3)_4.4H_2O$	Colourless, white	2·2	4·5	V.	V.	
Glaserite, *s.* Aphthitalite							
Glauber salt, *s.* Mirabilite							
Glauberite	$Na_2Ca(SO_4)_2$	White, grey	2·7	3	V.	V.	
Glaucodote	$(Fe,Co)AsS$	Greyish, white	5·9	5	IV.	M.	Cobalt
Glauconite	Fe,K,SiO_2 and H_2O	Olive, etc.	2·3	2	Am.	D.	A variable mixture
Glaucophane (Hornblende group)	$NaAl(SiO_3)_2 Fe,Mg,SiO_3$	Blue	3·1	6–6·5	V.	V. to P.	In crystalline schists
Gmelinite	$(Na_2Ca)Al_2(SiO_3)_4,H_2O$	Colourless, etc.	2·1	4·5	III.	V.	
Goethitite	$FeO.OH$	Brown	4	4·5	IV.	A.	Iron (62 per cent.)
Gold	Au	Gold-yellow	15·6–19·5	2·5	I.	M.	Usually alloyed with silver
Goslarite	$ZnSO_4.7H_2O$	White, grey	2	2·25	IV.	V.	Called White vitriol
Göthite, *s.* Goethite							
Grahamite	Hydro-carbon	Black	1·4	2	Am.	B.	Illuminating gas
Gramenite, *s.* Chloropal							
Grammatite, *s.* Tremolite							
Granatite, *s.* Staurolite							
Graphite	$C (Fe_2O_3$, etc.)	Iron-black	2·15	1	III.	M.	[stove-polish, paints Lubricant, crucibles
Grastite, *s.* Clinochlore							
Greenockite	CaS	Yellow to orange	4·8	3	III.	A.	Nearly transparent
Greenovite, *v.* Sphene	$CaSTiO_5$	Brown, green, etc	3·5	6	V.	G.	
Greenstone, Green vitriol, *s.* Melanterite							
Grossularite (Garnet group)	$Al_2Ca_3(SiO_4)_3$	Pale green	3·4-3·7	7	I.	V.	Includes all Ca-Al garnets
Grothite, *s.* Sphene							
Guanite, *s.* Struvite							
Guarinite	$CaTiSiO_5$	Yellow	3·48	6	IV.	A.	
Guayacanite, *s.* Enargite							
Guitermanite	$(PbS)_{10}(As_2S_3)_3$	Bluish-grey	5·9	3	Mass.	M.	Opaque
Gummite	$(Pb,Ca,Ba)SiU_3O_{12}.H_2O$	Reddish	4·1	2·75	—	G.	
Gymnite, *s.* Deweylite							
Gypsum	$CaSO_4.2H_2O$	White, grey, etc.	2·3	2	V.	V.S.	Plaster of Paris, artif. marble, fertiliser, cements
HÆMATITE	Fe_2O_3	Steel-grey, dark red	4·8–5	5·5-6·5	III	M., E.	Iron (70 per cent.), polishing powder, crayons, red paint
Hairsalt, *s.* Keramohalite							
Halite, *s.* Salt							
Hallite, *s.* Aluminite							
Halloysite	$Al_2H_4Si_2O_9,H_2O$	White, yellow, red	2·5	2	Am.	R.	Variety of Kaolinite
Halochalcite, *s.* Atacamite							
Halotrichite	$FeSO_4.Al_2(SO_4)_3H_2O$	White	1·95	—	V. or VI.	S.	An iron alum
Hamartite, *s.* Bastnäsite							
Hanksite	$(Na_2)_5CO_3 (SO_4)_4$	White	2·56	3·25	III.	V.	
Harmotome	$Al_2(Ba,Ca_2,Na_2,K_2)Si_6O_{16}$	White	2·4	5	V.	V.	
Harringtonite, *s.* Mesolite							
Hatchettolite	U,Ti,Nb,W,Sn,Ca,Y,Fe,K,Na, and H_2O	Yellowish-brown	4·8	5	I.	R.	Translucent

1 s

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Hauerite	MnS_2	Reddish-brown	3·4	4	I.	Sm.	
Hausmannite	Mn_3O_4	Brown	4·7	5·5	II.	M.	Manganese (71 per [cent.) ; rare
Haüynite, Haüyne	Ca,Na,(AlNa SO_4),$Al_3(SiO_4)_4$	Blue	2·4	5	I.	V. to R.	In Lapis lazuli. *See* p. 5856
Hayesine, *s.* Ulexite							
Heavy spar, *s.* Barytes							
Hebronite, *s.* Amblygonite							
Hedenbergite	$FeCa(SiO_3)_2$	Green	3·5	5	V.	V.	Augite group
Heliotrope, *s.* Bloodstone							
Helvite, Helvine	(Mn,Be,Fe),S.$(SiO_4)_3$	Yellow, brown	3·2	6	I.	R.	A tetrahedral garnet
Hematite, *s.* Hæmatite							
Hemimorphite, *s.* Calamine							
Herderite	$Ca[Be(OH.F)]PO_4$	White	3	5	IV.	V.	
Herrengrundite	$Ca(OH_2).2CuOH.2SO_4.3H_2O$	Emerald-green	3·1	2·75	V.	P.	
Hessite	Ag_2Te	Grey	8·5	2·5	I.	M.	Au also present
Hessonite, *s.* Grossularite ..	$Al_2Ca_3(SiO_4)_3$	Cinnamon-brown	3·5	7	I.	V.	Wrongly Hyacinth. *See* page 5855
Houlandite	$Al_2(Ca,Sr)H_4(SiO_3)_6$	White, red	2·2	4	V.	V.	
Hiddenite, *s.* Spodumene							
Hisingerite	FeO,SiO_2,H_2O, etc.	Black	2·75	3	Am.	G.	Probably a mixture
Honey-stone, *s.* Mellite							
Hornblende group	$(Mg,Fe)_3Ca(SiO_3)_4$	Blackish-green	3·1	5·5	V.	V.	Fibrous variety is [Asbestos
Hornquicksilver, *s.* Calomel							
Hornsilver, *s.* Chlorargyrite							
Hortonolite	$(Fe,Mg)_2SiO_4$	Yellow	3·9	6·5	IV.	V.	In chrysolite group
Hübnerite	$(Fe,Mn)WO_4$	Black	7·2	5	V.	Sm.	Tungsten
Humboldtine, *s.* Oxalite							
Humboldtite, *s.* Datolite							
Humite	$Mg_{13}(MgF)_4(MgOH)_2.(SiO_4)_8$	White	3·1	6–6·5	IV.	V.	Chondrodite group
Hyacinth	$ZrSiO_4$	Pink	4·65	7·5	II	A., R	Precious stone
Hyalite, *v.* Opal ..	SiO_2,H_2O	Colourless	2	6	Am.	V.	Transparent, the purest form
Hyalophane (Felspar group) .	$KBaAl_3Si_5O_{16}$	Colourless	2.8	6·25	V.	V.	Transparent
Hydrargyrite, *s.* Wavellite							
Hydrocyanite	$CuSO_4$	Pale green	—	2·25	IV.	—	Is anhydrous Chal- [canthite
Hydrohematite, *s.* Turgite							
Hydromagnesite	$3MgCO_3.Mg(OH)_2.H_2O$	White	2·14	3·5	V.	V.	
Hydrotalcite	$Al(OH)_3[Mg(OH)_2]_3.3H_2O$	White	2·07	2	III.	P.	
Hydrozincite	$(Zn.OH)_2Zn(OH_2)CO_3$	White, etc.	3·7	2·25	Mass.	D.	Earthy variety of Smithsonite
Hypersthene (Enstatite group)	$(MgFe)SiO_3$	Brown	3·4	6	IV.	V.R.	Variety of Pyroxene
ICELAND SPAR, *v.* Calcite..	$CaCO_3$	Colourless	2·6	3	III.	R.	Doubly refracting: [optical instruments
Ichthyopthalmit, *s.* Apophyllite							
Idocrase	$(AlO_2)_{12}(OH.Si_2)_{10}O_{77}$	Brown, grey, etc.	3·4	7	II.	R.	Frequently contains Fe
Ilmenite	$(TiFe)_2O_3$	Iron-black	4·7	6	III.	M.	Titanium (31 per cent.); worthless [for iron
Ilmenorutile, *v.* Rutile							
Ilvaite	$Fe_2Ca(FeOH)(SiO_4)_2$	Black	4	5·75	IV.	R.	
Indicolite, *v.* Tourmaline ..	*See* Tourmaline	Blue	3·1	7·5	III.	V.	*See* p. 5856
Iodargyrite	AgI	Yellow	5·7	2	III.	A.	Silver (46 per cent.)
Iodyrite *s.* Iodargyrite							
Iolite, *s.* Cordierite							
Iridosmine	Ir and Os with Pt metals	Tin-white	19–21	6–7	III.	M.	Gold-nib points, draw-plates, weight standards, ceramic enamel
Iron	Fe	Steel-grey	7·5	6	I.	M.	In meteorites, with [Ni, Co, etc.
Iron froth and glance, *s.* Hæmatite							
Iron pyrites, *s.* Ilvaite							
JACOBSITE	$2FeMnO_2.Mn$	Black	4·75	6	I.	M.	
Jacynth, *s.* Hyacinth							
*Jade	—	—	—	—	—	—	Chinese jade, used [for carving
Jadeite	$NaAl(SiO_3)_2$	Green	3·3	6·5–7	V., VI.	Sv.	
Jamesonite	$Pb_2Sb_2S_5$	Grey	5·7	2·5	IV.	M.	Devonshire antimony ore
Jargoon, *v.* Zircon	$ZrSiO_4$	Colourless, yellowish	4·5	7·5	II.	A.	Diamond substitute. *See* p. 5855
Jarosite	$FeO_3K(SO_4)_2 3H_2O$	Brown	3·25	3·5	III.	V.	
Jasper, *v.* Quartz	SiO_2, with Al_2O_3, Fe_2O_3, etc.	Red, yellow, green, etc.	2·7	7	Mc.	V.,O.	Coloured by impurities; carved ornaments
Jefferisite	$(Al,Fe,Mg)_4(SiO_4)_5.6H_2O$	Yellow	2·3	1·5	—	P.	Chlorite group
Jet	C,H,O, etc.	Black	—	—	Am.	V.	Resembles Cannel [coal; jewellery
Jordanite	$Pb_4As_2S_7$	Lead-grey	6·39	3	IV.	M.	

* Jade includes various minerals, of which the chief species are Jadeite and Nephrite (q.v.)

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
KAINITE	$KCl,MgSO_4,3H_2O$	Yellow	2.1	2·5	V.	V.	Fertiliser
Kalinite	$KAl(SO_4)_2.12H_2O$	White	1·75	2	I.	V.	Is potash alum. *See* Alum
Kaolin, Kaolinite	$Al_2O_3.2SiO_2.2H_2O$	White	2·5	1–2	V.	P. to D.	Porcelain, paper-making, chemical products
Keatingine, Keatingite *s.* Fowlerite							
Keramohalite	$Al_2(SO_4)_3.18H_2O$	White	1·7	2	V.	S., P.	
Kermesite	Sb_2OS_2	Cherry-red	4·5	1·5	V.	A.	Antimony (75 per cent.)
Kidney ore	—	—	—	—	—	—	Is Chalybite with Calcite veins
Kieserite	$MgSO_4.H_2O$	White, grey	2·5	3	V.	Gl.	
Klapothrite, *s.* Lazulite							
Knebelite	$(Fe,Mn,Mg)_2SiO_4$	Grey	3·9	6·5	IV.	Tc.	Olivine group
Kongsbergite, *s.* Amalgam							
Kraurite, *s.* Dufrenite							
Krennerite	Ag,Au,Te	White to yellow	8·3	—	IV.	M.	Composition uncertain
Kreuzstein, *s.* Harmotome							
Kuhnite, *s.* Berzeliite							
Kupferschaum, *s.* Tyrolite							
Kyanite, *s.* Cyanite							
LABRADORITE	$(AlSi_2)_2(Na,Ca)SiO_8,AlO_8$	White, grey	2·7	6	VI.	V. to R.	Felspar group; cut for cameos
Langbanite	$(Mn,Fe)_{22}Sb_2Si_4O_{35}$	Iron-black	4·9	6·5	III.	M.	
Langite	$[Cu_2(OH)_3]_2SO_4.H_2O$	Blue	3·49	2·75	IV.	V.	Translucent
Lanthanocerite, *s.* Cerite							
Lapis lazuli, *v.* Haüynite ..	$(Na_2,Ca)AlSiO_4$ (?)	Azure-blue	2·3	5·5	I.	G. to V.	In jewellery. *See* p. 5856
Lasurite, *s.* Lapis lazuli							
Laumontite, Laumonite ..	$Al_2(OH)_4Ca(Si_2O_5)_2.2H_2O$	White, yellow, red	2·3	3·5	V.	V., S.	In Canadian copper ores, etc.
Laurionite	PbOHCl	Colourless	—	3·25	IV.	A., S.	
Lazulite	$(Al.OH)_2(Mg,Fe,Ca)(PO_4)_2$	Blue	3	5·3	V.	V.	
Lazurite, *s.* Lapis lazuli							
Lead	Pb	Grey	11·37	1·5	I.	M.	*See* Index
Leadhillite	$4PbO.SO_3.2CO_2.H_2O$	White, yellow, etc.	6·3	2·5	V.	R.	In Lanarkshire
Lecontite	$(Na,NH_4,K)_2SO_4.2H_2O$	Colourless	2·4	2–2·5	IV.	V.	
Ledererite, *s.* Gmelinite							
Lederite, *s.* Titantite							
Lepidocrocite, *s.* Göthite							
Lepidolite	$Al_3Fe(Li,K,Na)_3(OH,F)_2Si_5O_{16}$	Violet, red	2·9	2·5	V.	P.	Mica group
Leucite	$AlK(SiO_3)_2$	Grey, white	2·5	6	I.	V.toR.	
Leucocyclite, *s.* Apophyllite							
Leucopyrite, *s.* Löllingite							
Levynite, Levyne	$CaAl_2Si_3O_{10}.5H_2O$	Colourless, etc.	2·12	4·25	III.	V.	Strongly doubly refracting
Libethenite	$(CuOH)CuPO_4$	Green	3·7	3·5	IV.	G.toV.	
Lievrite	$(FeOH)Fe_2Ca(SiO_4)_2$	Black	3·9	5·75	IV.	U.	Resembles Ilvaite
Lignite	C,H,O,N,S, etc.	Brown to black	1·4	2·5	Am.	R.	Brown coal, very abundant, almost worthless
Ligurite, *s.* Titanite							
***Limestone**							
Limonite	$2Fe_2O_3.3H_2O$	Brown	3·7–4	5·5	Am.	G., V., S.	Brown hæmatite. Iron (59 per cent.); polishing, paint
Linarite	$PbCu.(OH)_2SO_4$	Azure blue	5·4	2·75	V.	A.toV.	
Linnæite	$(Ni,Co,Fe)_3S_4$	Greyish black	4·9	5·25	I.	M.	Cobalt (57 per cent)
Liparite, *s.* Fluor							
Liroconite	$Al_4Cu_9(OH)_{15}(AsO_4)_5.20H_2O$	Bluish-green	2·8	2·75	V.	V. to G.	With Olivenite
Lithiophilite	$Li(Mn,Fe)PO_4$	Clove-brown	3·5	4·75	IV.	V.toR.	
Lithiophorite, *s.* Wad ..	$MnO_4.H_2O$, Li and Al	Bluish-black	3·2	3	—	D.	
Lithographic stone	—	—	—	—	—	—	A buff, compact limestone
Löllingite	$FeAs_2$	Tin-white	6·8	5	IV.	M.	
Ludwigite	$Mg_2O.FeO_2.BO_2$	Blackish-green	4	5	IV.	S.	Strongly pleochroic
Lydian stone, *v.* Quartz ..	SiO_2	Velvet-black	—	—	Mc.		Touchstone for gold (p. 5850)
MAGNESITE	$MgCO_3$	White, yellow, etc.	3	4·5	III.	V., D.	Basic-steel hearths; paper-pulp bleach, fire-proofing
Magnetite	Fe_3O_4	Iron-black	5	5·5	I.	M.	Principal iron ore (72 per cent.)
Magnetopyrite, *s.* Pyrrhotite							
Malachite	$(CuOH)_2CO_3$	Emerald-green	3·8	3·5	V.	V.,P.	Copper (57 per cent.); ornaments, jewellery, pigment
Malacolite, *s.* Diopside							
Malthazite, *s.* Smectite							

* **Limestones are only impure massive Calcite or Dolomite; varieties very numerous, depending on impurities; largely used in building**

Minerals.	Chemical formula or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Manganite	$MnO.OH$	Black, steel-grey	4·3	4·25	IV.	M.	Manganese (60 per cent.)
Manganocalcite, *s.* Rhodocrosite							
Manganostibiite	$Mn_2(Mn_8O_7)(Sb,As)O_4$	Black	—	—	IV.	O.	Found in embedded grains
*Marble							
Marcasite	FeS_2	White, yellow	4·7	6	IV.	M.	Iron (46 per cent.); jewellery
Marceline, *s.* Braunite							
Margarite	$H_2CaAl_4Si_2O_{12}$	White, grey, green	3	4·5	V.	P.	
Margarodite, *s.* Muscovite							
Marionite, *s.* Hydrozincite							
Martite	Fe_2O_3	Black	5	6–7	I.	Sm.	Iron (70 per cent.) A pseudomorph:
Matlockite	$PbOCl_2$	Yellowish	7·2	2·75	II.	A.	Translucent
Meerschaum	$Mg_2H_4Si_3O_{10}$	White	0·98–1·27	2·25	Am.	D.	Porous; tobacco pipes
Meionite	$Cu_4Al_2(AlO)(Si_2AlO_8)_3$	Colourless to white	2·7	5·75	II.	V.	
Melaconite	CuO	Iron-black	6	5	Y.	M.	Black copper ore (79 per cent.)
Melanophlogite	$Fe.SO_3$, and C	Brown, colourless	2·03	6·75	—	V.	Pseudo-isometric or II.
Melanterite	$FeSO_4.7H_2O$	Green	1·8	2	V.	V.	Copperas; commercially from pyrites
Mellite	$Al_2C_{12}O_{12}.18H_2O$	Yellow, brown	1·5	3	II.	G.	In Coal, Lignite, etc.
Menaccanite, *v.* Ilmenite ..	$(Ti,Fe)_2O_3$	Iron-black	4·7	6	III.	M.	Ti makes it worthless as iron ore
Mendipite	$Pb_3O_2Cl_2$	Yellow	7·1	3	IV.	A.	
Mendozite	$Na_2SO_4.Al_2(SO_4)_3.24H_2O$	White	1·8	3	Fi.	V.	Soda alum; calico-printing, soap making
Mercury	Hg, with Ag	Tin-white	13·5	—	I.	M.	Occurs liquid; in arts, science, and medicine
Mesolite	Na,Al,Ca,SiO_3 and H_2O	White, colourless	2·3	5	IV. & V.	V.	Between Natrolite and Scolecite
Mesotype, *s.* Mesolite, Natrolite, and Scolecite							
Metacinnabarite	HgS_8	Greyish-black	7·8	3	I.	M.	Similar to Cinnabar
Miargyrite	$AgSbS_2$	Grey to black	5·3	3	V.	M.	Silver *See* p. 812
†Mica							
Microcline (Felspar group) ..	$(K,Na)AlSi_3O_8$	White, yellow, etc.	2·5	6·25	VI.	V., P.	*See also* Amazon Stone
Microlite	$Ca_2Ta_2O_7$	Yellow to brown	5·5	5·5	I.	R.	Mn, Fe, Mg, K, and Na also present
Millerite	NiS	Yellow	5	4	III.	M.	Nickel (64 per cent.)
Mimetesite, Mimetite ..	$PbCl_2.3Pb_3As_2O_8$	Yellow, brown, etc.	7·1	3·5	III.	R. to A.	Lead. *See* p. 5985
Mineral coal, *s.* Anthracite							
Mineral wax, *s.* Ozokerit							
Minium	Pb_3O_4	Red	4·6	2·5	Am.	G., D.	*See* p. 5988
Mirabilite	$Na_2SO_4.10H_2O$	White	1·5	1·75	V.	V.	Glauber's salt
Mispickel	$FeAsS$	Tin-white	6	5·5	IV.	M.	Arsenopyrite, arsenic (46 per cent.)
Misy, *s.* Copiapite							
Mixite	$BiCu_{10}(OH)_8(AsO_4)_5.7H_2O$	Green	3·79	3·5	V. or VI.		Translucent to transparent
Mizzonite, *s.* or *v.* Wernerite							
Molybdenite	MoS_2	Reddish-grey	4·6	1·5	III.	M.	Molybdenum (60 per cent.)
Monazite	$(Ce,La,Di)PO_4$	Red, brown	5	5·25	V.	R.	Found as sand; gas mantles
Montebrasite, *s.* Amblygonite							
Monticellite	$Ca(Mg,Fe)SiO_4$	Colourless, etc.	3·15	5·25	IV.	V., R.	Olivine group
Montmorillonite	$H_2Al_2Si_4O_{12}$ (?)	Rose-red	2	1	Am.	W.	Soapy feel
Moonstone, *v.* Orthoclase *and* Oligoclase	Al,K,Na,Si_3O_8	White	2·5	6	V. & VI.	V.	Precious stone
Morvenite, *s.* Harmotome							
Moss agate, *v.* Quartz	SiO_2	Dark green	2·6	7	III.	V.	Contains dendritic MnO_2; jewellery
Mountain cork, *s.* Asbestos							
Mundic, *s.* Pyrites							
Muscovite (Mica)	$(K,Na)H_2Al_3(SiO_4)_3$	Grey, white, etc.	3	2·5	V.	P., Tp	In most granites; glass substitute, stove-doors, wall-paper mfr., electrical apparatus
NACRITE, *v.* Kaolinite ..	$Al_2O_3.SiO_2,2H_2O$	White	2·3-2·6	0·5–1		P.	
Nagyagite	$Au_2Pb_{14}Sb_3(S,Te)_{24}$	Grey to black	6·9	1·5	IV.	M.	Gold, a sulpho-telluride
Natrocalcite, *s.* Gaylussite							
Natrolite	$Al_2(SiO_4)_3Na_2H_4$	White, yellow, red	2·2	5	V. & IV.	V.	Dimorphic
Natron	$Na_2CO_3.10H_2O$	White	1·4	1–1·5	V.	V., E.	In solution in soda-lakes, Egypt, etc.
Necronite, *s.* Orthoclase							
Needle ore, *s.* Aikinite							
Neotocite	Mn,SiO_3,H_2O	Black to brown	2·75	3·5	Am.	Sm.	Opaque
Nephelite, Nepheline ..	$Al_8(Na_2K_2Ca)_4Si_9O_{34}$	White, grey, etc.	2·6	6	III.	V., R.	
Nephrite, *v.* Amphibole ..	$\left.\begin{matrix}Ca\\Fe\end{matrix}\right\} Mg_3(SiO_3)_4$	White to green	2·9-3·1	6–6·5	V.	V.	Carved into ornaments by early man; may be Actinolite or Tremolite

* Marbles are impure massive Calcite or Dolomite; many varieties, largely used in building

† Mica group includes many different minerals having similar cleavage. Commercial mica is Muscovite or Biotite

Minerals.	Chemical formula or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Nesquehonite	$MgCO_3.3H_2O$	Colourless to white	1·83	2·5	IV.	V., G.	Transparent to translucent
Newjanskite, *s.* Iridosmine							
Niccolite	NiAs, with Fe, Co,Sb	Copper-red	7·5	5·25	III.	M.	Nickel (43 per cent.)
Nickel bloom, *s.* Annabergite							
Nickeline, *s.* Niccolite							
Niobite, *s.* Columbite							
Nitre (Saltpetre)	KNO_3	White	2	2	IV.	V.	Gunpowder, nitric acid, medicine, metallurgy, pyrotechnics.
Nontronite	$Fe_2O_3.3SiO_2.5H_2O$	Yellow	2	2–4	Mass.	O.	Very similar to Chloropal
Nosite, Nosean..	$Al_3Na_5(Al,Na SO_4).(SiO_4)_4$	Grey, etc.	2·3	5·5	I.	V. to R.	
OBSIDIAN (a rock)	$KNa_3Al_2Si_{10}O_{25}$	Black, grey	2·2-2·8	7	Am.	V.	Principally Orthoclase; as pumice, polishing powder
Ochroite, *s.* Cerite							
Octahedrite, *s.* Anatase							
*Odontolite							
Oligoclase (Felspar group) ..	$Al_3.Na,Ca,Si_5O_8$	Green, white, etc.	2·56	6	VI.	R.	Common rock constituent
Olivenite	$(CuOH)CuAsO_4$	Green	4·3	3·5	IV.	V., S.	
Olivine (Olivine group) ..	$(Mg,Fe)_2SiO_4$	Green, yellow	3·4	7	IV.	V., R.	Includes Peridot and Chrysolite
Omphacite, *v.* Augite	$Mg,Ca(SiO_3)_2$	Green	3·2	6	V.	V.	
Onofrite	Hg(Se,S)	Black-grey	8·05	2·5	I.	M.	Opaque
Onyx, *v.* Agate	SiO_2	Various			Mc.		Mexican onyx is impure Calcite
Opal	$SiO_2.xH_2O$	All colours	2	5	Am.	V.,W.	Precious opal has a play of colours
Ophite, *s.* Picrolite							
Orangite, *s.* Thorite							
†Oriental amethyst, etc.							
Orpiment	As_2S_3	Lemon-yellow	3·48	2	IV.	R.	Arsenic (61 p.c.); king's yellow
Orthite, *s.* Allanite							
Orthoclase (Potassium Felspar)	$Al(K,Na)Si_3O_8$	White, red, etc.	2·5	6	V.	V.	Porcelain glaze; jewellery
Osmiridium, *s.* Iridosmine							
Oxalite	$(FeC_2O_4)_2.3H_2O$	Yellow	2·2	2	Mc.	Gl.	
Ozokerit, Ozocerite	Hydrocarbon, methane series	White to brown	0·95–1	1	Am.	R.,D.	Candle mfr., beeswax substitute
PACHNOLITE	$Na,Ca,F_3.AlF_3.H_2O$	Colourless, white	2·97	3	V.	V.	
Paisbergite, *s.* Rhodonite							
Parasit, *s.* Boracite							
Parisite	$Ce(CeF)(CaF)(CO_3)_3$	Yellowish-white	4·36	4·5	III.	V.	In emerald mines
Patrinite, *s.* Aikinite							
Paulite, *s.* Hypersthene							
Peacock ore, *s.* Bornite							
Pectolite	$Na_2Ca_2(SiO_3)$	Whitish, greyish	2·73	5	V.	S., S.	A Hornblende variety
Peganite	$(OH_3.Al_2PO_4)_2.3H_2O$	Green, etc.	2·5	3·5	IV.	V., R.	
Periclase, Periclasite	MgO	Colourless to green	3·67	6	I.	Tp., Tc.	
Peridot, *v.* Olivine	$(Mg,Fe_2)SiO_4$	Pistachio-green	3·4	7	IV.	V.	Precious stone
Perlite	$K_2Al_2Si_9O_{20}.H_2O$	Grey	2·4	5	Am.	V.,P.	A felspar
Perofskite, Perovskite ..	$CaTiO_3$	Black, brown, etc.	4	5·5	I.	R.,A.	
Petalite	$(Li,Na.H)Al(Si_2O_5)_2$	Colourless, etc.	2·43	6·25	V.	V., P.	
Petroleum	Mixture of paraffins	Black, brown, etc.	0·6-0·9	—	—	—	A liquid saturating sandstones. Illumination, heat, power, gas mfr., lubricants, etc.
Petzite, *v.* Hessite	$(Ag,Au)_2Te$	Grey to black	9	2·75	IV. (?)	M.	Gold, silver
Phacolite, *s.* Chabazite							
Pharmacochalcite, *s* Olivenite							
Pharmacolite	$(Ca,Mg)_3(AsO_4)_3.6H_2O$	White	2·6	2·25	V.	V.,P.	
Pharmacosiderite	$Fe(FeOH)_3(AsO_4)_3.6H_2O$	Green, brown	3	2·75	I.	V.	Pyroelectric
Phenakite, Phenacite	Be_2SiO_4	Colourless, etc.	3	7·75	III.	V.	Precious stone
Phillipsite	$Al_2(Ca,Na_2,H_2)Si_6O_{16}.6H_2O$	White	2·2	5	V.	V.	
Phlogopite	$(Al,Fe)_2(Mg,Fe)_6(K,Na)_2(OH,F)_3Si_6O_{21}$	Brown, red	2·9	2·5	V.	P.	Mica group
Phosgenite	$(PbCl)_2CO_3$	White, yellow, green	6·2	3	II.	A. to R.	Lead
Phosphorochalcite	$(Cu,OH)_3PO_4$	Green	4·2	5	—	G. to V.	Pseudo-malachite
Phosphorite, *s.* Apatite							
Physalite, *s.* Pyrophysalite							
Picotite, *v.* Ceylonite.. ..	$(Mg,Fe)O(Al.Cr)_2O_3$	Yellowish-brown	4·08	8	I.	Tc.	Chrome spinel
Picrolite, *v.* Serpentine ..	$(Mg,Fe)_3H_4Si_2O_9$	Green, yellow	2·5	4	IV.	W. to E.	A greasy variety is amorphous
Pictite, *s.* Sphene							

* Odontolite is blue fossil-tooth, very similar to true Turquoise. *See* pages 5853, 5856.
† Oriental amethyst, emerald, and topaz are violet, green, and yellow sapphires, respectively.

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Piedmontite	$Ca_2(AlOH)(Mn,Al)_2.(SiO_4)_3$	Reddish	3·4	6·5	V.	V., P.	Epidote group
Pinguite, *v.* Chloropal ..	FeO,Fe_2O_3,SiO_2	Green	1	2·3	Mass.	V.	Very similar to [Chloropal
Pistacite, *s.* Epidote							
Pistomesite	$(Mg,Fe)CO_3$	Yellowish	4	4	III.	V.	
Pitchstone	$Na_2Al_2Si_{10}O_{24}.3H_2O$	Green, red, etc.	2·2	5	Am.	R.	A natural glass
Pitticite, Pittizite	$Fe_{20}(OH)_{24}(SO_4)_3.10AsPO_4.9H_2O$	Brown	2·3	3	Am.	V. to G	
Plaster of Paris (*see* Gypsum)							
Platinum	Pt, with Fe,Ir, Os, etc.	Steel-grey	17-19	5·75	I.	M.	Scientific and surgical instruments, jewellery, photography, etc.
Plattnerite	PbO_2	Iron-black	9·4	—	III.	M.,A.	
Plumbago, *s.* Graphite							
Plumboferrite	$Pb(Fe_2O_2)_3$	Black	—	5	Mass.	—	
Polianite	Mn_2O_4	Steel-grey	4·8	6	II.	M.	
Polyarsenite, *s.* Sarkinite							
Polybasite	$(Ag,Cu)_{18}(Sb,As)_2S_{12}$	Iron-black	6·2	2·5	IV.	M.	Silver (75 per cent.)
Polycrase	$(Ca,Fe)_4Y_4UO_2Ti_{12}O_{35}2[Y(NbO_3)_3]$	Black	5	5·5	IV.	V. to R.	Yttrium, titanium, uranium, niobium
Polyhalite	$Ca_2,Mg,K_2(SO_4)_4.2H_2O$	Red, grey	2·7	3	Fi.	V.,R.	
Polymignyte	$Ca_4(Ce,Fe)_4.Ca(NbO_3)_2.(Ti,Zr,Th)_{10}O_{29}$	Black	4·8	6·5	IV.	Sm.	Ce, Nb, Th
Porcelain earth, *s.* Kaolinite							
Potash alum, *s.* Kalinite							
Potstone, an impure Steatite							
Prehnite	$Al_2Ca_2H_2(SiO_4)_3$	Green	2·8	6·5	IV.	V.	
Prosopite	$Ca(F,OH)_2.2Al(F,OH)_3$	Colourless, white	2·88	4·5	V.	V.	
Proustite	Ag_3AsS_3	Red	5·42	2·75	III.	A.	Silver (65 per cent.)
Pseudomalachite, *s.* Phosphorochalcite							
Psilomelane	Mn manganate	Bluish-black	4	6·25	Am.	Sm.	Very variable; [manganese
Pucherite	$BiVO_4$	Brown, red	5·9	4	IV.	A.	
Pumice. *See* Obsidian							
Purple copper, *s.* Erubescite							
Pyrargyrite	Ag_3SbS_3	Black to red	5·8	3	III.	M.A.	Silver (59 per cent.) [sulphuric acid
Pyrgom, *s.* Fassaite							
Pyrites	FeS_2	Brass-yellow	5	6·5	I.	M.	Iron (46 per cent.),
Pyrolusite	MnO_2,H_2O	Black	4·8	2	IV.	M.	Common ore for Mn [and MnO_2
Pyromorphite	$Pb_5Cl(PO_4)_3$	Green, brown, etc.	6·5–7·1	3.5	III.	R.toV.	
Pyrope	$Mg_2Ca_3(SiO_4)_3$	Blood-red	3·7–3·8	7–7·5	I.	V.	Bohemian garnet (wrongly Cape ruby)
Pyrophyllite	$AlH.(SiO_3)_2$	White, green	2·8	1·5	IV.	P.	Similar to Agalmatolite
Pyrophysalite	Al_2F_2O,SiO_4	Yellowish-white	3·49	8	IV.	V.	Opaque topaz
Pyrostilpnite	Ag_3SbS_3	Red	4·25	2·5	V.	A.	Silver
Pyroxene, *s.* Augite							
Pyrrharsenite, *s.* Berzeliite							
Pyrrhotite, Pyrrhotine ..	$Fe_{11}S_{12}$	Bronze-yellow	4·5	4·5	III.	M.	Iron (60 per cent.), ferrous sulphate, sulphuric acid
QUARTZ (silica)	SiO_2	Colourless and all colours	2·7	7	III.	V.toG.	Most common rock-constituent; glass mfr., pottery, metallurgy, etc.
Quenstedtite	$Fe_2(SO_4)_3,(H_2O)$	Reddish-violet	2·1	2·5	V.	V.	
Quicksilver, *s.* Mercury							
RALSTONITE	$(Na_2Mg)F_2.3Al(F,OH)_3.2H_2O$	Colourless, milky	2·6	4·5	I.	V.	
Realgar	As_2S_2	Aurora red	3·5	2	V.	R. to A.	Arsenic ore (70 per cent.), pyrotechnics
Red lead ore, *s.* Crocoite							
Red ochre, *v.* Turgite	Fe_2O_3	Red	—	—	Am.	E.	Mixed with clay; [pigments
Redruthite, *s.* Copperglance							
Resinit, *s.* Pitchstone							
*Retinite							
Rhætizite, *s.* Cyanite							
Rhodochrosite	$(Mn,Ca,Fe,Mg)CO_3$	Rose-red	3–5	4·5	III.	V.,P.,R.	French Mn ore (47 per cent.)
Rhodonite	$MnSiO_3$	Rose-red	3·5	5·5	VI.	V., P.	Manganese spar; [Mn (41 per cent.)
Rhodophyllite, *s.* Kämmererite							
Riebeckite	$2NaFe(SiO_3)_2.FeSiO_3$	Black	—	—	V.	V.	Hornblende group; similar to Acmite
Riemannite, *s.* Allophane							
Ripidolite	$Al_3(Mg,Fe)_5H_9Si_3O_{20}$	Green	2·7	2·5	V.	P.	Transparent, dichroic
Rock crystal, *v.* Quartz ..	SiO_2	Colourless	2·7	7	III.	Tp.	Carved and cut into ornaments
Rock salt, *s.* salt							

* Retinite. A generic term for various amber-like fossil resins—*e.g.*, Copalite

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Römerite	$Fe_2(FeZn)(SO_4)_4.12H_2O$	Brown, yellow	2·17	3·25	VI.	V.	Pleochroic, transparent
Roscoelite	$KH_8(Mg,Fe)(Al,V)_4.12SiO_3$	Brown, greenish	2·93	—	—	P.	Found in small scales
Rose spar, *s.* Rhodocrosite							
Roselite	$(Ca,Co,Mg)_3(AsO_4)_2.2H_2O$	Rose-red	3·55	3·5	VI.	V.	Tp.; turns blue heated to 100°C.
Ruby, *v.* Corundum	Al_2O_3	Red	4	9	III.	V.	Precious stone, p. 5855
Rutile	Ti_2O_4	Red, brown	4	6·5	II.	A.	Resembles Cassiterite; porcelain painting, artificial teeth
SAHLITE, *v.* Pyroxene	$(Mg,Fe)Ca(SiO_3)_2$	Green	3·25–3·4	6	V.	V.	
Sal ammoniac	NH_4Cl	White, yellow	1·5	1·75	I.	G. to V.	Volcanic product; commercially artificial
Salmiak, *s.* Sal ammoniac							
Salt, common	$NaCl$	White	2·15	2·5	I.	V.	In stratified formations, arid regions, lakes and seas
Saltpetre, *s.* Nitre							
Samarskite	$(Fe,Y,Ce,Er)_4.(Nb_2O_7)_3,UO_2$	Velvet-black	5·7	5·5	IV.	V., R.	Cerium and yttrium metals
Sandbergerite, *s.* Tennantite							
Saponite	$(FeO,CaO,MgO)_6SiOAl_2O_3,Fe_2O_3,Si_2O_3,13H_2O$	White, yellow	2·2	1·5	Mass.	G.	Scotch igneous rocks
Sapphire, *v.* Corundum	Al_2O_3	Blue	4	9	III.	V.	Precious stone, p. 5855
Sarkinite	$Mn(Mn.OH)AsO_4$	Rose-red, yellow	4·18	4·5	V.	G.	
Sartorite	$PbAs_2S_4$	Lead grey	5·4	3	IV.	M.	
Sassolite, Sassoline	$B(OH)_3$	White, yellow	1·5	1·5	VI.	P.	Native boric acid
Scapolite	$Al_2(AlO)Ca_4(Si_2AlO_8)$	Grey, white	2·7	5·5	II.	G., V.	
Scheelite	$CaWO_4$	Brown, yellow	6	4·5	II.	R., A.	Tungsten ore (63 per cent.)
Schirmerite	$(Ag_2Pb)_3Bi_4S_9$	Grey, black	6·74	—	IV. (?)	M.	Silver
Schorl, Schörl, *v.* Tourmaline							
Schorlomite	$(Ca,Fe,Mg)(Fe,Ti)_2.3SiTiO_4$	Black	3·85	7·25	I.	V.	
Scleroclase, *s.* Sartorite							
Scolecite	$CaAl.Al(OH)_2.3SiO_3.2H_2O$	White, yellow, red	2·3	5·25	V.		Pyroelectric, transparent
Scorodite	$FeAsO_4.2H_2O$	Green, brown	3·2	4	IV.	V.	Arsenic
Seladonite, *s.* Celadonite							
Semeline, *s.* Spinthère							
Senarmontite	Sb_2O_3	White, grey	5·2	2·25	I.	A., R.	Antimony
Sepiolite, *s.* Meerschaum							
Serpentine	$H_4Mg_3Si_2O_9$	White	2·5	2–4	V.	R. to G.	Building-stone; finer varieties as marbles
Seybertite	$H_6(Mg,Ca,Fe)_{10}.Al_{10}Si_4O_{36}$	Brown, yellowish	3	4·5	V.	P., Sm.	Building-stone; finer varieties as marbles
Siderite	$FeCO_3$	Yellow, brown	3·8	4	III.	V., P.	Iron ore (48 per cent.)
Sideronatrite	$Na_2(Fe.OH)_2(SO_4)_3$	Yellow	2·25	2·25	V. (?)		
Silex, *s.* Quartz							
Sillimanite, *v.* Fibrolite	$Al(AlO)SiO_4$	Grey, brown	3·2	6·5	IV.	R., V.	Dimorphic with Cyanite
Silver	Ag	Silver-white	10·5	3	I.	M.	Occurs fibrous, massive or in films
Silver fahlerz, *s.* Freibergite							
Silverglance, *s.* Argentite							
Skutterudite	$CoAs_2$	Tin-white	6–7	5·75	I.	M.	Cobalt
Smaltite, Smaltine	$(Co,Fe,Ni)As_2$	Tin-white, grey	6·7–6·8	5	I.	M.	Cobalt ore
Smectite	$Al_2H_2(SiO_3)_4.xH_2O$	Grey	2	1	Am.	W.	Soapy feel
Smithsonite	$ZnCO_3$	White, greyish	4·2	4·5	III.	V., R.	Zinc ore (52 per cent.)
Soapstone, *s.* Steatite							
Sodalite	$Al_3(Al.Cl)Na_5(SiO_4)_4$	Blue, grey, etc.	2·1	5·5	I.	G., V.	
Soda alum, *s.* Mendozite							
Spathic iron, *s.* Siderite							
Specularite, *s.* Hæmatite							
Sperrylite	$(Pt,Rh)(As,Sb)_2$	Tin-white	10·6	6·5	I.	M.	Found with Ontario nickel ores
Spessartite, Spessartine	$Mn_2Fe_3(SiO_4)_3$	Hyacinth-red	4·0–4·3	7	I.	V.	A garnet
Sphalerite, *s.* Blende							
Sphene, *v.* Titanite	$CaSiTiO_5$	Yellow	3·5	6	V.	G.	Often translucent
Spinel	$Mg(AlO_2)_2$	Black, red, green, etc.	3·5–4·9	8	I.	V., R.	Precious stone, p. 5855
Spinthère, *v.* Sphene	$CaSiTiO_5$	Green	3·5	6	V.	V.	Often seed-like form
Spodumene	$Al(Li,Na)(SiO_3)_2$	Grey, white, green	3·1	6	V.	V.	Used in jewellery
Stannite, Stannine	$Cu_2FeS_nS_4$	Grey	4·4	3·5	I.	M.	Tin pyrites; tin (27 per cent.)
Stassfurtite, *s.* Boracite							
Staurolite	$(AlO)_4Fe(AlOH)(SiO_4)_2$	Brown	3·6	7·5	IV.	V.	
Steatite, *v.* Talc	$H_2Mg_3Si_4O_{12}$	Grey, green, etc.	2·7	1–2·5	IV., V.	V.	Firebrick, mantels, French chalk, polishes, carving, etc.
Stephanite	$Ag_{10}Sb_2S_4$	Grey	6·2	2·75	IV.	M.	Silver ore (68 per cent.)
Sternbergite	$AgFe_2S_3$	Brown, yellow	4·2	1·5	IV.	M.	Silver

Minerals.	Chemical formulæ or composition.	Colour.	S.G.	H.	C.S.	Appearance.	Products, uses, or other remarks.
Stibnite	Sb_2S_3	Lead-grey	4·5	2·5	IV.	M.	Common antimony ore (71 per cent.)
Stilbite	$(Ca,Na_2,K_2)Al_2Si_6O_{16}.6H_2O$	White	2·1	4	V.	V., S.

LAW

Following THE CHURCHES from page 6607

THE LAW AS A CAREER

The Barrister. Examinations and Lectures. Success at the Bar.
The Solicitor. Commercial Law. Written and Verbal Contracts

THE term "lawyer" is used indiscriminately in England for the barrister and the solicitor.

Barristers differ from solicitors in their training, their functions, and their status. In no other country in the world, perhaps, is the distinction between the two branches of the profession so strongly marked. A wide chasm divides them. Of what the differences consist we shall learn in due course. At this point it will suffice to state that while the barrister is the advocate, the pleader, the man who voices the client's case outside (or inside) the bar of the court, the solicitors are the men of affairs who come in direct personal contact with the clients. In practice the barrister may only take his instructions from the solicitor, who is, so to speak, the steward or manager of the affairs of the lay client—*i.e.*, the member of the public who has need of legal assistance. The barrister may look to the solicitor alone for the payment of his professional fee, and, moreover, he has no right in law to recover it, except as money had and received by the solicitor on his (the barrister's) behalf. His services, in theory at least, are honorary; and for that reason, no doubt, many barristers where they have to deal with solicitors whom they regard with suspicion, refuse to go into court until payment is made in advance.

The Branches of the Profession. The young man who adopts law as a profession must make up his mind whether he means to choose the barrister or the solicitor branch; but otherwise there is no need to specialise until he is well over twenty-one. Whether a man means to be a barrister or a solicitor he cannot know too much about the things which have to do with the outside world. He will succeed best if he be a man of general information; the specialising in law will come later. Another word of warning may be given to the young man. Both professions—the Bar especially—are essentially "late-in-life" professions. The barrister must not hope to make a living wage before thirty, or riches—if he ever does make th m—before forty. The solicitor, unless he has a business of his own to fall into, must not be disheartened if he finds himself a managing clerk at thirty-seven. The would-be lawyer will have plenty of time to specialise in law when he is done with his general education. If he is fortunate enough to be able to go to a university, let him proceed patiently to his degree, whatever the subject he may choose. With this general preface we can proceed to deal with the two branches in detail.

THE BARRISTER

The first step to the Bar is to be enrolled as a student of one of the four Inns of Court. These are the Inner or Middle Temple, between the Strand and the Embankment; Lincoln's Inn, or Gray's Inn. Preliminary to admission, the young man must pass a qualifying examination consisting of elementary Latin and English dictation. He is, however, excused from this if he has passed a corresponding examination—*e.g.*, Responsions at Oxford [illegible] at one of the recognised universities. Once he is admitted a student he at once begins to specialise; and here, it may be remarked parenthetically, it will be lucky for him if his general knowledge includes the possession of one foreign language perfectly. In these days of universal education the barrister who is known to speak French or German will find himself in possession of an asset which may lead to a competence. Indeed, any specialty learnt in youth may prove the turning factor in victory to the middle-aged barrister. Even the possession of a hobby is enough to mark out a barrister from the "ruck," and (without illegal advertising) bring him into prominence and success. Some men have loved mechanics and scientific pursuits generally, have used their spare time from the law to follow out this bent, and have found it help them to a patent practice, than which the Bar offers nothing more remunerative. "Collect something, if only old violins," said a wise old Balliol tutor many years ago to the present writer, "and you will find that you will be known for that, and get on." But the advice must be followed with the utmost discretion. The young barrister who aspires to prominence by means of a hobby must do it in a blameless, ingenuous way.

The Barrister's "Dinners." The qualifying examination ended, the young man who desires to become a student must then be introduced by (or vouched for, as it amounts to) two barristers belonging to the Inn which he desires to join. These two members must sign a document, which stands as a reference for his respectability. He lodges £30 as security for his dinners in Hall, of which more later. He is now an admitted student and may proceed to "eat dinners." He must "eat" seventy-two dinners in all, or thirty-six if he is a member of a university. Not more than six dinners may be "eaten" in a term (three for members of a university). There are four terms in a year; accordingly the ceremony can be completed in three years at the shortest. Often men miss terms, with the result that it takes them four and five years to complete the required quota. And it is not an infrequent sight to see grey-haired students dining—men who began their terms thirty and forty years before, and are now finishing the requisite number after an interval of a career spent as Indian civil servants in India. The dinners are held in the halls of the various Inns. The dining terms are usually coincident with the middle portions of the legal terms.

Examinations and Lectures. While he is "eating" his dinners the student is able to turn his attention to the examinations which he must pass before he is able to proceed to his call. The Inns have joined together to supply the student with a very comprehensive series of lectures on the legal subjects in which he will be examined; and to encourage him to attend these lectures, the examinations are based directly upon the ground covered by the lecturers during the two years or so immediately preceding the date of the examination. But the syllabuses of these lectures are always to be purchased from the offices of the Council of Legal Education, Old Hall, Lincoln's Inn. Consequently, a student with any intelligence is well able to note

the ground covered without attending lectures. Where a student is reading for his degree up at Oxford or Cambridge he is quite unable to attend Bar lectures in London. If he is not at one of the universities it will pay him to attend the lectures assiduously. He will find the readers and lecturers appointed by the Inns of Court willing to help him, and there can be no doubt that he will shorten his labours very considerably. The subjects in which he will be required to pass a satisfactory test are given in the schedule on this page. They may be taken at different times, as will be seen from the appended form; and it may be said at once that the standard, though higher of late years, is not by any means a prohibitive one. Men are not "ploughed" in any great numbers; no doubt the theory being that any fairly intelligent man who desires to become a barrister should be allowed to do so. And then it resolves itself into a case of the survival of the fittest.

The Call to the Bar. When the student has passed all the examinations, and "eaten" his required number of dinners, he may proceed to his *call.* But certain preliminaries are still necessary. He must get a bencher of his Inn to propose him for call. There should be no difficulty about this. Some barrister of his acquaintance will be able to introduce him to a bencher. He must then pay £80 to his Inn, allowance being made for the £30 already lodged on account of battels, etc. That finishes the money part of his liabilities. His name is *screened* in Hall for a stated term before *call night.* "Call" nights come once in every dining term—that is, four times a year—viz., January, May, June and November. The ceremonies may differ a trifle in detail at each of the four Inns. At the Inner Temple, after dinner in Hall, the students about to be called are ushered into the "parliament chamber" or "common-room," where the benchers are drinking port and eating their dessert. The students are placed in a standing line along the walls of the room. Each one is given a glass of wine, and the benchers drink to them. The treasurer of the Inn, or the senior bencher present, makes them a little speech—generally telling them what a very difficult profession they have chosen. The senior student is then encouraged to make a suitable reply, and the ceremony ends. The young man has been *called* to the Bar, and is in a position to hold himself out for practice.

Technically, he may now consider himself a full-fledged barrister, but the custom of the profession has introduced a practice known as "reading in chambers." The young barrister, in return for a fee of £105, obtains the run of the chambers of some busy barrister for the space of one year. He has his desk in these chambers, reads all the briefs, draws pleadings, which his chief may or may not use according to their value, goes with his chief into court, and, in fact, "learns the ropes" of the profession which he has joined. There is no hard and fast rule about one year in one set of chambers, nor is it necessary for a man to wait to be called before he goes into chambers. He can enter while still a student and at any age the barrister with whom he reads may choose to take him. No man is eligible for *call* to the Bar under twenty-one, but anyone may become a student as soon as he can pass the qualifying examination for admission.

Again, as to the length of time in these chambers, many young barristers stay two years; others, again, stay six months in common law chambers, and six months in equity chambers—and try to find out in that way in which direction their bent or interest lies.

Specialising. Directly he has been "called," the young barrister has to make a very definite choice. He must make up his mind whether he will hold himself out for practice on the Chancery side, and become learned in conveyancing and trusts and partnership deeds and the like, or remain on the common law side of his profession, including anything from running down cases to libel and slander. He must make his choice advisedly, for, once started, he will find it exceedingly difficult to change over.

If the young practitioner elects to stay on the common law side, he will have to think of joining a circuit. Let him remember that this is a step to be taken early in his career. If he joins within a year of his "call" he will find no difficulty in his way. He must get a member of the circuit to propose him, he must dine three nights "on approval" at the circuit mess, and pay a matter of seven guineas as an entrance fee. Then his election will follow more or less as a matter of course. On the other hand, if he presents himself for election five or six years after his "call," he might find that the circuit refuses to elect him, on the theory that he has stood outside too long making up his mind which circuit to go, and therefore he may stand outside altogether.

The all-important question of chambers in town is another matter which concerns the young

SCHEDULE OF EXAMINATIONS FOR BARRISTERS

Examining Body and Grades.	Time and Place of Examination.	Subjects of Examinations.		Fees and Age Limits.
		Obligatory.	Alternative or Optional.	
THE INNS OF COURT	London		(For those who have not passed certain specified public examinations)	Not under 21
Preliminary ..	January May June November	Roman law, Constitutional law (English and Colonial) and Legal History Evidence Procedure, Civil and Criminal and Criminal law English law and Equity, including: (1) Law of Persons—Marriage and Divorce, Infancy, Lunacy, Corporations (2) Real and Personal Property and Conveyancing (3) Law of Obligations—Contracts, Torts, Estoppel, and Commercial law	Elementary Latin English Dictation	Included under total fee of £80 to the Inn

barrister. If he keeps to the common law he will elect to have his chambers in the Inner and Middle Temple; the equity man will set himself up in Lincoln's Inn or Gray's Inn. A good, small room, with the use of a clerk, can be obtained in any Inn for from £25 to £40 per annum, with a £5 minimum guarantee to the clerk; but the young practitioner cannot over-estimate the value of being in good and reputable chambers where there is plenty of bona fide work, even though he himself remains during the first years absolutely briefless. A good clerk who has his master's interests at heart helps i mensely towards final success.

Roads to Success. And now with our young barrister fully equipped, a member of a circuit, and settled in chambers in one of the Inns, the question that stares him in the face is "What chance has he of success?" There are two tests and two only, by which one may judge whether a man may succeed. First, "if a man can work when he has nothing to do"; second, "if a man can live and keep himself decent on nothing a year." Show me a man who can solve these two problems, and I will show you a future judge. In other words, the thing that kills most men, so far as the Bar is concerned, is the inability to keep alive their powers of application at a time when no solicitors want them. It is easy enough to get up at five o'clock in the morning and read briefs when you have got them to read; but the briefless junior who can get up at five o'clock and work hard is the man who will succeed. Naturally, the man with private means is in a better position to withstand the years of waiting, and that brings us to our second proposition, for names like Eldon and Herschell remind us that men have risen to the woolsack without a penny of their own. The secret of it has been their ability to live on nothing. Their absolute necessities they have supplied from teaching or writing for newspapers, but they have never let these avocations draw them away from the main object of their lives—the law. The work which brought them food and clothing was never allowed to invade the hours when they held themselves out for clients. What are the dangers of straying off the by-paths of law into literature only those know who have followed the will-o'-the-wisp of daily journalism. It is useless to deny that private means do away with the necessity of working at anything except the law. But there comes the danger of the young barrister throwing up his profession in disgust and spending his patrimony in a pleasanter and less arduous West End life.

"Devilling." Among the recognised roads to success is the practice of "devilling," or working at the briefs of a busy barrister who has far too much to do to read them himself. Many a man has thus come in contact with solicitors and succeeded to the practice of his "chief" when the latter "takes silk" or becomes a judge or a law officer of the Crown. But the "devil" must be a very good one, able to obtrude his personality quietly but firmly, and the "chief" must be a man of generous instincts, who does not keep his "Sydney Carton" rigorously in the background. Natures differ. Some barristers, with far more work than they can do in keeping with their duty to their clients, are willing to delegate it to the point of letting the "devil" have all the labour and none of the glory. They would not dream of letting their "devils" appear for them in court or come in contact with their clients. Happily, such men are few and far between. The majority of the profession are men with generous instincts, and the "devil" whose lot falls in fairly pleasant places will not only find plenty of work to do, but he will have the run of good chambers, and, into the bargain, be paid an honorarium for his trouble. Above all, he will have the pleasing feeling that he may step into his "chief's" practice, although, as a rule, when a busy junior leaves the outer Bar, his work generally becomes distributed among a number of other juniors left behind. But the "devil," if he is a man of any ability, will get some of it, and that will serve as a nucleus round which to build up a practice of his own.

Failure and Success. Failure at the Bar is a hard word, but it is a lot to be faced, and by very many. Of course, men drift away from the Bar into other employments. They become journalists and civil servants, and go into businesses (except solicitors' businesses, from which they are debarred). And if at forty they find themselves still hopelessly briefless, there always remains the West Coast of Africa—Lagos or Nigeria, or the Gold Coast! Other Colonial and foreign appointments are not numerous, and it must be stated that the briefless barrister without influence in high quarters need not hope for one. Unattractive as they may seem to ambitious twenty, utilitarian forty clusters after them. They range from Indian judgeships to West Indian law officers, and when one falls vacant there are about fifty applicants. The same may be said of the minor legal appointments in this country. County court judgeships are now eagerly sought after by "silks" in respectable practice. True, the emolument is only £1,500 a year, and the work hard and rather sordid. The same may be said of stipendiary magistracies, carrying £1,000 a year. A briefless junior, unless he had very influential friends, might just as well wish for the moon. To this extent, then, these minor appointments must yet be counted among the plums of the profession.

The High Court Bench. Of course, the biggest plums of the profession are puisne judgeships, lord-justiceships of Appeal, and law lordships. The salaries range from £5,000 to £7,000, the duties are responsible, and surrounded by a certain show of magnificence which makes them doubly attractive. No King's Counsel who has not a large practice need hope to be elevated to the bench unless he has made himself useful in political life by fighting for his party inside the House or out. If he is a Chancery judge, his work will always be in London; if a common law judge he may have to go on circuit four times a year, for which he receives ample travelling allowances and lodging money For the man who ends up a High Court judge, the Bar has, indeed, been a lucky speculation, but unfortunately few do.

THE SOLICITOR

The young man who decides to enter the lower branch of the legal profession must make up his mind to a longer term of pupilage, harder qualifying examinations, and possibly a position of lifelong subordination. On the other hand, he will earn a living wage much earlier in his career, while the mean level of pecuniary reward is certainly not less than that prevailing at the Bar.

The first step to become a solicitor is to pass a preliminary examination before entering into articles of clerkship to solicitors. Every man who wants to be a solicitor must first be an articled clerk—a species of apprentice to the practice of the law.

Examinations. First of all it may be mentioned that the examinations, and, indeed, all the official steps towards being enrolled, are conducted by the Law Society, Chancery Lane, London, W.C.,

the chartered company, so to speak, of the profession. And now to deal seriatim with the three examinations needed to qualify.

The Preliminary Examination is excused to certain candidates, as the following list shows.

EXEMPTIONS FROM PRELIMINARY EXAMINATIONS

Bachelors of Arts or Bachelors of Laws at the following Universities: Oxford, Cambridge, Dublin, Durham, London, Wales, Liverpool, Leeds, Royal University of Ireland, and Victoria University of Manchester; Bachelors of Arts, Masters of Arts, Bachelors of Laws, or Doctors of Law in any of the Universities of Scotland, none of such degrees being honorary.

Utter (junior) barristers in England.

Persons who have passed the following examinations:

First Public Examination before moderators at Oxford

Previous Examination at Cambridge.

Examination in arts for the second year at Durham.

Local Examination, Oxford (junior or senior).

Local (non-gremial) Examination, Cambridge (junior or senior).

Examination of the Oxford and Cambridge Schools Examination Board (higher certificate).

Matriculation Examination at Dublin or London (not necessarily in first division).

Examination for First-class Certificate of the College of Preceptors.

Provided the conditions set out below of the order of February 8th, 1905, be complied with, persons who have passed the following examinations are also exempt.

[(*a*) Latin shall be one of the subjects taken, and if Latin is not a compulsory subject the examination certificate shall state that the candidate has passed in Latin.

(*b*) All the subjects required to be taken by a candidate shall be taken at one examination, and the examination certificate shall state that they have been so taken.

(*c*) If any alteration be made in the regulations, character, or standard of an examination, this order shall immediately thereupon cease to apply to such examination]:

School-leaving Examination (Matriculation standard) of the University of London.

The examination of the Joint Matriculation Board of the Victoria University of Manchester, the University of Liverpool, and the University of Leeds.

The Matriculation or Entrance Examination of the University of Birmingham, and the School-leaving Examination (Senior Certificate) of that university.

The Matriculation Examination of the University of Wales.

The Examination for the Senior Certificate of the Central Welsh Board under the Welsh Intermediate Education Act, 1889.

The Responsions Examination at St. David's College, Lampeter.

The Local Examination of the University of Durham, Senior Pass Certificate, and the Junior Certificate, with at least second-class honours.

All persons who have obtained certificates of having passed the Preliminary Examination, or are exempt therefrom, may enter into articles of clerkship.

All persons exempted from the Preliminary Examination pay an additional £2 on giving notice for the Intermediate Examination (Judges' Order, June 28th, 1904).

For full particulars respecting this examination, the student is referred to schedule on this page.

No books will be previously specified for the language examinations, but passages will be given for translation at sight, with the assistance of a dictionary. Candidates must bring their own dictionaries.

Candidates are required to give, at least 30 days before the day appointed for the examination, notice to the Secretary of the Law Society of the *languages* in which they propose to be examined, the *town* at which they wish to be examined, and

SCHEDULE OF EXAMINATIONS FOR SOLICITORS

Examining Body and Grades.	Time and Place of Examination.	Subjects of Examinations. Obligatory.	Subjects of Examinations. Alternative or Optional.	Fees and Age Limits.
THE LAW SOCIETY	London and some of the principal towns.			Not under 21. For admission on the Roll of Solicitors.
Preliminary ..	February May July October	Dictation English Composition Mathematics: (*a*) Arithmetic; (*b*) Algebra, inclusive of simple equations and elementary; (c) Geometry as treated in Euclid I. to IV. Geography of Europe and History of England Latin—elementary	Any two of the following languages: Latin, ancient Greek, French, German, Spanish, Italian.	£4
Intermediate ..	January March June November	Elementary works on the laws of England. Elementary questions on accounts and bookkeeping	—	£6
Final	January March June October	Principles of the Law of Real and Personal Property, Conveyancing Procedure in all divisions of the High Court, Ecclesiastical and Criminal law, and practice and proceedings before Justices of the Peace	—	£10. £15 when Intermediate Examination is excused

their *age* and *residence*, and *place* or *mode of education*.

Articled Clerks. The Preliminary Examination satisfactorily disposed of, the young candidate may now enter into his *articles*.

The usual period for service under articles is five years, but for graduates of universities who are exempted from the Preliminary Examination, and for persons who have been called to the Bar, and are of less than five years' standing as barristers, the period is three years.

Persons who have passed the following examinations need serve only for four years:

First Public Examination before moderators at Oxford.

Previous Examination at Cambridge.

Examination in arts for the second year at Durham.

Entrance Examination at Dublin, having passed in honours.

Matriculation or Entrance Examination at London, Birmingham, or University of Wales, first division.

The Responsions Examination at St. David's College, Lampeter.

The Examination of the Joint Matriculation Board of the Victoria University of Manchester, University of Liverpool, and University of Leeds, first division.

Articled clerks bound for four or five years may serve one year with the London agent, and one year with a barrister or special pleader. Those bound for three years may serve one year with the London agent, but they cannot serve any part of the term with a barrister or special pleader.

The stamp duty on the articles is £80, and on further articles 10s.

Articles cannot be stamped after the date thereof, except on payment of penalties.

The articles must be enrolled and registered at the society's office within six months after execution. The fee payable to the society for registration is 5s.

When articles are left at the office of the Law Society for registration, a statutory declaration, impressed with a 2s. 6d. stamp, made by the attesting witness as to the due execution, must be produced, together with the certificate of having passed the Preliminary Examination or one of the examinations exempting from it. All certificates are returned with the articles.

The solicitor to whom the clerk is articled will also require a fee calculated on a basis of £300 for the whole five years.

The choice of a solicitor to whom to be articled will usually prove a more or less personal affair; but it is generally best for the clerk—like the youthful barrister—to go to the office, or chambers, where there is plenty of work to be had. He will gain experience more rapidly, see a greater variety of men and affairs, show his metal, and, if he is really a man of grit, be trusted with really responsible work.

Intermediate Examination. Every articled clerk, with certain exceptions, is required to pass the Intermediate Examination. He may present himself at any time after completing twelve months' service in his articles.

The subjects of the Intermediate Examination are such elementary works on the laws of England as the examination committee may from time to time appoint for that purpose, and elementary questions on accounts and bookkeeping.

The particular books selected for the examination are named in the month of July in the year previous to that for which they are selected.

If the candidate passes the examination he will receive a certificate to that effect; but in case he fails to do so he may, provided he has given the proper notice, attend any subsequent examination; but if he shall not have passed the examination before the expiration of twelve calendar months after the date when one-half of his term of service shall have expired, his final examination shall be postponed for so long a period as may intervene between the expiration of such last-mentioned twelve calendar months and his passing the examination, or for such shorter time as the examination committee shall direct. Should a candidate fail in accounts and bookkeeping only, he shall be allowed to come up again in those subjects without postponing his final examination, and if he passes in bookkeeping only he will not be required to come up again in that subject.

EXEMPTIONS FROM INTERMEDIATE EXAMINATION

All persons exempted from the Intermediate Examination in Stephen's Commentaries are required to pass in bookkeeping.

The following certificates are accepted in place of the Intermediate Examination: (1) A certificate of having before or after entering into articles passed the examination required for the degree of B.C.L. or LL.B. at one of the following universities in the United Kingdom—*viz.*, Oxford, Cambridge, London, Dublin, Durham, Wales, Birmingham, Liverpool, Leeds, or the Victoria University of Manchester; or (2) a certificate of having before entering into articles taken honours in the Final Honour School of Jurisprudence at Oxford or in the Law Tripos at Cambridge.

Candidates who are exempted from the Intermediate Examination in Stephen's Commentaries pay an additional fee of £5 on giving notice for their final examination, but no fee is payable by them for the examination in bookkeeping.

The fee payable on giving notice of examination is £6, and for a renewed notice £3.

Final Examination. The articled clerk has still one examination to pass. The subjects included, and other particulars, are given in schedule.

Candidates are required to give notice in writing *forty-two days* at least before the date of the examination to the Secretary of the Law Society, Chancery Lane, London.

Candidates are also required, *at the same time*, to leave with the secretary of the society their articles of clerkship and supplemental articles (if any), and certificate of having passed the Intermediate Examination, together with answers to the questions as to due service and conduct, to be answered by the candidate and his principal and agent, if any. Prints of these questions can be obtained on application at the office of the Law Society.

Notice of the desire of a candidate to compete for honours must be given when notice is given for final examination.

Admission to the Roll. It only remains to add the rules necessary to enable the qualified man to apply for admission on the roll of solicitors:

Notice for admission must be given to the Law Society six clear weeks *before* the first of the month in which such application is intended to be made; and such notice can be given before the applicant has passed the Final Examination.

No person can be admitted until he has attained twenty-one years of age, and until his term of service has expired.

If at the time of passing the Final Examination the term of service has not expired, further testimonials from the Principal will be required from the date of such examination to the expiration of the Articles; and where the candidate was under 21 years of age at the time of passing the examination, and has since attained that age, a letter from him to that effect will be required.

In order to avoid delay the Articles of Clerkship, the Final Examination Certificate, any further testimonials or letter required as above mentioned, and the Admission Certificate, impressed with the revenue stamp of £25, together with the fee of £5 payable to the Society, should be left at the office of the Society one week before the expiration of the six weeks.

The Admission Certificate will thereupon be sent to the Master of the Rolls for signature, and, when signed, the applicant's name will be entered on the Roll of Solicitors. The Notice for Admission will be received by post, but the Admission Certificate, after it has been signed, must be applied for at the office of the Society.

Admission cannot be ensured during vacation.

The Form of Notice may be obtained from most law stationers; and the Admission Certificate, with the stamp impressed, may be obtained from Somerset House.

So much, then, for the machinery The aspirant will see that it means many examinations, many years' pupilage, a good deal of hard money in fees and for "articles." During these years he must live, for he will get no salary. Consequently, it may be said with confidence that the man who desires to become a solicitor must be prepared to spend at least £1,000 before he can hope to be in a position to earn money at his profession. Now let us look at his chances of success.

The Chances of Success. It may be said at once that the young solicitor well recommended and with average intelligence may always be sure of a living wage. He may have to look about him for some time, but in the end he will run across some vacancy—a post in an office worth £200 a year, with the chances of rising to managing clerk at double the salary. Of course, the competition is a growing one, and the salaries show a proportionate tendency to diminish, but there is nothing like the penury and starvation to be faced by the barrister at the beginning of his career. There are also a number of official positions under Government, at home and abroad, for which solicitors alone are eligible, as well as municipal appointments—town clerks, clerks to borough councils, and the like. Of the former variety—carrying salaries from £400 to £1,000—it may be said that "influence" is the one thing needful. The young practitioner lacking influential friends must not hope to get a salaried post under Government, except perchance a legal post in West Africa, for which barristers and half-pay military officers are not forthcoming. Of the municipal appointments in the market, few go to any but solicitors of "standing." Carrying, as they do, salaries of £700 to £1,500, they are run after by men with practices, usually local practices.

The Varieties of Work. The young solicitor who means to fight his way through to a practice of his own may find it useful to consider the varieties of work comprised in his profession. These varieties are endless, and range from the City solicitor, with wealthy City firms and railway companies among his clients, to the police-court practitioner, whose advice is sought by the drunk and disorderly. Possibly the soundest basis of division is between litigation and non-litigous work. Many large firms have an abundance of both varieties. One department looks after the concerns of omnibus companies or railway companies, who are always being sued for damages for accidents; another department looks after the conveyancing needed by private clients. A will has to be made, a marriage settlement drawn up, a mortgage settled. Contracts are drafted in the solicitor's office, and any dubieties connected therewith which may lead to litigation come back to him to be dealt with. Company work is a very special and still remunerative branch, though to a certain extent the glory of this species of solicitor's business has departed. The solicitor whose name appears on the prospectus of a new issue not only charges a handsome fee for that, but the legal work in drafting the various documents required by law in the initiation of the company.

The Family Solicitor. The old family solicitor constitutes yet another variety. In his strong-boxes are all the deeds connected with the relations, pecuniary and otherwise, of clients, who place the utmost reliance in him. But he will be a wise man if he refuses to be made the repository of valuable scrip and money. That, so often, is the beginning of confusion and the loss of trust funds, which end in penal servitude for the solicitor. The proper place for securities is the bank; and solicitors are beginning to be more and more chary of allowing their offices to be used as banks.

COMMERCIAL LAW

In the course of his daily business there are certain fundamental principles of law which a man is required to know, for it must be remembered that ignorance is no excuse in law. True, in these days of complicated rights and special knowledge, there is always a solicitor to whom the business man may have immediate recourse, but it is possible for a good deal of mischief to be done before he is even aware that his business has brought him within a thousand miles of litigation. A letter may be written binding the sender to an arrangement the exact contrary to what he had intended; liabilities may have been incurred far beyond those anticipated by either of the parties. It is, then, the object of this article to supply a handy *vade mecum* which will prevent ineffaceable errors before the solicitor has come upon the scene; or, better still, to render the presence of a solicitor unnecessary. Without pretending to be exhaustive, the article will at least aim at being complete.

Reduced to its simplest elements, all business is a matter of buying and selling.

There are modifications of this primal basis, of course; but ultimately every man who goes down to his office day by day, either to work for himself or for his employer, goes down either to buy or to sell, generally to do both—to buy to sell again, or even to sell to buy back.

In England we have no code, unfortunately, but the law relating to the sale of personal property is to all effects codified by the *Sale of Goods Act*, 1893, which every business man should keep in his office. In it he will find much which he need not try to understand. But there are, on the other hand, certain sections which he will do well to get by heart. Thus in Section 3 it states that:

> *A contract of sale may be made in writing (either with or without seal), or by word of mouth, or partly in writing and partly by word of mouth, or may be implied by the conduct of the parties.*

Verbal Contracts. The business man who bears that in mind will never find himself pinned down to a bargain which he had never intended to make. So many men have an invincible conviction that they can never be bound to anything until they have set pen to paper, and had the result stamped at Somerset House. When once the

community has rid itself of this pleasing fiction, the law courts may close for lack of work. The section speaks for itself, and does not need comment. Enough to say here that signed and sealed documents play a very small part in fifty per cent. of the sales which take place daily. The fishmonger who sells a pound of salmon may or may not give a receipted bill to the customer; in any case, this document is nothing more than an evidence of the sale which has taken place without it, and is perfectly valid without it. On exchanges hundreds of thousands of pounds' worth of securities or commodities pass from seller to buyer by the medium of a single word, or even a nod. The contract note which follows is evidence of the same; but the bargain is perfectly good in law before the contract note has passed, and will be enforced.

A and B, who exchange informal letters agreeing on the one hand to buy and the other hand to sell, say, ten thousand tons of cement, are in contractual obligation to each other. Only, in all these bargains made by word of mouth or informal letters this single point is essential, both *parties must mean the same thing.*

Lawyers call it being "ad idem." Let us illustrate this doctrine by a concrete example. Smith writes to Jones. "Will you buy my house at Oxford as it stands?" Jones writes to Smith in reply: "Yes, I will buy your house. Of course, it is freehold?" If, as a matter of fact, Jones's assumption is wrong, and the house is not freehold, there then has never been a completed bargain between the parties. But even if Jones's assumption is right, it is arguable that there has as yet been no completed bargain on the letters, since Jones, instead of sending back an acceptance, sends an acceptance modified by another question.

Again, Robinson may say to Jackson, who is a coffee broker: "What can you do for me to-day?" Jackson merely answers: "Ten bags," to which Robinson merely nods and walks out. A dispute arises, and the courts will have to decide that particular transaction upon the custom of that particular trade, or, more likely, the habitual method of business between Robinson and Jackson. For there can be no doubt but that on the face of it there has been a contract.

Conditional Agreements. But supposing Jackson in reply to Robinson had said "Ten bags if cleared," and Robinson had nodded and gone out, the result would not have been a bargain, since Jackson's offer to sell was conditional upon a certain event, though in the event of the fulfilment of that condition the bargain becomes fixed. If, however, Jackson had merely said "Ten bags if I can," then there would have been no bargain at all.

Let us stop for a moment at the answer, "Ten bags if cleared." Here we have not a sale, but *a conditional agreement to sell,* for under the Sale of Goods Act, "where the transfer of the property in the goods is to take place at a future time or subject to some condition thereafter to be fulfilled, the contract is called an agreement to sell." And "an agreement to sell becomes a sale when the time elapses or the conditions are fulfilled subject to which the property in the goods is to be transferred."

In most cases bargains are struck by the medium of the pillar-box. The merchant in his office carries through most of his business by correspondence. Therefore it should be noted that the *acceptance of any offer becomes irrevocable when the letter containing any such acceptance has been posted.* The moment when the letter of acceptance is put in the public letter-box is the moment when the contract is complete. Evidence of such posting is evidence of completion. And the same rule applies to acceptance by telegram. Directly the telegram has been despatched the acceptance becomes irrevocable.

The Law and Private Pillar-boxes. In connection with acceptance by letter, a word may be said about private posting facilities which have sprung up in large institutions, such as offices and hotels, of late years. The Postmaster-General has allowed these buildings to be equipped with pillar-boxes, which, though within their private premises, are directly under the control of the postal authorities. They are cleared by the postmen of the district, who alone have the key. But proof of posting in them cannot be taken as evidence in a court of law as the completion of any bargain. Why, it is difficult to say. Possibly because the box is not situated in a public place.

In connection with the irrevocability of such acceptance by post, it may be useful to point out these three concise rules:

1. *An offer cannot be withdrawn after the acceptance has been duly posted.*

Thus A writes fully offering to sell a horse to B. The latter posts his acceptance, and in the meantime, before the acceptance reaches A, the latter has repented him of his original offer. It is too late to withdraw.

2. *The withdrawal of an offer must reach the other party before he has duly posted his acceptance.*

3. *An acceptance once posted cannot be revoked.*

There, then, we have in as few words as possible the main facts which a business man should know in his daily life so far as the acceptance of contracts is concerned. Let him disabuse his mind of the common belief of the ignorant that he is not bound to anything until his signature, properly witnessed by competent witnesses, has been affixed to the terms of the bargain, and the resulting document signed, sealed, and delivered. There is no magic in writing, nor in seals or stamps. True, the law has given validity to seals and stamps which it denies to verbal agreements, but there may be no seals, no stamps, no writing, and yet a perfectly valid and binding agreement.

Written Contracts. We come, then, in the conclusion of this branch of our subject, to *the need of writing* in the making of contracts. In other words, how far are contracts governed by *the Statute of Frauds,* that enactment passed in the reign of Charles II. (1677) which, with its undoubted salutary uses, has managed to create more confusion in the minds of subsequent citizens than any other single entry upon the statute book.

It is not necessary to repeat here the actual Section 17 of the Statute of Frauds, for it is in substance re-enacted in Section 4 of the Sale of Goods Act, which section runs as follows:

A contract for the sale of any goods of the value of ten pounds or upwards shall not be enforceable by action unless the buyer shall accept part of the goods so sold, and actually receive the same, or give something in earnest to bind the contract, or in part payment, or unless some note or memorandum in writing of the contract be made and signed by the party to be charged, or his agent in t at behalf.

The provisions of this section apply to every such contract, notwithstanding that the goods may be intended to be delivered at some future time, or may not at the time of such contract be actually made, procured, or provided, or fit or ready for delivery, or some act may be requisite for the making or

completing thereof, or rendering the same fit for delivery.

There is an acceptance of goods within the meaning of this section when the buyer does any act in relation to the goods which recognises a pre-existing contract of sale, whether there be an acceptance in performance of the contract or not.

The explanation of the sections given above would take up far more space than we have at our disposal. It will no doubt suffice to say here that they in no way conflict with what has already been said in this article as to the validity of sales made by word of mouth (parole evidence) or by actions (such as nodding at an auction, and the fall of the hammer), without words. The full significance of the Statute of Frauds may indeed be put in less than a dozen sentences. Its intention was to prevent the enforcement of verbal contracts above a certain value, unless the defendant could be shown to have executed the alleged contract by partial performance as manifested by part payment, or part acceptance, or unless his signature to some written note or memorandum of the bargain could be shown.

Thus a contract note referring to the sale of stocks and shares would be necessary to enforce an action to enforce completion, unless there had been partial delivery or some act which can be construed into partial performance. In such construction the custom of any particular trade or business may be called in aid—as, for instance, in stock exchange cases where the mode of business has been the same from time immemorial. But it must be remembered that the Statute of Frauds has no concern with written contracts which have been duly signed; for in those cases the common law affords sufficient guarantees against frauds and perjuries. In a word, the business man must remember that though his spoken word may lead him into an irrevocable bargain, the law requires certain *actions* as corroboration of the binding remarks uttered. Contracts duly signed and witnessed and stamped, will, in all cases where the business man who needs them is wise, be drawn up by a solicitor. Hence the legal requirements of such documents need not be considered further in this place.

Sample and Warranty. Another branch of the law of sale and purchase which affects the everyday life of the business man is the *quality of the thing sold.* Very often, and it cannot be otherwise, he finds himself face to face with this difficulty. He has bought goods on the word of the seller as to their quality, and then finds them inferior. The whole subject concerns the doctrines of *sample and warranty,* which can be dealt with shortly, so far as they give rise to questions which the business man may find that he has to deal with on the spot before he has time to get legal advice.

Upon this subject, then, the sections of the Sale of Goods Act are clear and precise:

Sect. 13.—Where there is a contract for the sale of goods by description, there is an implied condition that the goods shall correspond with the description; and if the sale be by sample, as well as by description, it is not sufficient that the bulk of the goods correspond with the sample if the goods do not also correspond with the description.

Sect. 14.—Subject to the provisions of this Act, and of any statute in that behalf, there is no implied warranty or condition as to the quality or fitness for any particular purpose of goods supplied under a contract of sale, except as follows:

(1) Where the buyer, expressly or by implication, makes known to the seller the particular purpose for which the goods are required, so as to show that the buyer relies on the seller's skill or judgment, and the goods are of a description which it is in the course of the seller's business to supply (whether he be the manufacturer or not), there is an implied condition that the goods shall be reasonably fit for such purpose, provided that in the case of a contract for the sale of a specified article under its patent or other trade name there is no implied condition as to its fitness for any particular purpose.

(2) Where goods are bought by description from a seller who deals in goods of that description (whether he be the manufacturer or not), there is an implied condition that the goods shall be of merchantable quality; provided that if the buyer has examined the goods, there shall be no implied condition as regards defects which such examination ought to have revealed.

(3) An implied warranty or condition as to quality or fitness for a particular purpose may be annexed by the usage of the trade.

Sect. 15.—(1) A contract of sale is a contract for sale by sample where there is a term in the contract expressed or implied to that effect.

(2) In the case of a contract for sale by sample:

(a) There is an implied condition that the bulk shall correspond with the sample in quality.

(b) There is an implied condition that the goods shall be free from any defect, rendering them unmerchantable, which would not be apparent on reasonable examination of the sample.

Sect. 33.—Where the seller of goods agrees to deliver them at his own risk at a place other than that where they are when sold the buyer must, nevertheless, unless otherwise agreed, take any risk of deterioration in the goods necessarily incident to the course of transit.

Transport of Goods. The concluding paragraph, which is sufficiently explicit, brings us to the consideration of the *transport of goods,* a wide and intricate subject which keeps the commercial court in London busy from year's end to year's end.

Section 20 of the Sale of Goods Act lays it down very clearly that:

Unless otherwise agreed, the goods remain at the seller's risk until the property therein is transferred to the buyer, but when the property therein is transferred to the buyer, the goods are at the buyer's risk whether the delivery has been made or not.

Provided that where delivery has been delayed through the fault of either buyer or seller, the goods are at the risk of the party in fault as regards any loss which might not have occurred but for such fault.

The business man may say that the above section is simple enough when someone has explained to him what is meant by the phrase "when the property therein is transferred." The answer is not so simple. The transference of the property may depend upon the conditions of the contract. Thus, the undertaking of a seller to ship a *complete* cargo on board steamship X—— at buyer's risk, would clearly in law be said to contemplate that the goods remain at seller's risk until they are all on board and *complete.* In truth, questions of this kind have vexed and will continue to vex lawyers, and laymen should leave them severely alone.

The rule of thumb which may guide the business man in such matters is this: Has he absolute controlling possession of the goods? If so, the responsibility is upon him, as seller or buyer, to see that they are not damaged in delivery, and his remedy is against the carriers for damage.

Continued from page 6657

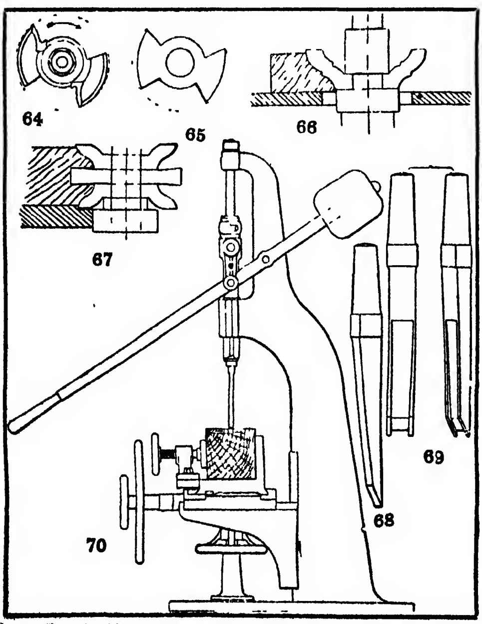
MISCELLANEOUS MACHINES

Varieties of Mortising Machines. Tenoning, Boring, and Dovetailing Machines. Special Lathes for Working Wood

By FRED HORNER

THE cutters and cutter-blocks employed in the planing and moulding machines described in the previous article embody numerous shapes, the simplest of which are those for plane surfaces, having flat knives bolted to the sides of a cylinder or block in the manner shown in **57** [page 4583], the length ranging from a few inches to two or three feet. Moulding cutters are also made as shown on that page. A very popular class of cutter-head for matching and moulding—the Shimer—differs radically in having a number of bits of circular form bolted around a circular head, the bits being set alternately so that each takes its share of the cut to right and left. The outline to be formed is imparted to the bits, which cut by one edge, produced by filing in a gap in the circle; the form remains unaltered until the bit is worn out.

The vertical spindle moulding machines use a variety of cutters. In the *French*, or slotted spindle a thin steel blade is fixed in a slot in the spindle end, and its edge being formed to correct outline, it is turned over forcibly like a scrape to produce a working edge. The French cutters are used chiefly for special classes of work, as the blades can be made cheaply and quickly. A common method is to fit flat cutters between grooved collars, as illustrated in **62** [page 6656]. Sometimes also an ordinary square block is fixed to the spindle end, to receive flat moulding cutters. Solid cutters bear some resemblance to milling cutters for metal, in having the moulded outline formed on the circumference.



64-67. Moulding cutters **68 and 69.** Mortising chisels **70.** Hand mortising machine

Sharpening is done on the flat between the teeth. The non-reversible types have a clearance in one direction [**64**]; the reversible class are flatter on the periphery [**65**], so that either edge may come into operation as the machine spindle is reversed. Four, eight, or ten cutting edges are produced, according to whether the cutters have two, four, or five teeth [see **58**, page 4583]. Figures **66** and **67** illustrate their application, the first showing the use of the work itself to press against the guide collar under the cutter, the second that of a separate pattern plate to which the moulding is attached.

Mortising Machines. These, which are intended for cutting the slots or mortises in timber, are of vertical or horizontal types, the latter chiefly for light work. The commonest method is to use a chisel [**68**], resembling a hand mortising chisel, but held in a spindle, and fed down by hand or power. An improved form now in general use is the *self-coring* type [**69**], which has two projecting lips, which, being tapered inside, have the effect of drawing the chips from the mortise at each stroke, thus keeping the hole clear. Figure **70** shows a plain hand mortising machine, by the Carron Company, from which it will be seen that the timber is gripped in a vice by a handwheel and screw upon an upper slide which can be moved longitudinally by rack and handwheel, and also laterally, while vertical adjustment is produced by screw and handwheel beneath the knee. The spindle, which fits within a sleeve sliding in a hexagon bearing, is reciprocated up and down by the long pivoted lever, counterbalanced to bring the spindle to the top of its stroke automatically. A handle and collar is fitted on the spindle, by means of which it can be rapidly reversed, to make the chisel face round in the opposite direction for finishing both ends of a mortise. A boring attachment is often fitted to hand machines, for preparing holes ready for mortising; the attachment comprises a vertical spindle, carrying an auger, revolved through bevel gears and handle.

Figure **71** gives side and front elevations of a very complete mortiser by John McDowall & Sons, in which the boring spindle is a permanent fitting, set to one side, but in line with the mortising chisel, so that after boring a hole, the timber may be shifted longitudinally to bring it under the chisel stroke. The boring spindle is driven at 800 revolutions per minute by a belt on the small pulleys at the rear, and is fed downwards by pulling on a pivoted lever. The chisel spindle, guided in a circular bearing, is reciprocated by the crank disc at the top, making 300 revolutions a minute. The connection to the spindle is a graduated-stroke device, by means of which the stroke of the chisel is increased by stages, instead of descending the full length at once, with consequent jar. The effect is obtained by a peculiar arrangement of connecting levers, seen clearly in the front view, and brought into play by a treadle. In the normal state with the treadle at its highest, the chisel is stationary, although the

crank-disc is revolving, so that there is no necessity for stopping the latter frequently. A self-acting reversing motion is fitted to the chisel spindle, consisting of a cord driven down from the crank-disc shaft round an idler to a pulley on the spindle; the cord is put into action by touching a handle. In wheelwrights' shops a special attachment is fitted to the table of mortising machines, for cutting the mortises in wheel naves; the latter are held between two headstocks, one of which has a dividing plate, so that the mortises can be pitched out accurately around the periphery. The table is made to cant, in order to cut mortises at various angles.

A peculiar class of tool used for mortising comprises a combination of an auger and a chisel, the former revolving inside the latter, and clearing out the centre of the hole, while the square corners of the chisel finish the angles. This, the *hollow* chisel [72], is used in both vertical and horizontal machines, and is very rapid and neat in its action. The auger, which has a support near the cutting edges of the chisel, draws the chips out of the hole and away through the openings in the side of the chisel. Another remarkable style is the *chain* mortiser, which runs an endless pitch-chain around a sprocket wheel and a plain roller, while the back is supported by a flat bar. Each link of the chain has a tooth formed on it [73], so that as the chain travels it cuts a slot equal to its width. The rate of movement is about 1,500 ft. per minute. The chips are drawn out of the mortise on the rising side of the chain. The work is done with great rapidity, and the tendency to split the wood is not nearly so marked as is the case with a reciprocating tool.

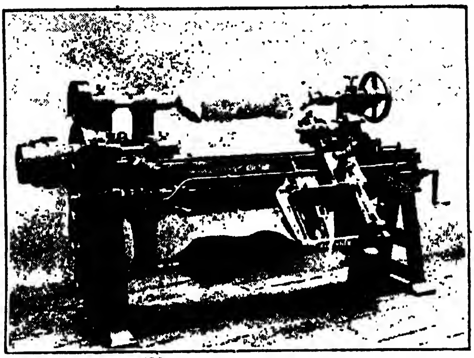
Tenoning Machines. Tenoning is performed by cutter blocks or by tenoning irons. The first-named operate laterally, and the machines which use them have two spindles, above and below the timber [74]—Thomas White & Sons—both driven from a single belt, which is provided with a tightening jockey pulley. The cutter or adze blocks have their irons set on the skew, and have provision for cutting the shoulders on the timber. The timber is clamped to a carriage which runs by rollers on cross-rails. In cutting double tenons, a vertical spindle is required on the machine, to carry a drunken saw, or a narrow cutter-block, which makes the centre cut. *Scribing*, or preparing a shoulder to receive a moulding may be also done with a vertical spindle, running a suitable block. Tenoning can be done on the vertical shapers, employing long-armed tenoning irons, drunken saws, or cutter-blocks.

Boring Machines. These are comparatively simple in construction. Spindles are single, or multiple; the plainest class is the wall or pillar machine [75], which consists of a framing supporting a spindle, a sleeve, mitre gears, belt pulleys, and a lever arrangement for feeding. The self-contained machines include a pillar, on the front face of which the table is adjustable up and down to suit the thickness of the work. The spindle is pulled down in a similar manner to that in 75. The multiple spindle machines embody a number of spindles, each holding a different-sized auger, so that any size hole within the range can be bored without the trouble of changing tools. The railway-carriage and waggon shops especially favour these machines for boring the heavy framings. In some instances, the spindles may

be angled for boring sloping holes. Horizontal boring machines are used to much less an extent than vertical ones, being chiefly designed for small work, such as bor'ng dowel holes in the edges of boards. The augers used in the machines described are of the usual twist types, some of which are illustrated in 41 on page 4481.

Dovetailing Machines. Dovetails are usually cut by revolving cutters, having two lips, and a body the form of which corresponds to the tapered outline of the dovetail. In the single-spindle machines the timber is clamped and moved along in definite stages, controlled by a slotted dividing plate matching the pitch of the dovetails. But a much greater output can be secured by increasing the number of spindles, to cut all the dovetails in one side of a board at one traverse. Armstrong's machine employs two saws, set at certain angles in relation to each other and to the board, which is clamped to a sliding table, fed intermittently. The work turned out on the machine is somewhat rough, though suitable enough for boxes and packing cases.

Corner locking is practised very largely in place of dovetailing, and consists in forming rectangular teeth which interlock and hold very firmly. As the form of cut lends itself to very rapid output, a good deal of box and case work is now corner-locked instead of dovetailed. The machines employed have a table on which the work, which may include a pile of boards, is clamped, and a revolving spindle holding a number of narrow cutters attacks the edges and cuts out the series of notches.



78. COPYING LATHE

Lathes. An ordinary turning lathe is illustrated in the succeeding article on Wood Turning, so that we shall only concern ourselves here with special types, which are designed for repetition work. The *Blanchard* or *copying* lathe produces objects of regular or irregular shape from a pattern or copy. Gun-stocks, spokes, hammer handles, boot lasts, brush handles, etc., are among the chief pieces turned out. The principle is that of rotating the copy, and the work, and causing a roller to press against the copy, thus coercing a rocking rest which carries a revolving cutter head in contact with the wood. The contour of the copy is therefore reproduced on the work. In 78, by Kirchner & Co., Leipzig, an excellent idea of the relation of copy and work, in this case the body of a toy horse, may be gained. The travel of the slide along the bed is effected by a screw operated through friction feed, and reversed automatically at the end of the traverse. The cutters are in the form of thin loops of steel, sharpened to a keen edge.

Back-knife lathes are a class for producing circular work of varied contour, such as chair and table legs, balusters, etc. The tools are held in a rest, and controlled by a pattern; the back knife is held in a frame in a sloping fashion, and the movements of the slide-rest and the knife are timed so that the latter comes down the back of the work and finishes it to correct outline as the roughing tool passes along.

The *rounding* machines perform a plain class of turning by very simple means, comprising a revolving mandrel carrying a cutter, which acts on the stuff, which is simply slid through.

Sand-papering Machines. These include the use of drums, discs, and belts, each suited to particular classes of work. The belts are run over pulleys, which can be drawn apart to give the required tension. Articles having curved outlines are treated on the belts, which give to the conformation and enable curves and hollows to be treated. The drum machines are of two types, one [76]—John McDowall & Sons—with a flat table, over which the work is passed, touching the drum surface. An exhaust fan removes the dust as fast as it is created. The other drum type has three drums, over which the wood is passed by eight geared feed rolls. Each drum has a side oscillating motion to prevent the formation of scratches. A machine by the J. A. Fay & Egan Co., of Cincinnati, O., is shown in 79. Small sanders with vertical spindles are constructed on the lines of the vertical shapers. Disc sanders resemble the disc grinders used by metal-workers, and the work is presented upon a table to the disc. For large areas the *flexible arm* machine is of great value. The sand-paper is strained over a wooden disc, supported at the end of an articulated frame, which, by virtue of its jointing, can be brought anywhere over a large table. The driving is effected by belts from pulleys on the standard to the left [77]—A. Ransome & Co., Ltd.—thence through the jointed portions to the pulley on the disc spindle. A handle allows the operator to feed the disc downwards

MANUFACTURING EXPLOSIVES

The Materials and Processes in the Manu'acture of Gunpowder, Nitro-glycerin, Dynam.te, Blas.ing Gelatin, Cordite, Ballistite, and Guncotton

Continued from page 6620

SINCE its inception until the present day the manufacture of explosives has been associated with the study of chemistry. Whoever may have been the genius that first applied the fireballs of the ancients to the propulsion of projectiles, there can be little, if any, doubt that these early experimenters were among the fore-runners of the modern chemist —the al-chemists. No definite date can be given for the invention of gunpowder, but the first references to its use as a propelling agent date from about the middle of the fourteenth century. From that time onward it spread throughout Europe with great rapidity, as the numerous references to it in early European literature show. Gunpowder at the beginning of the nineteenth century was essentially the same as when first invented. A few slight alterations in the proportions of the ingredients and a little more care in their purification covers the improvement effected. Inventive ingenuity seems to have turned in the direction of firearms, satisfied that the propelling agent was more than sufficient for the work it had to do.

It was not until the middle of the nineteenth century that the series of discoveries was made which revolutionised the explosives industry. In 1845 Sch nbein showed that cotton could be rendered explosive by treatment with nitric acid, and experiments by numerous other chemists soon reduced the discovery to a practical basis. The invention of nitro-cotton was followed in 1846 by the discovery of nitro-glycerin by the Italian chemist Sobrero, and Alfred Nobel, whose name is inseparably associated with high explosives, succeeded in overcoming the difficulties connected with the application of it to practical purposes.

The two essential discoveries on which the whole science of high explosives is founded are those of nitro-cotton and nitro-glycerin. The great majority of the explosives at present on the market under an infinity of names are mixtures in which the principal constituent is one or other of these substances.

Gunpowder. Black powder differs from nitro-cotton or nitro-glycerin in being a mechanical mixture, not a chemical compound. Its ingredients are simply intimately mixed together and are quite inert towards one another until the application of heat causes them to combine chemically, with formation of a mixture of gaseous compounds. It is this rapid chemical action or combustion which, owing to the great expansion due to the formation of gases, causes the explosion. The ingredients—sulphur, saltpetre, and charcoal—are mixed in the proportions which give fairly complete combustion, and, consequently, leave a very small amount of residue. Sulphur and charcoal are both combustible bodies, requiring only a sufficiency of oxygen with which to combine to convert them into gaseous compounds—the oxides of sulphur and carbon. Saltpetre, or potassium nitrate, is a salt rich in oxygen. Under the application of heat the oxygen in the saltpetre is transferred to the sulphur and carbon, with formation of gases. At the same time nitrogen, also a gaseous body, is liberated from the saltpetre, and other complicated changes take place which it is not necessary to detail here.

Saltpetre. Saltpetre is a natural product, found as a crust on the surface of the land in various parts of the world, notably in Bengal. The crude saltpetre is collected and its solution purified by crystallisation—that is, it is dissolved in water, freed from dirt and other insoluble matter, and evaporated by heat, so that the salt crystallises from the concentrated liquor in a purified form. The Government factory at Waltham Abbey, which may be used as a type of a modern explosives factory, refines its saltpetre as follows The vats in which the crude salt is dissolved are fitted with a perforated false bottom, through which solid impurities settle out. Heat is applied, and when the solution boils it is skimmed, and the false bottom, containing the dirt, is withdrawn. When all the scum has been removed, the solution is run through cloth filters into shallow pans, where the crystals separate. During crystallisation the liquor is kept in motion so that the crystals may be small. As they form they are withdrawn from the solution and drained. The crystals are then washed several times with water. The mother-liquors and wash-waters are, of course, worked up with subsequent batches of crude salt.

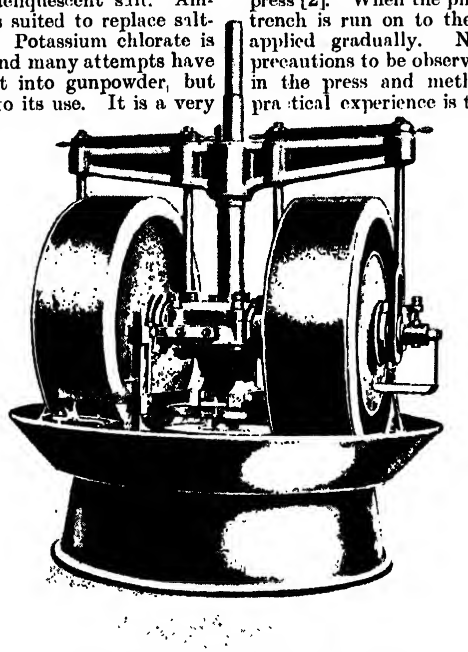
A large proportion of the saltpetre now used on the Continent is prepared artificially, from sodium nitrate or Chili saltpetre, and potassium chloride. These salts are both found native, and by double decomposition they may be converted into potassium nitrate (saltpetre) and sodium chloride (common salt). These salts are then separated from one another by crystallisation, which is rendered possible by their different degrees of solubility in water.

Sulphur. Sulphur, the second ingredient of black powder, is also obtained from the earth, large quantities coming from the numerous mines in Sicily. The crude ore is burnt in heaps, so that the sulphur melts and runs into a receptacle, from which it is drawn off and run into moulds. Before being incorporated into powder it has to be refined. The method in use at Waltham Abbey is substantially as follows. The crude sulphur is introduced into a still which can be closed by a cover. This is in connection with two receivers, one of which is used to collect the vapours before and after the actual distillation, the other to collect the purified sulphur. During the early part of the distillation the vapours are conducted to the former, where they cool in the form of flowers of sulphur. These are collected and re-distilled as crude sulphur. When the vapours from the retort change colour from yellow to purple, they are conducted to the second receiver, which is cooled by water, as is the pipe leading to it. The sulphur condenses in the pipe and runs into the receiver in liquid form. Another source of sulphur, which has come to the front only within recent years, is the Chance process for the recovery of sulphur from the waste-heaps of the soda factories. The sulphur obtained by this process is purified as described above.

Charcoal. Charcoal was formerly obtained by burning wood in large heaps in such a way that it was only partially consumed. This old and extravagant method is now entirely superseded. The wood is subjected to a destructive distillation in closed cylindrical vessels. At Waltham Abbey the plant consists of a large cylinder into which a number of smaller cylinders, charged with wood and closed, are packed. The large cylinder (which is built into a furnace) is heated, the wood is charred and the small cylinders, still closed, are removed while hot, and cooled before they are opened. In this way a great loss of charcoal, due to contact with the oxygen of the air while hot, is avoided. The charring of the wood is also easily regulated.

Within the past century many changes have naturally been suggested in the composition of gunpowder. The use of sodium nitrate as a substitute for potassium nitrate is found unsatisfactory, as the former is a very deliquescent salt. Ammonium nitrate is even less suited to replace saltpetre for the same reason. Potassium chlorate is a salt very rich in oxygen, and many attempts have been made to introduce it into gunpowder, but there are many objections to its use. It is a very dangerous salt to manufacture on account of its great oxidising power and sensitiveness to friction, and powders containing it evolve hydrochloric acid in the gun when fired. The introduction of charred straws to replace charcoal was an important advance, producing a slow-burning powder suitable for large guns, of high efficiency, especially when moulded in the prismatic form, which is described later.

The Grinding Mill. The sulphur, saltpetre, and charcoal are ground to fine powder separately in a grinding mill, which may be of almost any form. In early times the ingredients were mixed, and then ground and incorporated in one operation; but this plan was very unsatisfactory, as the mixture was never sufficiently intimate, and the danger of explosion from friction was much greater. The powdered ingredients are weighed out in the proportions desired, and mixed roughly in a copper drum by means of a revolving shaft fitted with forked arms. Great precautions are taken to prevent any foreign matter, such as scraps of iron, from getting into the charge.



1. INCORPORATING MILL (Fried. Krupp)

The roughly mixed charge—a "green charge," as it is called—is thoroughly mixed in an incorporating mill of the edge-runner type [1], the more modern of which have suspended runners, never actually touching the bed. The runners weigh about four tons, and the largest charge mixed at a time is 50 lb. to 60 lb., depending on the nature of the powder. The charge is spread upon the bed of the mill, and sufficient water added to prevent the material rising as dust, but not enough to cause the powder to cake on the runners. During the mixing, additional quantities of water are added as the early supply is evaporated. The mixing lasts from three hours to six hours, varying with the type of powder. A special drenching apparatus is fitted up, which pours water over the incorporating mill in the event of the ignition of the charge. When the mixing is completed, the powder is in the condition of mill-cake.

Breaking the Mill-cake. This mill-cake is broken to a convenient size by wooden hammers, and then passed through a breaking-down machine, which consists essentially of two pairs of brass rolls. The cake is roughly ground on the upper rolls, and falls through on to the second pair, where it is crushed to a fine powder. The pressing of this powder into a hard cake is now carried out, as a rule, by means of a hydraulic press. Alternate layers, consisting of powder and ebonite plates, are built on top of one another on a trench which runs upon the bed-plate of the press [2]. When the pile is of sufficient height, the trench is run on to the bed-plate, and pressure is applied gradually. Naturally, there are many precautions to be observed, and certain peculiarities in the press and method of manipulation; but practical experience is the best, and is, in fact, the only means of becoming acquainted with the details of the process. The pressure is continued for a time, averaging about half an hour. The trench is then withdrawn, and the edges of the cakes cut off, as they are not pressed to the same density as the body of the cake.

The cake has now to be transformed into the shape of grains. It is first broken to suitable size by means of wooden hammers, and then run through a breaking-down machine and sieved to size. The revolution of the disc breaks down the lumps of cake, which, when they are sufficiently small, fall through the perforations on to a second perforated tray with very small holes, through which the too finely pulverised portion is sifted off. This second sieve may be made of hair instead of being perforated, and the first sieve is often in the form of finely-meshed brass gauze. A number of these granulating sieves, with weighted discs, are connected together for economical working. By passing the grains through sieves of various-sized mesh, the powder may be sorted out into the sizes required for various purposes.

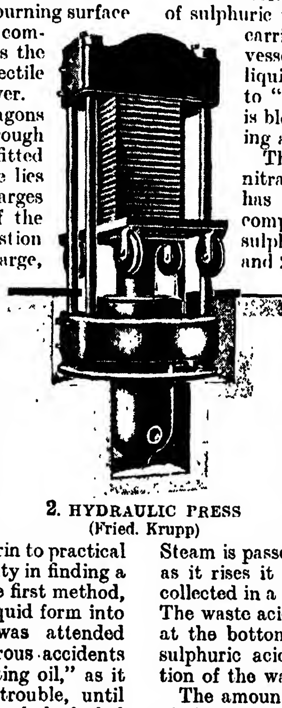
Glazing and Drying Gunpowder. The powder is glazed by being rotated in a drum for some hours, the time varying with the size of the granules. After this it is dried. The drying-room is a large chamber heated by steam, in which trays containing the powder are laid out in racks. The temperature employed varies from 100° to 140° F., and the powder takes from six to twelve hours to dry. When dry, the dust which is present among the grains is separated by rotating the powder for some hours in a closed cylindrical sieve, a small quantity of graphite being added to give a final gloss. The powder is again passed

through sieves of various sizes in a final sorting operation to separate the different sizes of grains. The powder is now finished, and requires only to be blended to be ready for use.

Composition of Gunpowder. The composition of gunpowder varies in different countries, and also in accordance with the purpose for which it is destined; but the most largely used formula, and the one most generally accepted, is: saltpetre, 75 parts; sulphur, 10 parts; charcoal, 15 parts. All other formulæ approximate closely to this.

In addition to ordinary rifle, sporting, and blasting powders, there are many varieties of gunpowder manufactured of which space does not permit description. Compressed powder is, however, of sufficient importance to receive some mention. The object of using compressed powder for large guns is to prevent too rapid combustion at the actual moment of firing. It is desired that the pressure in the gun should be small to begin with, and then rapidly increasing as the projectile nears the muzzle of the gun. By having the powder in blocks with holes through the centre of them—the so-called "prism powder"—a small burning surface is obtained, which increases as the combustion goes on; and as it increases the pressure grows greater, and the projectile is invested with greater carrying power.

Prism powder is made in regular hexagons with a number of holes running through them. These hexagons can be fitted accurately together so that no space lies between in any direction. Large charges are made up by fitting a number of the hexagons together, and the combustion takes place from the interior of the charge, thus giving the required increase in surface. It will readily be seen that did the burning begin on the outer surface, the burning area would be steadily decreasing instead of increasing. The prisms are made by hydraulic pressure, and the composition is practically identical with that of ordinary black powder, except in the case of cocoa, or brown powder, which consists of: potassium nitrate, 79; sulphur, 3; and charcoal, 18.



2. HYDRAULIC PRESS
(Fried. Krupp)

Nitro-glycerin. When Alfred Nobel attempted to adapt nitro-glycerin to practical purposes, he experienced great difficulty in finding a suitable form in which to use it. The first method, that of running the explosive in its liquid form into boreholes, and then exploding it, was attended with great danger, and many disastrous accidents occurred. The carriage of the "blasting oil," as it was called, was another source of trouble, until it was found that the solution in methyl alcohol greatly decreased the liability to explosion. The alcohol was evaporated immediately before the nitro-glycerin was required for use. Even then, however, the disadvantages of a liquid explosive were numerous, and it was not until Nobel succeeded in finding a suitable absorbent that nitro-glycerin became a success.

Nitro-glycerin is a chemical compound, formed by the action of nitric acid on ordinary glycerin. The glycerin used for the nitration is practically pure. It must contain only minute traces of mineral matter, and its ash should be below 0·10 per cent. It is prepared by the distillation of the crude glycerin from the soap and candle factories, and in some cases is purified in the explosive factory. Needless to say, the glycerin is thoroughly tested in the laboratory before being used on the manufacturing scale.

Ingredients in Nitro-glycerin. Although the active agent in the nitration of glycerin is nitric acid, in practice a mixture of nitric and sulphuric acids is used. When nitric acid acts on glycerin, nitro-glycerin and water are formed. As the action goes on the increasing quantity of water rapidly dilutes the nitric acid, with the result that the action slackens and side reactions are set up. To obviate this, some body is required which has an affinity for water, and which will absorb it as soon as it is formed. Strong sulphuric acid is found to be best suited for this purpose, as in the mixture with nitric acid it has no action on the nitro-glycerin. The nitric acid used is, as a rule, prepared in the factory where it is to be consumed, and in come cases sulphuric acid plant has been fitted up. The strongest acids are used, the nitric being of 1·5 specific gravity, and the sulphuric about 1·842. The proportions of the mixed acid vary in different factories, but on the average the mixture is about three-parts of sulphuric to two parts of nitric. The mixing is carried out in large wrought-iron cylindrical vessels supplied with air to agitate the liquids, and the acid is run from them to "moutejus," or "eggs," from which it is blown under high pressure to the nitrating apparatus.

The waste acid—that is, the acid after nitration, from which the nitro-glycerin has been completely separated—varies in composition, but averages 67 per cent. of sulphuric acid, 11 per cent. of nitric acid, and 22 per cent. of water. It is not found to be practicable to make up this waste acid to its original strength, and use it to nitrate a fresh charge of glycerin, so it is subjected to a process of denitration. Various methods are used to separate and recover the acids, and of these the following has been widely adopted. The waste acid, freed from nitro-glycerin, is allowed to percolate from top to bottom of a tower, various devices being made use of to expose as large a surface of the liquid as possible. Steam is passed in at the bottom of the tower, and as it rises it carries away the nitric acid, which is collected in a dilute state in earthenware receivers. The waste acid, freed from nitric acid, is collected at the bottom of the tower, and consists of dilute sulphuric acid, which is concentrated by evaporation of the water from it.

The amount of acid required to nitrate one part of glycerin varies in different works, but is usually from seven to eight parts, and the yield of nitro-glycerin is from 200 per cent. to 220 per cent. of the glycerin used.

Nitrating Apparatus. The first operation in the actual manufacture is the nitration. For convenience of working, the whole plant is arranged so that at the conclusion of each operation the nitro-glycerin may flow downwards to the building in which the next stage is carried out. Thus, the nitrating house is, if possible, situated at the summit of a small hill. If such be not available, the buildings are arranged artificially one above another. In any case the plant is usually known as a "hill." The nitrating apparatus [3] consists of a large lead-lined tank, in the interior of

which are a number of lead coils, through which cold water flows during the nitration, the object being to keep the temperature down. At the bottom of the tank is a perforated lead pipe, for the admission of air, to keep the contents in a continual state of movement. A lead cover is fitted over the tank, perforated with a small hole through which the thermometer bulb passes down into the acid, and with a large hole connected with a pipe to carry off the acid fumes to a condensing apparatus. Several thick glass windows, L, circular in shape, are inserted in the cover, so that the contents of the tank may be observed. There is an inlet pipe for the mixed acid, and another for the glycerin, the latter being sometimes sprayed in by means of an air-jet. At the bottom of the tank is an outlet pipe through which the charge is run off when the nitration is finished. During the nitration the outlet pipe is invariably in connection with a large tank of water called the " drowning tank," so that in the event of any abnormality in the nitration the whole charge may be drowned by the turning of a cock.

Working the Nitrating Apparatus. The mixed acid is weighed out and run into the nitrating apparatus. When the man in charge is satisfied that everything is in order, he turns on the air pressure so that the acid is kept in continual movement. Meanwhile, the weighed quantity of glycerin (from 700 lb. to 900 lb.) has been run into a small tank M, at some height above the nitrator, and connected to it by a pipe. In winter it is necessary to have the glycerin slightly warmed, so that it will pass readily through the injector. The glycerin is now added in a thin stream, the man in charge of the operation keeping his attention continually fixed on the scale of the thermometer, where a red line at the figure 22° C. denotes the point above which the mercury must not be allowed to rise. In Germany and other Continental countries nitration is carried out at from 25° C. to 30° C., but in Great Britain 22° C is the usual limit. By regulating the flow of glycerin, and the supply of water to the coils, the temperature can be maintained constant to a degree during the nitration.

The Separating Tank. When the whole of the glycerin has been added, the charge is allowed to remain in the nitrator until the temperature falls to about 17° C. The outlet pipe is then disconnected from the drowning tank, and connected to the separating tank in the building below—the separating house—and the whole charge run into this tank. The separating tank varies in construction according to the method of separation used. In this country the nitro-glycerin is usually skimmed by hand, and the tank is a lead-lined rectangular apparatus whose bottom slopes towards one end, where the outlet pipe is situated. In this tank the charge remains until the nitro-glycerin has all risen to the top. This takes from 1½ to 2½ hours. The nitro-glycerin is skimmed off by means of an aluminium skimmer, shaped like a soup-plate with a handle over the top. As it is skimmed it is poured into a sloping trough, from which it runs through a lead pipe to the tank in which it receives its first washing, to remove the greater part of the acid from it—the " pre-wash tank." When all the nitro-glycerin has been removed by skimming as far as possible, the charge of waste acid is run out of the separating tank and conducted to a large building filled with lead vats. These are filled up with the waste acid and the latter allowed to rest for some days so that the last of the nitro-glycerin may rise to the top. The vats, which are wide at the base, taper at the neck, so that the small quantity of nitro-glycerin may be readily skimmed off with a dipping ladle, or this process of after separation may be obviated by the addition of small quantities of water to the waste acid, which prevents further formation of nitro-glycerin, and permits of immediate denitration of the acid (patent, Nathan, etc.).

Meanwhile, the main body of the nitro-glycerin, which has been skimmed in the separating house, is subjected to a preliminary washing with dilute sodium carbonate in a tank situated in the separating house.

Washing Nitro-glycerin. The nitro-glycerin is now run out of the pre-wash tank through a series of pipes or covered gutters (the latter being often preferred, as they are more easily cleaned in case of stoppage) to the wash-tank in the washing-house. The wash-house contains large tanks each capable of washing about a ton of nitro-glycerin. At the back of this building is a small shed in which the solutions of soda are made up and heated by steam. The sodium carbonate solution and hot water are run into the washing-tank and mixed by air pressure with the nitro-glycerin, the temperature of the whole not exceeding 30° C.

After fifteen minutes' agitation with the soda, the air supply is shut off, and the soda rises to the top. A few minutes are allowed for the separation of the soda, and it is then skimmed off, or run off by means of rubber tubes situated at different levels in the tank, so that the top layer may be completely removed without loss of nitro-glycerin. The washings with soda are repeated three or more times until purification is complete. In early work with nitro-glycerin many of the serious accidents were due to the presence of traces of acid in the explosive. Slight decompositions set in and the nitro-glycerin gradually became very unstable.

To free the nitro-glycerin from sodium carbonate, one or more water washes are given after the soda has been drawn off.

The Process of Filtering. As a rule, the nitro-glycerin is weighed off in the washing-house. From the wash tanks it is run into a reservoir tank through a filter, which renders it clear in colour, removing the minute particles of water with which it is mixed. The filter consists of a cloth filled with dry common salt or sponges. Below the reservoir tank stands a weighing machine, or measuring vessels may be used to avoid this. Boxes are brought in containing the weighed quantities of the other ingredients of the explosives. These are placed upon the weighing machine, tared carefully, and the requisite amount of nitro-glycerin weighed in. The boxes are then removed from the platform of the machine, and the nitro-glycerin mixed roughly with the solid ingredients by hand. This obviates the difficulty of conveying the nitro-glycerin from place to place in the liquid state, a proceeding which is fraught with some danger.

Throughout the whole of the operations described above great precautions are taken to avoid all chances of explosion. The clothes of the men engaged in the manufacture are made specially for them, and are without any metal buttons. Pockets are also forbidden, so that there may be no temptation to bring unauthorised articles into the danger area. At the door of each building rubber shoes are put on over the boots, so that no grit from outside may be brought into the buildings. The Government and factory regulations are posted prominently in every building, and they are read over to the men by their foreman at frequent intervals.

Dangers of Nitro-glycerin. Of all explosives, nitro-glycerin is the most dangerous to handle and manufacture. It will readily be seen that a liquid is less easily removed entirely when the vessels containing it have to be cleaned out. In the case of a spill, also, it is extremely difficult to clean up the last traces. At one time, the floors of all buildings in which nitro-glycerin was used were composed of fine sand, which was frequently changed; but the advantages accruing from this plan were more than neutralised by the danger of grit getting into the apparatus.

In winter, the liability of nitro-glycerin to freeze is a source of much trouble. The buildings are kept heated by steam heaters, but the pipes and gutters connecting the buildings are very apt to be frozen up in the morning when work is due to begin, notwithstanding all precautions. Nitro-glycerin solidifies at 80° C., so that in even moderately cold weather this trouble occurs. Unfortunately, also, in the solid state, it is much more dangerous to handle. Thus, the mere fracturing of a crystal has been known to cause explosion. Strangely enough, if proper precautions are taken, nitro-glycerin may be cooled far below its ordinary freezing-point without becoming solid; but the least shaking of the liquid, or the addition of a small crystal of solid nitro-glycerin is sufficient to cause it to solidify suddenly. This is the phenomenon of super-cooling. The only safe method of thawing nitro-glycerin is by means of warm water, but this will be referred to in detail later.

Medicinal Use of Nitro-glycerin. Nitro-glycerin has a very strong action on the heart, and is used medicinally in infinitesimal doses in cases of *angina pectoris.* The novice, on entering a building where the manufacture is being carried on, is seized with a violent throbbing of the head which develops into a bad headache, lasting throughout the remainder of the day. In bad cases, sickness, with violent vomiting, occurs. These symptoms are most marked when the explosive comes into contact with the skin, as it is absorbed through the pores and thus enters the system. In a few weeks most of the workers become quite inured to nitro-glycerin, and though their arms may be soaked in it above the elbow, they suffer no ill effects. Should they be away for a week or two, however, on returning to work they are again subject to headaches. There seems to be no permanent ill effect to the workers, as they appear as healthy as workers employed in any other class of labour.

When pure, nitro-glycerin is colourless, but the commercial variety is generally slightly yellow. It is without smell, and has a sweetish taste. It is soluble in benzene, ether, alcohol, and other organic solvents, but insoluble in water. A drop of nitro-glycerin explodes when struck with a hammer on an anvil. When the liquid is heated in any quantity, it explodes at about 180° C., though very small quantities have been raised to much higher temperatures without detonating. Of course, combined heating at much lower temperatures (below 100° C.) gradually decomposes nitro-glycerin, and it explodes with violence.

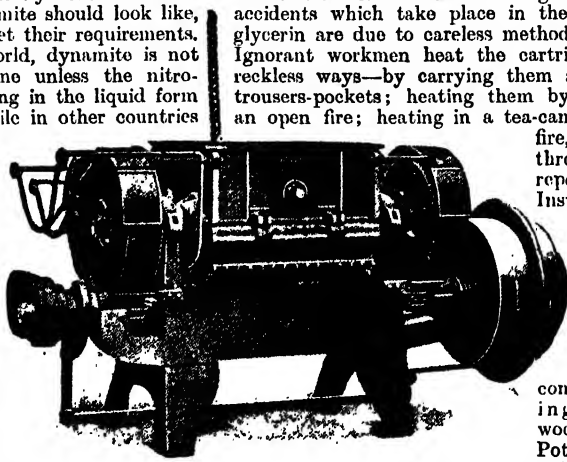
Dynamite and Other Nitro-glycerin Explosives. As stated above, it was found that the use of nitro-glycerin in the liquid state was too dangerous, and it became necessary to find some means whereby it could be obtained in a more suitable form. The attention of Nobel, among other investigators, turned to the discovery of some substance with which it could be mixed to give a plastic mass which could be easily handled, and which would at the same time retain the explosive properties of nitro-glycerin. Amongst the early attempts may be noted that of mixing the liquid with black gunpowder and filling the cartridges with the mixture. Alfred Noble discovered the suitability of kieselguhr for the purpose, and the explosive made with its aid is used in large quantities to the present day.

Kieselguhr is an infusorial earth, made up of the shells of minute diatoms. It is found in some parts of Germany, and in the north of Scotland, near Aberdeen. The earth varies very much in appearance, that found in Germany being almost pure white, while Scotch "guhr" is dark grey, almost black. As found in nature, kieselguhr contains a large proportion of organic matter, which has to be burnt off before the earth is used. It may either be piled in heaps and burned — which process takes some days—or roasted in furnaces. When calcined in this way, kieselguhr is usually of a salmon-pink colour, and very light and impalpable. Under the microscope it is seen to consist of innumerable minute structures of many different shapes. The source of the guhr may often be told by an examination of the structures. The latter are hollow or tubular, and are capable of absorbing a large quantity of nitro-glycerin. Dynamite usually contains 25 parts of guhr to 75 parts of nitro-glycerin, and is only sufficiently moist to adhere when pressed.

Preparing Dynamite. Dynamite is prepared almost entirely by hand. The kieselguhr, after it has been calcined, is ground in a mill, and then weighed out in suitable quantities. Considerable care has to be taken with the grinding. It is necessary to break the calcined lumps to powder, but if the milling be carried on over long, the structures of the shells will be broken down and the absorptive power of the guhr greatly decreased. Thus, samples calcined and mixed with nitro-

glycerin in the laboratory show an absorption greater by several points per cent. than the same guhr calcined and ground on the larger scale. The weighed quantities of guhr are placed in large wooden boxes with brass fittings, and conveyed on trucks to the wash-house where the nitro-glycerin is stored. The necessary amount of the latter is weighed in and the box removed from the weighing machine to a bench, where a workman, with sleeves rolled up to the shoulder, roughly mixes the ingredients with his hands. This rough mixing is given in order that the nitro-glycerin may not be lying in pools in the box during its conveyance from the wash-house to the mixing-house. The boxes are again placed on a truck, and taken to the mixing-house, where the dynamite is thoroughly mixed. A small quantity (usually about ½ per cent.) of sodium carbonate is added, and uniformity of composition is obtained by repeated rubbing by hand through brass sieves. The consistence of the dynamite is of great importance. As it is mostly used by miners, who have their own ideas—mostly without foundation—as to what good dynamite should look like, it has to be prepared to meet their requirements. Thus, in our part of the world, dynamite is not thought worthy of the name unless the nitro-glycerin may be seen exuding in the liquid form on the cartridge paper; while in other countries an exudation such as this is considered a proof of inferiority. The manufacturer must consider these prejudices, and bear in mind the destination of a batch while it is being made, so that he may regulate the proportions. As a matter of fact, the slight difference in proportion required to change the dynamite from dry to damp will make little if any difference on its explosive power.



4. EXPLOSIVE MIXING MACHINE
(Werner, Pfleiderer & Perkins, Ltd.)

Making Dynamite Cartridges. When mixed and sieved, dynamite is a chocolate-coloured, soft, mealy material, and is ready to be pressed into cartridges. This operation is generally carried out in a machine worked by hand. A funnel-shaped cavity tapers at the bottom into a brass tube the diameter of the cartridge which it is desired to make. A plunger with a brass, or preferably a hard wood, head, works up and down in the funnel, pressing the dynamite with which the latter is filled through the tube. The plunger is worked by a lever handle at right angles to it. The handle is pressed down, carrying the plunger down through the funnel, and by means of a spring it rises ready for the next stroke. The operator rolls a cartridge paper round the tube at the bottom of the funnel, folds in the ends, and presses down the lever several times until the paper is filled. The cartridge is then removed from the machine, the upper end of the paper folded in, and the operation is finished. A considerable amount of practice is required in order to know just how much pressure to apply with each stroke of the plunger. Too great pressure forces the dynamite into a solid lump and causes the nitro-glycerin to exude on to the cartridge paper.

The earlier forms of this machine were very unsatisfactory. The loose dynamite worked its way into the joints of the machine, and in the course of time a bearing heated, or a sharp tap of metal on metal caused the explosive to fire. Immediately the whole stock in the building flared up and the occupants were lucky if they escaped with their lives. So many modifications and improvements have been introduced that the machine is now almost entirely without danger to the operator. As a rule, several cartridge machines are fitted to the walls of a small wooden hut, which is isolated—as are all explosive buildings—by high banks of earth or sand.

Disadvantages of Dynamite. The great disadvantage of dynamite in practical use is its liability to freeze in winter. When frozen, it is as hard as stone, and an attempt to insert a detonator into the cartridge would be not only difficult, but highly dangerous. Consequently, dynamite must always be thawed in winter before use, and the only safe method of thawing it is to place the cartridge in a warming-pan, which is a water-jacketed pan, within the double walls of which water at 60° C. is contained. A great many of the accidents which take place in the use of nitro-glycerin are due to careless methods of thawing. Ignorant workmen heat the cartridges in many reckless ways—by carrying them about in their trousers-pockets; heating them by placing near an open fire; heating in a tea-can over an open fire, etc. A glance through the annual report of the Chief Inspector of Explosives would furnish many such instances.

There are many modifications of dynamite on the market, containing such ingredients as wood-pulp, etc. Potassium nitrate, sodium nitrate, ammonium oxalate, and other salts are incorporated with other modifications, each being used to gain some special advantage for the explosive.

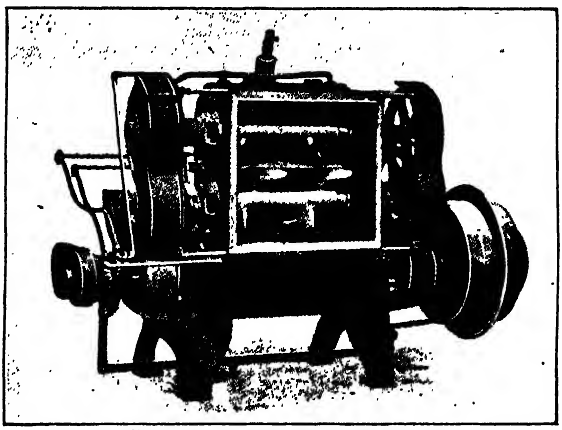
Blasting Gelatin. The invention, by Nobel, of blasting gelatin greatly reduced the consumption of dynamite. He found that by mixing nitro-glycerin with collodion cotton, a weakly nitrated cotton soluble in ether alcohol, and heating the mixture, a homogeneous gelatinous mass was obtained, which possessed great advantages over any existing explosive. Roughly speaking, the proportions of the mixture are about 90 parts nitro-glycerin to 10 parts of nitro-cotton, but the quantities vary with different makers. The nitro-glycerin is added to the nitro-cotton in the wash-house, and mixed there roughly, as mentioned above. The mixture is conveyed to the gelatin house, where it is heated in a copper or brass pan, by means of a water-jacket, to a temperature of about 45°—50° C. The pan is fitted with stirrers which keep the mass in movement. Specially modified Werner and Pfleiderer mixers [4 and 5] are generally used. A batch of blasting gelatin is mixed and gelatinised in about an hour.

The solid gelatinised mass is cut into smaller lumps and carried to the cartridge-making huts, which differ from the dynamite huts in the cartridge

machines used. The machine is practically an ordinary sausage machine. It consists essentially of a spiral working within a cover. The gelatin is placed in a small hopper and the first coil of the spiral catches it and carries it along towards the nozzle, from which it appears in the form of a long continuous sausage. The whole machine is made of brass, and the spiral is actuated by a shaft turned by hand. Nozzles of different sizes can be fitted to the machine, according to the size of the cartridge desired. The continuous gelatin sausage is cut into suitable lengths by means of a wooden hinge, the lengths are rolled in paper, and the cartridges are ready to be packed.

There are many modifications of blasting gelatin, just as there are of dynamite. The method of manufacture is, however, essentially the same. The best known of these are gelatin-dynamite and gelignite, the former being a blasting gelatin containing a certain proportion of wood-pulp, and the latter containing wood-pulp and potassium nitrate. These ingredients are incorporated with the explosive during gelatination. Other gelatin explosives are manufactured, containing ammonium oxalate.

Cordite. Cordite, which was patented by Sir F. A. Nobel and Professor Dewar, is also a gelatinised mixture of nitrated cotton and nitro-glycerin; but in this case the cotton used is guncotton, the most highly nitrated cotton. The mixture cannot be gelatinised simply by dissolving the guncotton in nitro-glycerin, as it is not soluble. Consequently, some medium is required to render the gelatinisation possible, and for this purpose acetone is used. The guncotton and nitro-glycerin are mixed together in the required proportions (cordite as originally used consisted of 58 per cent. of nitro-glycerin, 37 per cent. guncotton, and 5 per cent. vaseline), and acetone is added and hardened into the mass. To this, after about 3½ hours mixing, the correct amount of vaseline is added, and the whole mixed for 3½ hours more in a Werner and Pfleiderer mixing machine. When the mixture is thoroughly gelatinised, it is removed to the press-house to be formed into the cords in which it is used. For this, hydraulic pressure is required, and special presses have been designed to meet the requirements. The soft gelatin is placed in a steel cylinder and pressed by a tightly-fitting plunger through a hole situated at the other end of the cylinder. As the cords are pressed out, they are rolled upon reels and removed to a drying-house where the acetone is evaporated. Large sizes of cordite are not reeled up, but are cut to the required length at once and dried in trays. The temperature at which drying is carried out is about 100° F. Recently, the composition of cordite has been altered, and the new explosive is known as "Modified Cordite." The process of manufacture is, however, essentially the same.



5. EXPLOSIVE MIXING MACHINE
(Showing trough tilted)

Ballistite. Another smokeless powder similar to cordite in some respects is *ballistite*, the invention of Alfred Nobel. It is composed of 50 per cent. of soluble nitro-cotton and 50 per cent. of nitro-glycerin. In this case the soluble cotton will not dissolve directly in the nitro-glycerin, as it does in the case of blasting gelatin, as the proportion of nitro-cotton is too great. Consequently, a solvent is used as with cordite, in this case, benzene. In many respects the process of manufacture is similar to that of cordite, but the form of the finished explosive is different. The gelatinised mass is pressed through heated rolls and emerges in the form of a thin sheet, which is cut up by another machine into small squares.

Nitro-cotton. The principle of the manufacture of nitro-cotton is the same as that of the manufacture of nitro-gylcerin—namely, the treatment of the substance to be nitrated with strong nitric acid. Here, also, a mixture of nitric and sulphuric acids is used, with the object of removing the excess of water formed. The cotton used is received in the explosive factory in large compressed bales. It is the waste from the cotton mills. Before it can be nitrated it must be subjected to a preliminary purification to free it from dirt, grit, oily matter, etc., and to get it into a suitable state of division for nitration. It is then placed in stoves and dried at about 100° C., being withdrawn from the stoves and weighed just when required for use.

The great difference between the nitration of glycerin and cotton lies in the fact that the former, on treatment with nitric acid, always — with one exception—gives the same product—tri-nitro-glycerin; whereas cotton gives a whole series of nitro-derivatives according to the constitution of the acid mixture. Guncotton is the compound in which the greatest amount of nitration has taken place, six molecules of nitric acid being combined with two molecules of cotton. Other nitro-cottons have been isolated, containing five, four, three, and two nitro groups. Soluble cotton or collodion cotton is a mixture of these lower nitrated cottons. It is used in the manufacture of blasting gelatin, and also in many other industries. Nitro-cotton of a very low degree of nitration is used for the manufacture of articles of the celluloid class. When very slightly nitrated, its liability to explosion is slight, though it is still highly inflammable. In the following description of the method of manufacture we shall consider guncotton, the most highly nitrated cotton, to be the variety under treatment.

The mixed acid used is prepared as described under Nitro-glycerin. It consists, on an average, of one part of nitric acid to three parts of sulphuric acid, both being highly concentrated. A very large excess of mixed acid is required, compared to that actually taken up by the cotton. As a result, the waste acid is still fairly strong, and is made up to its former

composition by adding more strong acid, and used again for another batch of cotton.

Manufacturing Guncotton. As a typical example of the manufacture of guncotton, the main lines of the method employed at Waltham Abbey may be followed, although it must be remembered that each factory has its own peculiarities. The years that have been spent on the investigation of nitro-cotton have produced much information, a great deal of which has never reached beyond the works in which it originated.

Quantities of dried cotton of about 1¼ lb. weight are dipped into a tank or "dipping-pot" containing a large excess of mixed acid. The mass is removed with a large pronged fork as soon as it is soaked with acid, and placed in small earthenware jars shaped like ordinary pails and having earthenware covers. The cotton soaks up about eleven times its own weight of acid in the dipping-pot, and is allowed to retain it in the earthenware jar for about twenty-four hours. A large number of these jars are placed on a tiled floor or pit, a little lower in level than the surrounding floor, so that water may circulate round the jars and keep the temperature down. Even with this precaution there is some danger of the acid cotton "fuming off." One of the jars may become overheated, and rapid decomposition takes place, with liberation of great volumes of brown fumes. The decomposition spreads to other jars, and unless the area affected is isolated at once, decomposition may become general. The men in charge immediately remove the pots in the neighbourhood, and allow those which have fumed off to die down. No explosion takes place, the only danger being from the fumes which are generated and affect the lungs.

Treatment After Nitration. When the nitration is completed, the contents of the jars are emptied into a centrifugal machine, the basket of which is made of finely perforated wrought iron. The transference from the nitrating jars to the centrifugal is as rapid as possible, as it is desirable that the nitro-cotton should not be in contact with the air while it contains a large proportion of acid. Even while in the centrifugal, fuming-off or firing is not at all uncommon. When the basket is charged with acid cotton, the centrifugal is set in motion and the excess of acid is forced out through the perforations. When this operation is completed, the nitro-cotton is removed as quickly as possible from the basket and put under water in a wash tank. Fresh water flows through the tank, loss of nitro-cotton being prevented by a sieve over the outlet pipe. The continuous changing of the water, and the agitation and pressing caused by the paddle-wheel, remove the excess of acid from the cotton. When it is at last neutral to litmus paper the excess of water is removed in a centrifugal machine. Although the nitro-cotton after this preliminary washing is apparently free from acid, it has been found that this is far from being the case. In the early days of nitro-explosives numerous decompositions accompanied by explosion took place when guncotton was stored for any length of time. Sir Frederick Abel was the first to point out the reason of this. The fibres of the cotton are hollow, and at the end of the nitration are filled with acid. It was found that no amount of washing was sufficient to remove this acid completely, and until Sir Frederick Abel proposed the disintegration of the fibre, nitro-cotton was a highly dangerous body in practice.

Before pulping, however, the guncotton is boiled for some time in large wooden vats. The vats are filled with guncotton and water, steam is passed in from below, and the boiling continued for a varying time, as much as three to four days being sometimes given.

Purifying and Drying Guncotton. As mentioned above, it is necessary to destroy the tubes of the cotton fibres before the purification can be complete. This is done in the pulping machine [6]. A revolving drum, the circumference of which is fitted with knives, rotates in a trough. At one part of its course is a set of closely-set knives, between which and the knives of the drum the guncotton is crushed and cut. The trough contains a quantity of guncotton in water, and as the drum rotates it carries part of the guncotton round to the fixed set of knives. The space between the rotating knives and the fixed set can be regulated, so that it is comparatively large towards the beginning of the pulping, and is decreased as the operation goes on. The water in the trough may be changed continually as in the preliminary washing, or the pulping may be carried out with one water, and the pulped cotton washed afterwards with repeated quantities of warm water. When the pulping and washing are finished, the guncotton should be perfectly free from acid. Samples are drawn from it, and the "heat test" is applied. The guncotton must now stand the test for the regulation time. The excess of water is removed by again centrifugalising or by a moulding machine, this time a flannel cloth or bag being placed inside the basket of the machine, as the guncotton is in such a fine state of division that ordinary perforations would not keep it back. If not required for immediate use, guncotton is usually stored wet. As it comes from the centrifugal it contains from 25 per cent. to 30 per cent. of water, and it is stored in closed boxes until required.

The drying of guncotton is carried out in a building with a lead floor and zinc-lined walls. It is fitted with racks for the trays on which the explosive is to be placed. Great care is exercised to prevent grit of any kind from getting into the building. Heat is supplied by blowing in hot air, and the temperature is kept at about 40° C. Guncotton is not usually dried until it is required for incorporation with the other ingredients of the explosive to be made, as it is so much more safely stored wet.

Compressed Guncotton. A very large proportion of the guncotton manufactured is used in the form of compressed slabs. In making compressed cotton the drying described above is not carried out. Guncotton is uniformly mixed with pure water, when the exact weight required for the slab has been weighed out, by means of a stirring arrangement. This wet cotton is placed in moulds, in which the required slab is shaped, and a large part of the water pressed out. The pressure at this stage is usually applied by hand, and the slab, though of the correct shape and area, is still about three times the weight required, after it has been moulded. In order to reduce it to the right thickness and the desired solidity, hydraulic pressure is necessary. The pressure used is very similar to an ordinary hydraulic press, capable of exerting a pressure of from 7,000 lb. to 15,000 lb. to the square inch, but has certain slight modifications. The finished compressed slabs, if required for building up charges for mines, etc., must be of a smooth surface so that they will fit closely together. In order to get the surface smooth and even, the slabs have to be planed, filed or turned, as their shape makes convenient. The compressed cotton should contain at least 30 per cent. of water in order that this trimming may be done safely, and the surface coming in contact with the tool must be kept cool by a constant application of cold water. When

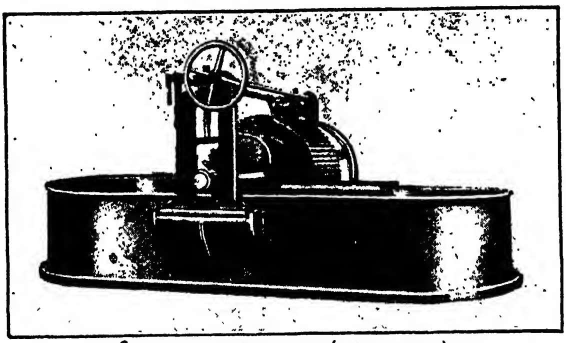
slabs are required with holes through them too small to be conveniently made under the press, they are drilled out in the ordinary way, heating being prevented by means of cold water

Collodion Cotton. The manufacture of collodion cotton, or soluble cotton, depends for its success greatly on the proportions and strength of the acid mixture. The process of nitrating and washing is the same as for guncotton. The proportion of the acids averages about 50 parts of nitric to 50 parts of sulphuric, and more water is present, but the time during which the cotton is allowed to remain in contact with the mixed acid is much shorter than in the case of guncotton.

There is no difference in appearance between cotton fibre and nitrated cotton fibre. Of course, after the fibre has been destroyed in the pulping machine the nitro-cotton loses its characteristic appearance, and on drying is a fine soft white dust. Wet guncotton is not considered an explosive, and the rules and regulations regarding explosives do not apply to it until it is dried. Thus the buildings in which it is stored while wet do not need to be isolated like nitro-glycerin buildings. The drying-rooms or stores, however, into which the cotton goes wet, to come out again dry, are considered as explosive buildings, and arranged accordingly.

Other Nitro-bodies. Many other substances have been experimented with, with a view to forming explosive nitro-derivatives, and a number of such compounds are actually in use. Picric acid, which is the tri-nitro derivative of phenol, or carbolic acid, is the most important of these. It is formed from phenol by first forming a compound of the latter with sulphuric acid and then precipitating the phenol-sulphuric acid by means of nitric acid. The picric acid thus formed must be washed free from sulphuric acid. Picric acid is a bright yellow crystalline solid which has a very bitter taste, and is slightly soluble in cold water, and more readily in hot water. It was long used as a dye before its explosive properties were discovered. Its principal application in the explosives industry is in the manufacture of the French explosive, melinite, and the British lyddite. In its original form, melinite consisted of 30 per cent. of guncotton and 70 per cent. of picric acid, but it is stated to be greatly altered. The composition of lyddite is not generally known, but it is stated to be picric acid melted, and run into moulds, together with an oxidising agent.

The nitro-derivatives of benzene and its homologues are also used in the preparation of explosives. They are not so highly explosive as nitro-glycerin or nitro-cotton, but in combination with oxidising agents they are frequently used. Thus roburite is a mixture of di-nitro-benzol with ammonium nitrate. Another such explosive is composed of nitro-toluol and potassium chlorate.



6. PULPING MACHINE (Fried. Krupp)

Detonators. A considerable industry connected with explosives is that of making percussion caps [see page 6618] and detonators. The detonators now used for exploding charges in mines, etc., may be said to be simply very large percussion caps. Mercuric fulminate is the substance always employed. It is prepared by acting on 1 part by weight of mercury with 10 parts by weight of nitric acid (Sp. gr. 1·4), the solution heated and 8·3 parts by weight of methylated spirit added. The fulminate settles in crystals, which are thoroughly washed. Still in its wet state the fulminate is taken to drying-rooms, where it is spread on the topmost of a series of layers of cloth, which cover a steam-heated copper table. The water is driven off at a low heat, and when cool the fulminate is taken to the mixing-room, where it is mixed with 25 per cent. of chlorate of potash.

The detonator factory, for its size, occupies a good deal of ground, the huts being placed widely apart, and surrounded with high brick walls or mounds of earth. The detonator tubes are made of drawn copper, and vary in length from 1½ in. up to 6 in. The average diameter is about the thickness of an ordinary lead-pencil. The tubes are filled into plates containing one hundred, and are charged with the mixed fulminate. The fulminate is subjected to pressure sufficient to reduce its bulk to one-half its loose state. The detonators are then cleaned and packed in boxes containing sawdust. Fulminate of mercury is an extremely sensitive substance, a scratch with a pin being sufficient at times to explode it. These detonators in use are ignited by means of safety fuses, or by means of electricity. Safety fuses are simply a train of gunpowder contained in a tube of fabric covered with a more or less water-resistant material such as pitch. Electric fuses are made on two systems, which have been named High and Low Tension. The former consists of a readily ignitable mixture covering the ends of the wires, which are fixed in the detonator tube in close proximity to the fulminate. The latter consists of a bridge of fine platinum wire connecting the ends of the two wires and surrounded by a fine dry guncotton. When a current of electricity is passed over the wire it sets fire to the combustible substance, which in turn ignites the fulminate, and this, being placed within or in close contact to the charge of explosive, detonates the latter.

There are six factories in Great Britain engaged in the manufacture of dynamite and blasting powders generally; twenty-two factories for making nitro-compound explosives (dynamite, guncotton, smokeless powders); fourteen factories for making fuses and fog-signals; and in the aggregate the number of factories authorised for the manufacture of all kinds of explosives was 150 in 1902.

ARMS AND AMMUNITION *concluded*

DYEING IN VARIOUS INDUSTRIES

The Dyes Used and the Processes in Dyeing Stone and Marble, Sand, Horn, Ivory, Bone, Mother-of-Pearl, Celluloid, Glue and Soap

By HERBERT ROBSON

Dyeing Marble and Stone. Marble and stone in general have no combining powers for colouring matters of any kind, whether mineral or organic. The mineral pigments are always inorganic compounds of great stability, a circumstance to which they owe their pre-eminence in the matter of fastness, but which renders them inapt to take part in further chemical action after their formation.

Mineral pigments, however, can be formed in the outer layers of the article to be dyed, but they are not much used for marble dyeing. This is to be regretted as, although they give a little more trouble than the coal-tar dyes, they produce excellent results and at the same time greatly increase the durability of the stone and its resistance to weather. The particles of colouring matter deposited in the manner to be presently described in the very substance of the stone materially assist the natural cement present in giving strength to the mass, and in resisting the penetration of water and other destructive agents.

The only way to colour a stone is to form the pigment in the stone by soaking the mass first in one solution, and then in another, which by reacting chemically with the first will produce the pigment desired. For instance, the successive use of potassium ferrocyanide and ferric-chloride produce a blue. The use of solutions is, however, attended with considerable practical difficulties. In close-grained stones, such as marble or hard limestone, penetration is difficult, and when the second solution is employed the first portions of pigment produced are near the surface of the stone and hinder the penetration of the second liquid. The secret is to employ liquids which produce pigments of great body so that even a thin deposit just below the surface will give a sufficient colour.

Mineral Dyes for Stone. In this way satisfactory yellows can be got with chromate of lead, greens with arsenite of copper, blues with ferrocyanide of iron, and reds with iodide of mercury. The solutions must be used diluted and as hot as possible so as to secure penetration. The work is difficult and requires a good deal of practice, as the strength of the solutions, the necessary temperature, and the time to be expended vary within wide limits even with two specimens of the same kind of stone.

Solutions of verdigris in alcohol give a good green to stone, but a better vehicle for the verdigris is melted wax. When this is employed the verdigris must be as finely ground as it is possible to get it. When this precaution has been taken very good penetration is secured, and the wax has the advantage of assisting in the subsequent polishing of the stone.

An excellent yellow can be dyed on stone with an ammoniacal solution of auramine. The penetration is fairly good and the colour is very fine. Weber's method of dyeing stone, and especially marble with iron, deserves mention. The marble is painted over with tincture of steel as sold by the druggists (an alcoholic solution of ferric chloride). It is then dried and put in a damp place. The iron salt decomposes and ferric oxide and basic salts are formed in the body of the stone and colour it yellow. Permanganate of potash is an excellent brown dye for stone and gives extremely good penetration.

An excellent mineral black can be obtained by soaking the stone in an alcoholic solution of corrosive sublimate. The solution is applied hot with a brush till no more is absorbed. The stone is then wiped and enclosed in a chamber in which it is exposed to the action of sulphuretted hydrogen. The gas penetrates in a way which no liquid can do and forms black sulphide of mercury in the pores of the stone. It only remains to mention that acid liquids must not be applied to marble or limestone as they react chemically with the stone.

Natural and Coal-tar Dyes on Stone. As regards natural dyes, logwood and red wood are used, and to a less extent cochineal, dragon's blood, and gamboge. These are used by repeatedly painting the stone with a hot solution in methylated spirit of the dry extract obtained from the dye-substance. The painting is repeated, drying the surface after each application until the desired depth of tint has been obtained. Aqueous solutions of the extracts can be used for cheap work but they give hardly any penetration. Subsequent heating of the dry stone increases the fastness of the colour, but may make the shade somewhat paler, in which case some more tincture must be applied with the brush. Gambier and annatto answer well for brown, used in alcoholic solution.

The coal-tar dyes are largely used for marble and stone dyeing. Any coal-tar colour can be employed which will dissolve either in spirit or in fat. The penetration is aided by heat. It is clear that colours produced in stone by these means depend largely for their durability on the protection of the stone itself. It is, however, possible in some cases to mordant a stone by the use of hot aqueous solutions of dye and mordant used in succession so as to form a lake in its pores, but the difficulties attending the process are very great and it is never resorted to in practice except on a very small scale. Among the coal-tar dyes most used by the stone dyer are Methyl Violet, Nigrosine, Auramine, picric acid, Alkali Blue, Bismarck Brown, Rhodamine, Eosine and Fast Green.

Difficulties of Dyeing Stone. One general difficulty met with by the stone dyer, whatever may be the nature of the stone he is treating or of the dye he is using, remains to be mentioned. It is impossible to get any but a very small piece of any stone, whether natural or artificial, which is of absolutely uniform texture throughout. This want of uniformity is very apt to cause a similar unlevelness in the dyeing. In fact, dyeing forms a very good test of the differences of texture in a stone. Nothing can be done to counteract these differences but to get the most thorough penetration of the parts of the stone just below the surface that can be obtained, by the prolonged action of hot liquids. In this way

the different absorptive powers of various parts of the stone are to a great extent discounted. Where, however, there is a regularity in the differences of texture in various parts of a stone a skilful dyer can take advantage of the fact to produce ornamental effects. For example, agates are soaked in solutions of aniline dyes, whereby beautiful bands of colour are produced and show up the striped structure of the agate to perfection when it is polished and cut.

Dyeing Sand. Apart from a rather old-fashioned ornamental use, coloured sand is employed by hydraulic engineers. It is not an easy thing to dye, as the colour must resist water and rubbing. Good effects, however, can be got with the azo colouring matters. For instance, 100 lb. of sand can be dyed by dissolving 1 lb. of beta-naphthol and 1¼ lb. of caustic soda in 3 gallons of water. The sand is stirred up slowly in this and then, according to the tint desired, the requisite quantity of azo colour is added.

Dyeing Horn. Horns are outgrowths of the skin of the head of cattle, goats, sheep, the rhinoceros, etc., and are formed round bony processes of the skull called *horn cores*. They are of the same substance as hair and finger-nails and the feathers and beaks of birds. The antlers of a deer are bony and are not composed of horn. The horn of commerce is chiefly obtained from oxen, cows, sheep, and goats. The horn substance, like wool, is composed of carbon, oxygen, nitrogen, hydrogen and sulphur. The presence of sulphur is important to the dyer. Horn often requires bleaching before dyeing, on account of its strong natural colour in many cases. There is much difficulty in bleaching horn without injuring the fibre and loosening the cohesion of the tissue. Peroxide of hydrogen seems to be the safest agent and gives good results in careful hands. Andes recommends whitening horn with chloride of lead. This process has, however, the drawback that the lead salt blackens in time in the air of towns owing to the formation of lead sulphide.

Horn is dyed principally with coal-tar dyes, but dyewoods are also used to some extent. Black, though it can be dyed with anilines, is more commonly got by the use of a warm solution of lead salt, which forms lead sulphide with the sulphur of the horn. An equally good result is obtained with mercury sulphide instead of lead sulphide. Nigrosine or aniline and bichromate gives, however, better results. Logwood on an iron mordant is also sometimes used for black dyeing, the black being tinted with fustic in the usual way. Aniline dyes are best used in alcoholic solution. Methyl Violet, Bismarck Brown, Aniline Yellow, indigo-carmine, and Malachite Green are all favourite dyes. Greens are dyed on horn by combining a blue with a yellow. Heat should always be avoided in horn dyeing as it tends to warp the material, and this is one of the reasons for using spirit solutions of anilines. They require no mordanting, while the water-soluble anilines require a mordanting with caustic potash or soda and the penetration of the mordant is not very satisfactory if it is used cold.

Dyeing Ivory. Ivory has no chemical affinity for colouring matters. The permanence of any artificially produced colour upon ivory depends, therefore, on the protection of the bony matter into which the colour has penetrated to some extent. The processes employed in dyeing ivory are very similar to those used for bone, but there are two points of difference between bone and ivory which have to be kept in view. In the first place, ivory has far less organic matter in its constitution than bone, and, in the second place, it is much denser and closer in texture than bone.

The first of these differences is in the favour of the ivory dyer. He has no fatty constituents to contend with, and these are perhaps the worst difficulties in the way of getting level shades, and are very troublesome to remove. The second, however, cuts the other way. Successful dyeing of ivory depends little on the colouring matter used. Once a dye or a lake has been formed in the superficial layers of the mass the ivory is coloured, and the colour is protected by the hard tissue of the bone. Penetration is, therefore, the main thing to be considered, and it will be evident that prolonged heating is usually required in dyeing such a closely-knit substance as ivory.

Nearly all the ivory of commerce is made from elephant tusks, the canine teeth of that great quadruped, and weighing sometimes as much as 2 cwt. each. Khartoum, on the Upper Nile, has an important ivory market, but signs are not wanting that the African elephant will soon be a rarity.

Seasoning Ivory for Dyeing. Ivory must be seasoned before dyeing. If this precaution is not taken, the colour will be very liable to change or to rub off. The cutting of ivory has also a great influence on the subsequent dyeing. Sawing has a marked tendency to colour the ivory yellow, probably by reason of the heat developed during the process, and also possibly on account of rust particles upon the saw. It is a good plan when sawing ivory with a circular saw to have the lowest third or so of the saw immersed in water, whereby heating of the saw is prevented. Six months is a fair average time to store ivory for seasoning.

As will be gathered from preceding remarks, ivory is perfectly catholic in its reception of colouring matters, whether dyes, pigments, or lakes. Nevertheless, the whole art of ivory dyeing consists in a proper handling of the various synthetic coal-tar dyes. A few mineral pigments are used for ornamental work, but the methods of applying them are troublesome, and they are employed only when brilliant colours have to show some amount of resistance to exposure to the elements. Provided that time is allowed for proper penetration of the liquids used, ivory can be dyed by any of the processes in vogue in textile dyeing. It can be dyed in one bath with a substantive dye, or in two baths with an adjective dye and a mordant, or by reagents, which will cause the precipitation of an insoluble pigment in the cells of the tissue. The absorption of dyes of any kind is frequently assisted by a previous treatment of the ivory with dilute nitric or hydrochloric acid. The acid dissolves out some of the mineral matter of the ivory, especially from the very hard superficial layers, and thereby is a great assistance to penetration. The action of the acid requires skilled supervision, however. The hardness of the original ivory can be restored after the ivory has been scoured, rinsed, and dried by heating it in dry common salt, but the loss of strength is irremediable, and must not be carried too far.

Bleaching Ivory. As regards bleaching, which is often a necessary preliminary to dyeing light shades on ivory, one of the best bleaching baths is one of bran, unslaked lime, and water. Bleaching powder answers well, but must be used for a long time in a weak bath, and on removal therefrom the ivory must be rinsed carefully at once, and then dried in hot sawdust. If the rinsing is not thorough, the ivory is very apt to

crack on drying. Peroxide of hydrogen and sodium peroxide are also excellent for bleaching ivory, as is solution of sulphurous acid. Gaseous sulphurous acid —that is, the fumes of burning sulphur—must on no account be used, as the sulphuric acid formed rots the ivory. Old yellow ivory can be restored to its original colour by exposure to the direct rays of the sun. This fact is well known to pianoforte players, who preserve the whiteness of the keys by leaving the lid open in the sunlight.

Dyes for Ivory. Black is dyed on ivory with logwood and bichromate in two baths, and also with Nigrosine. Red is dyed with cochineal or Brazil wood. Another method is to boil scarlet wool in water, adding carbonate of potash at intervals until the dye is extracted. A little alum is then added, the solution is filtered, and the ivory is soaked to shade in the filtrate. The dye-liquor must on no account be hot, but it is advisable to have it warm to save time. Picric acid or other soluble dye gives an excellent yellow, as does fustic on a tin mordant. Blues are dyed almost exclusively with anilines, which have practically ousted indigo-carmine from the ivory painter's palette. Methyl Violet of various shades is used for violet. Alkanet was used before the discovery of the coal-tar colours, but its colours are very loose to light. Greens are dyed with anilines, or by combining a yellow with a blue. The old method was to dye a blue with indigo-carmine, fix with tin salt, and then turn to green in a fustic bath. Browns are dyed with anilines—such as Bismarck Brown—and with cutch, but most of the ivory in this country is dyed with permanganate of potash, like wood. Most of the aniline browns can be shaded with red or other colours. Greys are got with baths which are the same as for black, but weaker.

There is yet one method of treating ivory which, although it is scarcely a dyeing process, is well worth mentioning. The ivory is soaked in a weak solution of nitrate of silver in the dark until it has acquired a dark-yellow colour. It is then taken out, rinsed, and exposed below the surface of water to the direct rays of the sun. In a few hours the ivory will have assumed a deep velvety black colour, and it is then removed and rubbed dry with a clean cloth. Chamois leather will give a bright silvery lustre to the objects treated by the above process. When adjective colours are made use of, and the dye and mordant baths cannot be combined, the dyebath must always come first, and the ivory should be rinsed before going into the mordanting bath. The great rules are never to hurry the process, and to aid the absorption by a moderate amount of heat. In the case of very hard and close ivory a preliminary boiling in water, the ivory going hot from the water into the dye or mordant bath, is of great assistance. Solutions of coal-tar dyes in alcohol generally penetrate better than aqueous solutions, but the latter are, of course, cheaper than the former.

Dyeing Vegetable Ivory. Vegetable ivory is the kernel or albumen of the seeds of a South American plant known as *Phytelephas macrocarpa.* The seeds are about the size of a hen's egg, and grow from four to nine together in clusters, which sometimes weigh 25 lb. or even 30 lb. It is always dyed with coal-tar colours, but the dyeing requires special experience, as the texture of the substance varies greatly with the age of the plant, the time of harvesting, and with the variations in the climate which occurred during the ripening of the fruit.

A few general rules, however, can be laid down. The ivory must be perfectly clean to begin with. It must be entered into plain water, and the dye gradually added when the bath has been brought to the boil. Great care must be taken to keep the bath constantly boiling during the dyeing, and to add the dye only as it is taken up by the ivory—that is, to keep the bath itself clear and light in colour. As soon as the proper shade is reached, the ivory is at once removed and dried without rinsing. It is then carefully polished with a clean and very soft woollen rag.

With the softer kinds of vegetable ivory a boiling with soap, followed by a good rinse, helps the absorption of the dye. Among the coal-tar colours used, Nigrosine, picric acid, Malachite Green, Methyl Violet, and Fuchsine are the most generally employed. Dyewoods are still used, however, to some extent, especially cutch and logwood. A good black, is got by boiling in a strong solution of logwood extract for half an hour or more, according to the closeness of the texture, and then mordanting in a cold bichromate bath. With cutch for brown, the mordant used depends on the shade. Ferrous sulphate, bichromate of potash, and sulphate of copper are all used.

Dyeing Bone. The dyeing of bone is a comparatively easy matter, as the coal-tar dyes penetrate it very readily, especially in hot solutions. In the great majority of cases no mordant is required, as the substantive dyes answer every requirement. In the case of the basic dyes, the best mordant is tin-salt. It is a good plan to facilitate the penetration of the substantive dyes, and also of any mordant that may be used as a preliminary to working with any adjective dye, by dissolving out part of the lime salts of the bone by means of dilute nitric or hydrochloric acid. This is, however, a very delicate operation, as, if it is carried too far, the appearance will be spoiled and it will become apt to crack or even to crumble. It is nevertheless an indispensable preliminary to treatment with aqueous solutions, although in most cases alcoholic liquids penetrate well without its aid.

Tannin must not be employed as a mordant. It acts upon the gelatin in the bone, and not only prevents proper penetration of the dye, but is absolutely destructive to all uniformity of shade.

Dyewoods, especially logwood for black, are used in bone dyeing, but, as in other departments of dyeing, they are rapidly giving place to the artificial colouring matters. Nigrosine dyes bone black without any mordant, and without heat, for example, and has therefore an advantage over logwood in every possible way. The best yellow dye for bones is picric acid, which can be toned by the simultaneous use of other yellows. The faster colour got by mordanting in a hot solution of bichromate and then dyeing in a hot solution of a lead salt is now rarely seen. Reds and blues are dyed with many substantive coal-tar dyes. Blue can also be dyed with indigo-carmine, but the bones must be first treated with dilute acid.

In all cases, the coal-tar dyes should be used in solution in spirit. It is an excellent plan to dye in a still, by which means a large proportion of the methylated spirit used is recovered, while the heat greatly favours the penetration of the dye. The use of water should be avoided in dyeing bones with artificial dyes on account of its softening and dissolving action upon the gelatin of the bone. In some cases, however, the gelatin has been to a large extent removed by bleaching the bones in boiling lyes or in a solution of chloride of lime or sulphurous acid. In this case the use of water in dyeing is not so objectionable.

The best results are always got by dyeing perfectly fresh bones. These, when thoroughly cleaned from adhering particles, want no bleaching as a rule even for dyeing light shades. When bleaching is indispensable, the best agent is peroxide of hydrogen, used after the exterior of the bone has been freed from grease by rubbing with petroleum ether. If sulphurous acid is used it should be employed in concentrated aqueous solution so as to act quickly. The gaseous acid is not suitable for bleaching bones as it has a tendency to warp the fibre.

Dyeing Mother-of-pearl. Mother-of-pearl is difficult to dye on account of its hardness and close texture. It is usual to dye the finished object, such as a button, as it is impossble to dye through thick material without injuring the lustre; articles made out of mother-of-pearl dyed before fashioning remain colourless at the edge. The rough and damaged places of the button or other article are first dyed; the dye goes most strongly into defective places, such as edges and cracks, so they become coloured before the lustrous surface is dyed. Mother-of-pearl is sensitive to the action of chemicals, and hence it is necessary to use very weak acid solutions, only lukewarm, and to let them act for the shortest possible time only.

Mother-of-pearl is yielded by a large number of mollusca, and various kinds of it are recognised in commerce, such as white, black, goldfish, burgos, etc. The various kinds differ in hardness, strength, lustre and colour, and in their receptivity of dyes and in the dyed effects they produce.

The following are the most important sorts:

Egyptian mother-of-pearl, from the Red Sea and the Persian Gulf. This has little lustre and is bent into small trough-like shapes.

Macasoar mother-of-pearl, from Australia. This consists of white flat shells with a high lustre. A single shell may weigh over 4 lb.

Manila mother-of-pearl, which is yellowish, and very lustrous and iridescent.

Lingah shells, trough-shaped, and having a bluish green shimmer.

Tahiti mother-of-pearl, the best black sort; the inferior sorts are called Gambia.

Auckland mother-of-pearl, flat, thin and greyish.

Banda Onithisif pearl, consisting of second rate bluish shells with yellowish green edges.

Mulles, consisting of whitey-blue shells with red edges.

Sea ears, especially Japanese, having a splendid lustre, are chiefly used for panels.

Burgos, which gives good effects on dyeing.

Mississippi. This variety consists of thick shells, white and very hard, and difficult to work.

Preparing Mother-of-pearl for Dyeing. The first thing to be done is to free the mother-of-pearl from grease, and, if light colours are to be dyed, it must then be bleached. The grease is removed by treatment with benzene, ether, or tetra-chloride or carbon, followed by ammonia, or a three to five per cent. solution of carbonate of potash or soda. Caustic soda corrodes some kinds of mother-of-pearl. The cleansed material is rinsed in water, and should be fingered as little as possible.

The dyeing is done cold, if possible, and it is better to dye for a long time in a warm bath than to hasten the process by greater heat. Many dyes—for instance, Chrysoidine—go on nearly instantaneously. Others, such as Tartrazine and Quinoline dye only slightly after long standing. The greater the lustre of the mother-of-pearl the harder it is to dye it. As the dye ought not to injure the lustre, time should only be allowed for the dye to get into fine cracks, and between the layers, watching the process with a good magnifying glass.

The organic matter generally takes the dye before the mineral portion of the shell, and in many cases forms lakes, which hide the iridescence too much.

Dyeing in Aqueous Solution. The old process with silver salts often combined with aniline dyeing with the idea that the colour is then faster. To imitate black mother-of-pearl, the most prized variety, immerse it in a solution of 4 oz. of nitrate of silver in 100 oz. of ammonia; tilt the vessel about from time to time, and after a few days' immersion in the dark expose it to diffused sunlight. The colour can be strengthened with pyrogallol. In dyeing "natural black" the object is exposed to sulphuretted hydrogen as well as daylight. Whatever may be done the black is really nothing more than a slate grey. It can be browned with dilute tincture of iodine.

A solution of indigo-carmine in twenty times its weight of boiling water is used for blues; and picric acid and indigo-carmine for greens; curcuma for yellows. A fine cheap brown is got with permanganate of potash.

Of the artificial dyes, the basic ones go on faster for the most part, and they combine also with the mineral matter. The acid dyes combine with the organic matter only, as can be seen on microscopic examination. No mordant is needed with the basic dyes, but a little acetic acid should be added to the water used to dissolve the dye. Before dyeing, the mother-of-pearl must be cleansed and well soaked with water. Dissolve from 1 to 3 per cent. of dye in water, warm if necessary, to from 50° to 60° C., and leave the pearl in the bath till it has the right shade. The following basic shades answer very well in a warm neutral bath: Chrysoidine, Bismarck Brown, Leather Brown, Leather Yellow, Phosphine, Auramine, Magenta, Victoria Blue, Methylene Blue, Methylene Grey G or NO, Navy Blue, Methyl Violet 2R, 6B, or R, Crystal Violet, Brilliant Green, Malachite Green, Safranine, and Rhodamine B, 5B, or G. Chrysoidine and Vesuvine dye very quickly. Victoria Blue, Rhodamine, Indoin Blue BB, Rubine, Brilliant Green, and Guinea Green dye quickly with 2 per cent. of alum.

Dyeing Mother-of-pearl with Acid Dyes. In dyeing with acid dyes, make the dye to a paste with acetic acid, adding to the bath a little oxalic acid. This addition should be always made with Fast Red A, Navy Blue, Ponceau R and 3R, Cotton Blue, and Azo Yellow. The following are the best acid dyes for mother-of-pearl; Acid Green, Guinea Green, Acid Magenta, Acid Violets N, 5B, and 6B, Water Blue, Lyons Blue, Naphthol Blue, Fast Blue, Ponceau 2R and 3R, Orange II., Mandarine Fast Yellow, Fast Blue, and Induline. All eosines and erythrosines do well. Nigrosine answers well, but Quinoline Yellow and Uranine do not.

Fine browns and blacks are got by combining Magenta and Malachite Green, Bordeaux by combining Magenta with Bismarck Brown. To get a fine black with a greenish shade, dye with Malachite or Acid Green, and cover with Nigrosine.

Fine beiges and Havanas are got by combining Chrysoidine or Bismarck Brown and Fast Blue or Nigrosine. Equal parts of Rhodamine B and Orange II. give a brilliant red.

In dyeing with adjective dyes, the result is usually dull. The best dyes are Alizarine Red, PS or W, Alizarine Blue W and Black W, Anthracene Brown W, and Alizarine Orange W. Dye at the boil with Turkey red oil and ammonia, or ammonia only. Dyeings with the zinc dust and alkali indigo

vat do not answer very well. Indigo-carmine gives better results. Fine shades can be got by the prolonged action of organic compounds which become coloured on exposure to air—for instance, paraphenolene diamine, amidophenol dioxynaphthaline and pyrogallol—mordanting first with cuprate of ammonia or with pyrolignate of iron. We can also use the substantive dyes, such as Congo, Benzopurpurine, Diamine Blue, or Bordeaux Oxamine Blue, and the Immedial dyes; but the results have no good lustre, and the mother-of-pearl is often attacked by the alkaline bath.

Dyeing Mother-of-pearl in Spirit Dyes. This method is the easiest, but the colours obtained are looser than the above. The first process is to soak the mother-of-pearl in a solution of carbonate of potash in ten to twelve times its weight of warm water. In this solution the mother-of-pearl is kept for an hour or so. This opens the pores and permits the absorption of the dye, and also gets rid of any grease that may be present. The mother-of-pearl is then rinsed and dried. No exact time for the action of the lye can be given, as it depends on the shade required. Up to a certain point, the longer the carbonate of potash is allowed to act the more dye the mother-of-pearl can absorb, and so the darker will be the shade. Reds are dyed with spirit solutions of any spirit-soluble red dye; yellows with tincture of picric acid or Aniline Yellow. Curcuma, gamboge, or Persian berries can also be used as tinctures. Blues are dyed with a spirit coal-tar blue, or with sulphindigotic acid diluted with water according to shade. Indigo-carmine is also employed. Greens are got either with a spirit-soluble green, or by combining a yellow and a blue; browns with a spirit solution of a coal-tar dye, or with tincture of iodine. Violets are dyed with spirit-soluble anilines, or with a solution in water of indigo-carmine turned to shade with liquid ammonia.

Dyeing Celluloid. Celluloid was accidentally discovered in the search for high explosives, and is a compound of guncotton and camphor. Its dangerous character has been enlarged upon, but it is entirely harmless if it is kept out of the way of sparks or flame, and it is very easily worked and dyed. It can be carved or turned like wood or ivory, and, moreover, unlike these materials, it can be moulded. When it is steeped in boiling water it becomes malleable, and can then be moulded into any desired shape, which it will retain on cooling. This ease of manipulation has caused it to find a large number of uses, and although many of these are to be condemned, it is very suitable for some purposes.

It is largely used for the handles of surgical and optical instruments, and in these articles it has to a great extent supplanted ebonite, on account of its far lower price. Washable collars, fronts, and cuffs are made by covering both sides of a piece of linen or calico with a thin coating of celluloid, securing a smooth surface and adhesion to the fabric at the same time by subjecting the material to heavy pressure between rollers.

As it is translucent and easily dyed, celluloid is largely used for cigarette and cigar holders and for mouthpieces of pipes. Quantities of "tortoise-shell" combs are made of it, and it masquerades as "ivory" for card-cases, visiting cards, photographic mounts, flower vases, cane and umbrella handles, piano keys, billiard balls, toy balloons, napkin rings, and many other small articles. It is dyed also for these uses and for making artificial flowers. It forms an excellent sheathing for ships' hulls, being far cheaper than copper, and far more durable. Curiously enough, however, although this fact has been known since 1881, prejudice and conservatism have successfully resisted hitherto the introduction of celluloid into the shipbuilding trade. This use of celluloid will undoubtedly become one day the most important of all. No marine organisms will grow upon it, so that its use would obviate all necessity for using poisonous and expensive anti-fouling compositions.

The only objection to celluloid is its inflammability, and when articles formed of it are worn, such as combs and collars, this has caused very serious accidents. All the numerous attempts so far to make celluloid uninflammable without affecting its usefulness have failed. So far they have taken two directions. On the one hand, chemists have tried to make a "non-flam" celluloid by adding a third substance, such as a silicate or borax. On the other hand, attempts have been made to substitute an uninflammable substance for the camphor. There is no doubt that a fortune awaits the inventor of an absolutely harmless celluloid.

Celluloid is invariably dyed with coal-tar colours. For single colours the coal-tar dye is added to the materials in the process of incorporation. For dyeing patterns on celluloid, the finished article is coated with a resist, usually paraffin or beeswax, and the parts to be dyed are then laid bare. The whole article is then immersed in a cold solution of the dye. In a few cases heat may be required to make the dye penetrate, in which case a comparatively infusible resist, such as asphalt, is used. In no case, however, may too much heat be used, or the celluloid itself will be softened and lose its shape.

Dyeing Glue and Gelatin. Dyeing these substances, which are virtually the same, glue being merely impure gelatin, is a simple matter enough. The uses of both glue and gelatin depend upon their complete solubility in hot water, and hence it is evident that only such dyes as possess equal solubility are suitable for dyeing them. At the same time any dye which has that property can be used, provided also that if the gelatin is to be used as food the dye is a non-poisonous one.

Dyeing Soap. The dyeing of soap appears to be merely an act of making a mechanical mixture of the dyestuff and the soap. There is no chemical combination between essential constituents of a soap and the colouring matter, such as occurs when vegetable fibres are dyed, and with animal fibres to a still greater extent. Nor is it desirable that such should happen with soap. The dyes which dye textile fabrics substantively—that is, without the intervention of any third substance or mordant—do so by forming with the fibre a substance or substances insoluble in the liquids which come into contact with the fabric under ordinary circumstances. It is evident that the formation of such bodies when soap was dyed would be quite out of place. A soap is not intended to be insoluble in water, and all of it that goes to form a lake is wasted, besides forming an unpleasant sediment in the water. For the same reason, the use of mordants is, of course, to be avoided in soap-dyeing, as their function is to form insoluble lakes with the dyes. It is true that in this case there is no loss of soap, but the objectionable sediment will still be there and will be very apt to stain the skin or articles washed with the soap.

DYEING *concluded*

THE RELIGION OF MAN

Beginnings and Primitive Elements of Religion. Religion is not Ecclesiasticism. The History of the Ecclesiastical System and the Doom of its Power

By Dr. C. W. SALEEBY

THE modern scientific study of mankind has enabled us in some cases to lay down propositions which have been definitely proved to be true of men everywhere as they at present exist upon the earth. For instance, we are able to say positively that some form of marriage, however degraded, exists amongst all human societies at present extant, and that there is no human society which does not punish infidelity on the part of the married woman. Similarly, we are able to state as a scientific fact that there is no known race, tribe or society of men—with the doubtful exception of the Veddahs—which is without a religion. Arguing, as in so many other instances, from the existing facts to that remote past of humanity which we cannot directly see, we may reasonably infer that the origin of religious beliefs is exceedingly remote, and that since they first arose man has been "a religious animal." Doubtless there may be found in high or in low societies isolated individuals who are completely non-religious, having neither beliefs nor interests that can come under this category. But these are relatively rare and abnormal exceptions. Anthropology clearly indicates that man in general is a creature who creates among other things religious beliefs.

The Beginning of Religion. It is possible, the present writer thinks, for psychology to indicate to us with absolute clearness the point in the evolution of man at which religion began to play a part in his history. It was, we believe, that point at which man first became self-conscious, being, as Hamlet says, "with such large discourse, looking before and after." The conscious but not self-conscious dog has no religion, no place for a religion, no possibility of a religion. It is the being who looks before and after who is religious. Now, if we be asked whether any point can be named, even in the light of modern evolutionary beliefs, at which the predecessor of man became man, the answer must surely be that it was the point at which he achieved self-consciousness: and then assuredly religion must have been born. If these assumptions be correct it is coæval with mankind, and if we assert, as we are entitled to do, that something which is of the nature of religion is an almost necessary attribute of a self-conscious creature, then we may be assured that, as religion has been coæval with man, so it will be coæval with him, even though its

"Outward forms that bear
The longest date do melt like frosty rime,
That in the morning whitened hill and plain
And is no more."

In our brief survey of the history of religion we are compelled to recognise that, in its origin, its relation to anything that we can now call truth is at the very best almost desperately remote.

Primitive Religion. Primitive religion, in a word, is pure superstition, grossly false, without any relation to morality; and when it first assumes a relation to morality it countenances and insists upon such practices as human sacrifice, which are essentially immoral. We need not hesitate to admit what in any case we must admit, provided that we fully appreciate the monstrous falsity of the argument which would seek to discredit all religion on account of the facts of its whole history. The same argument would, of course, discredit all science. Primitive science was simply superstition; indeed, primitive religion and primitive science were one and the same, and both were equally false. If all religion is to be discredited because it began in beliefs we cannot now share, so must we discredit all science—which began with those same beliefs.

The Roman writer, Petronius Arbiter, laid down the doctrine that "Fear first made the gods." On his part we may say that this was a guess, or rather that he inferred it from his observation of human nature, without having made any comparative anthropological study. Precisely the same is the case of our own writer Hobbes, who said, "The Feare of Things invisible is the natural Seed of Religion." The comparative study of the beliefs of man is of much later date than even Hobbes, but it has abundantly and conclusively demonstrated, by the inductive method, the truth of the proposition which he and his Roman predecessor expressed. This is to say that earnest students all over the world have found fear of the invisible, and of the visible too, to lie at the basis of the lowest religions now extant: and no one questions the propriety of the inference from the lowest forms of existing religion to its earliest stages—now gone for ever.

The First Forms of Religion. There has been definitely abandoned, as without any warrant at all in facts, the theory that the lowest forms of religion described by missionaries, men of science and others, are cases of degeneration from a primeval monotheism or belief in one God. At one time this opinion was generally held, and it was supposed that only under special guidance was man able to preserve in its purity the belief with which he started. This opinion, however, was essentially pre-evolutionary, and we now know it to be untrue. It is now maintained by no one.

Let us now ask ourselves whether it is possible to express in any kind of category the forms which primitive religion took, and which it

still takes in primitive peoples or in minds of the primitive type. There has been wide discussion, that still persists, as to which form of primitive religion was really the first. It is impossible to discuss this matter here, but the controversy rages between those who insist that ancestor-worship is the primitive religion and those who insist that Nature-worship is the primitive religion.

The Worship of the Dead. Ancestor-worship is, at any rate, an indisputable form of religion. According to Herbert Spencer, who based his theory upon very wide study of the psychology of the savage, religion took its first form in ancestor-worship, which itself arose in dreams. As John Fiske says ("The Idea of God," page 66): "No one has ever discovered a race of men devoid of a belief in ghosts. This belief may clearly be traced to the facts of dreams. The savage, unlike the educated man of to-day, makes no sharp distinction between the reality and validity of his waking experiences on the one hand, and the experiences of sleep—namely, dreams—on the other hand. The contemplation of the facts of sleep, which to the observer suggest the absence of the informing inhabitant of the body, and of the facts of dreams, which seem to prove that the inhabitant, while out of the body, may roam afar and then return—these gave rise to what is, perhaps, the first speculative belief of the human mind—the belief in ghosts."

If now we consider the case of death, we shall see how the same theory is applicable to it; nor is it difficult to understand how the ghost of, for instance, a great chief may be regarded as still powerful and demanding obedience and respect. As to the absolute priority of this kind of belief as against a belief in the presence of informing spirits in the sun, the trees and other phenomena of Nature, we may merely quote, without commenting upon it, the argument of Herbert Spencer that surely a belief in the spirits of the dead—who have lived—must have preceded a belief in spirits of such an object as a rock; this second belief would spring from the first.

The Fear of the Dead. However that may be, we find this element of the worship of the dead in primitive religion, probably as the primitive religion; and it is our duty before we go any further to rid ourselves of a very common misconception as to its character. We commonly think of this form of religion as ancestor-worship, and this word suggests to us the name of such a great moral teacher as Confucius and the practice of ancestor-worship as it may now be seen in China and Japan. But we are profoundly in error if we imagine that modern ancestor-worship, moralised and beautified by the slow progress of the human mind, is one and the same thing as primitive ancestor-worship. That there are beautiful elements in the modern practice we all admit. We read of simple and noble Japanese ceremonies, which, though we may believe them to be based upon erroneous beliefs, yet undoubtedly have fine elements in them. But the primitive worship of those who had been powerful in their lives was a thing awful and horrible to contemplate. It had no vestige of a moral element. It was rooted in fear, and fear alone kept it alive; it was not originally the worship by a given man of his own especial ancestors; it was simply the fear of those who had been dangerous and tyrannous in their lives, and who in their now invisible shape were more terrible than ever. In order to placate the feared departed, the living were burdened, were tortured in body and in mind, and unthinkable thousands of men, women, and children were slain. There has been no more horrible thing upon the earth than the beginnings of religion. Primitive religion contains no moral elements, but, on the contrary, constantly defies and denies the laws of love and the sanctity of life. It contains no elements of value to the intellect of man or to his sense of beauty. That anything good and great should arise from such ghastly beginnings is one of the great marvels, as it is, perhaps, one of the great lessons and parables, of human history.

Nature-worship. The other form of primitive religion is Nature-worship. Here we do not ask whether it was later than ancestor-worship, or earlier, or of independent origin. Of its essential superiority to the primitive worship of the spirits of the dead—which, be it remembered, was only a worship of the spirits of the dangerous dead—there can be no question. However gross its superstition, it had in it elements which made for higher things, just as primitive ancestor-worship, as we have seen, was capable of developing into such things as reverence for aged parents. Primitive nature-worship began as a belief in the incarnation, so to speak, of active and more or less potent intelligences in the great material phenomena of the world around us. Its particular form depends, of course, upon the particular aspects of nature in various places. The mountain or the forest or the sea or the cliff may acquire special importance according to local circumstances. Certain great phenomena of nature, however, are common to all men, and chief among these are the heavenly bodies. The evident potency and majesty of the sun made him a more or less universal object of Nature-worship in innumerable forms. These take, of course, various more or less poetic shapes—poetic imagination being a very ancient attribute of man; and, according to the measure of the individual intelligence, the sun may be conceived as himself a living god or as a fiery chariot which daily carries the sun-god across the sky, or, more philosophically, as the symbol or sign of a god that is somewhere behind him.

The Forms of Science. Or the former belief may become still more subtle, as where, for instance, fire is conceived as the origin and regenerator of all things, and the sun is worshipped as the greatest visible manifestation of this creative power. From the remotest ages the sun has been an object of the worship of mankind, and it need hardly be said that the study of that single branch of comparative religion, which may be called *solar myths*, is a matter for endless volumes.

In primitive religions we find varying proportions of both of these primitive elements—

ancestor-worship and Nature-worship. That both arose in fear, there can be no question ; that it is difficult to observe in the beginnings of either much or anything that commands our respect can also not be questioned. Yet, as we have seen that the worship of the dead is capable of vast elevation, so also we must recognise, even in the rudest forms of Nature-worship, the germs of philosophy and science.

This last point must be insisted upon. It is perfectly evident that the fear of the great phenomena of Nature necessarily involves an interest in them, and that this interest necessarily involves their study ; but this study, whilst, among other things, it will assuredly diminish the original fear, so also gradually reveals many aspects of Nature hitherto unsuspected. The fear of eclipses, for instance, leads to an interest in eclipses, and this to their study, until it is found that certain eclipses recur at regular intervals. The fear has now vanished, and may well be replaced by a fine and all but religious wonder ; while there is slowly born the idea of natural law. In a thousand cases this process has occurred, until at last there is fully realised the idea, gradually becoming familiar to our own age, of the supreme unity and orderliness of Nature—and, therefore, of That of which Nature is only the manifestation. Thus it is not impossible to trace from rude beginninge, even from the agonies of fear in the savage heart at nothing worse or more significant than a shadow, the gradual development of one of the sublimest ideas which have yet found their way into the human mind.

The Birth of Knowledge. Observe how this fear, and interest born of fear, and study born of interest, and knowledge born of study, affects the idea of God. When Nature was conceived as an awful collection of more or less independent powers, who might war among themselves, but all of whom dominated over man, then evidently was the age of polytheism. Only with the growth of knowledge was it possible for this to be replaced by the immeasurably higher idea of monotheism. This step in the development of religion has unquestionably been due to the growth of knowledge. Contrary to the ordinary belief, science—which is the pursuit of truth—so far from being the enemy of true religion, is necessarily its best friend. Doubtless it has destroyed innumerable false religions, and that great work is not yet done ; doubtless the official exponents of those religions have had to suffer, and have sometimes honestly and sometimes dishonestly condemned the growth of knowledge as impious, and declared that there were things which we were not meant to know—as, for instance, when it was an immoral and legally condemned act to make any anatomical inquiry into the structure of the human body. But, on the other hand, it may assuredly be demonstrated that the growth of any order of truth, while it involves the destruction of falsehood, can never injure any other order of truth, but must, on the contrary, purify and help it.

Hitherto, we have considered briefly the main aspects of the genesis and development of religion in general in terms of its beliefs. There are, however, two other great facts of religion as history reveals it; one is the relation of religion to morality, and the other is the fact of religious institutions, which, in the widest sense of the word, may be called *Established Churches.* And first, as to the relation of religion to morality. It is one of the commonest and most erroneous of all popular beliefs that there is an essential relation between all religion and all morality. This belief does not withstand a moment's reflection or the observation of a single day. On the contrary, it is definitely known that whilst the greater part of past religion has been closely associated with the most horribly immoral practices, religion at its birth had no relation whatever, essential or accidental, to morality.

Morality is Older than Religion. Furthermore, it is an indisputable truth that morality, just as it precedes any kind of religious idea in a tiny growing child, so is also immeasurably older than any religion, even if we grant, as we must, that religion is probably as old, or very nearly as old, as man himself. The tigress that will give her life for her cubs ; the baboon whose case is mentioned by Darwin, and who, having gained a place of safety, returned, through his enemies, to rescue a little one that had been left behind—these are instances which demonstrate, what no one in the twentieth century can dispute, that the beginnings of morality can be traced far down in the scale of animal life. The lowest of known vertebrates is the fish, and among certain fishes there is found not merely maternal care—one of the oldest, the noblest, and most purely moral things in the whole world—but even a very much later thing, paternal care. Morality and religion have wholly independent origins, love being older and stronger than any church or any system of religious beliefs or practices that has yet expired, or has yet to expire, upon the earth ; while we observe also that the association of morality and religion in more recent times furnishes promise of the most precious kind for both. Among all living students of religion, not in its historical and comparative aspects, but in its aspects as a great fact in human life to-day, there stands out a sincere and noble and profound thinker, Professor Harald Höffding, of Copenhagen. In his "Philosophy of Religion" he insists that past students have paid too much attention to the transition in the history of religion between polytheism and monotheism, and that, as was originally asserted by Tiele, " the transition from Nature religions to ethical religions is the most important transition in the history of religion."

The Gap Between Morality and Religion. This is not to assert that before such a great transition occurred there was no moral element in religion. As Höffding says : " Since the worship of the family, of the clan, or of the nation is shared in by all, it helps to nourish a feeling of solidarity which may acquire ethical significance." In such a case, the fact of having common fears, if no more, may increase a man's sympathy with his neighbour, which is the

beginning, the end, and the whole of morality; but how tremendous is the gap between this stage, which may involve implacable hatred of those who have a different religion, and the command of Confucius, that we should do as we would be done by, or the final statement of morality in the words of Him who said, "But I say unto you, love your enemies, bless them that curse you, do good to them that hate you, and pray for them which despitefully use you and persecute you." (St. Matt. v. 44.)

Ecclesiasticism. There remains the necessity for alluding to a great world fact, which in modern terms is sometimes called *Ecclesiasticism* and sometimes *Clericalism.* With the birth of religion, or closely following upon it, there came the appointment or self-appointment of special individuals who had a special association with it. This fact makes the primitive "medicine-man" one of the most interesting figures in history, as the evolutionary germ of churches on the one hand and of science on the other. In him the differentiation had not yet occurred. Such scientific knowledge as he had or pretended to have was one with such religious knowledge as he had or pretended to have. He would transmit his pretended secrets, together with some small measure of real Nature-knowledge, to his children or to initiates. Thus, there arises a priestly race or caste or class. In its remoter past the existence of this class, together with the institutions which it creates, and with its close associations with any other governing powers that there may be—the union of Church and State being one of the primitive facts of society, preceded only by a still more primitive stage in which they were identical—was by no means a wholly undesirable fact.

Ecclesiasticism is not Religion. All students of primitive religion are compelled to agree as to the disciplinary importance of early religious institutions. The same is, of course, true of early military institutions. The record of war and of Ecclesiasticism is not a wholly pernicious one. They had their place and their function, constantly and closely linked, so that there was always the Ecclesiastical sanction for war which, when successful, of course increased the power and reign of the Ecclesiastical system. They made for the preservation and success of larger and larger societies, which at last could spare some of their own energies for their internal concerns, and thus made the first steps in the direction of civilisation. Such propositions as these are quite distinct from any assertions as to the relations of Ecclesiasticism to essential morality. There is no essential morality in discipline, for instance, any more than there is essential morality in obedience—which, in the history of man, has far oftener been vicious than virtuous. But such things as discipline and obedience, strongly aided by the Church with its secular arm, have played an apparently necessary part in the past development of large societies.

That there is no essential relation between Ecclesiasticism and religion is evident directly we grasp the idea that religion is either a personal matter or not really religion at all; it is demonstrated by the fact that there have been and are unquestionably religious people who own no Ecclesiastical form or system; and far more by the fact that the supreme religious figures of history have been supreme because they have raised their brave and solitary voices against the established Ecclesiasticism of their day. By such Ecclesiasticism they have commonly been murdered.

The Greatest Murderer in History. The actual record of the so-called religion which establishes itself as a human institution is one of the few unmitigated horrors of the past. Ecclesiasticism has initiated and carried on countless unnecessary wars; it has made numberless martyrs; it is the greatest murderer in history; its murders have taken many forms, whether those of human sacrifices to a fetish in the heart of Africa or the burning of witches in our country only a century or two ago, or the burning of such great philosophers as Giordano Bruno, or the poisoning of Socrates, or the throwing of Christians to the lions by Roman Ecclesiasticism, or the murder of tens of thousands of Christians by Christian Ecclesiasticism, Catholics by Protestants, Protestants by Catholics, Christian missionaries by African head-hunters, or brave and faithful savages by a militant Christianity. Religious persecution has been initiated by all forms of Ecclesiasticism in all ages in precise proportion to their power.

Churches have at times displayed an interest in the advance of knowledge within due limits. Sincere and honest thinkers have freed their souls, even while their bodies still wore the garments of one Ecclesiasticism or another. Their reward has been the reward of Bruno. Ecclesiasticism, however, has never desired to share its knowledge with the people. In its own interests it has always desired to teach the people certain things—namely, such things as make for its own interests. To the growth of knowledge outside its own limits, and independently of its sanction, Ecclesiasticism, whether as Fetichism, or when taking to itself the noblest Name named of men, has necessarily been, and must continue to be until the hour of its death, an implacable foe.

The Dying Empire of Ecclesiasticism. There is no historian of human knowledge but lends his testimony, willingly or unwillingly, to this most shocking truth. Ecclesiasticism, however, is dying, and that rapidly. All over the world its empire can be seen to crack from day to day. If its almost measureless past be gazed upon, and its past potency, we may recognise that it is as good as dead. The immediate problem which faces mankind, and especially those who love the great religious truths, is as to how this noisome corpse is most decently and expeditiously to be buried. Thereafter these words of John Ruskin may be men's guide: "For there is a true Church wherever one hand meets another helpfully, and that is the only holy or Mother Church which ever was, or ever shall be."

BOOKBINDING & PUBLISHING

The Characteristics of Good and Cheap Bindings. Sewing with Cords and Tapes. Covering and Tooling. The Attractive Trade of Book-publishing

BOOKBINDING

By F. Sangorski and G. Sutcliffe

BEFORE entering upon the technical details of bookbinding, it will be advisable to give an explanation of the composition of a book, and of the sizes in which books are made. A book is printed on sheets, and the size of these sheets and the number of times which they are folded decide the size of the volume. The sheets are generally used in the following sizes: Foolscap, 17 in. by 13½ in.; medium, 24 in. by 19 in.; crown, 20 in. by 15 in.; royal, 25 in. by 20 in.; post, 19¼ in. by 15¼ in.; super-royal, 27 in. by 21 in.; demy, 22½ in. by 17½ in.; imperial, 30 in. by 22 in.

When the sheets are folded once they make a folio-sized volume; twice, quarto (4to); three times, octavo (8vo); four times, 16mo; and five times, 32mo.

A book is said to be a "crown 8vo," or a "demy 8vo," when sheets of "crown" or "demy" size are folded three times. When folded, each sheet is called a *section*, and consists of the number of "leaves" into which the sheet has been folded—an 8vo volume having, for instance, eight leaves in each section—each leaf consisting of two pages. The top edge of a book is termed the *head*, the bottom edge the *tail*, and the front edge the *fore-edge*.

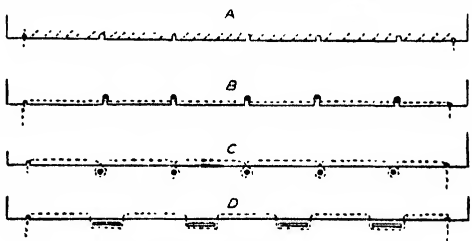
Bookbinding is divided into three branches—sewing, forwarding, and finishing. With sewing are included all the processes which ultimately end in the sewing of the sections together. Forwarding comprises the processes which complete the binding of the book; and finishing, the processes which result in the decoration of the binding.

Machine Binding. The demand for inexpensive binding, brought about by the increase in cheap literature, has led to the introduction of machinery into the craft. With publishers' cloth bindings, the processes from beginning to end are carried out by machinery. But though by this means cheap work is produced, it is usually at the expense of the quality of the binding. If the best work be required, it must be done entirely by hand, with just the aid of such appliances as have been in use almost since the invention of bookbinding. As, however, there are now so many books that are not worth the expenditure necessary for the best binding, the use of machinery is compulsory; but a method should be adopted that will allow the use of machinery without seriously damaging the binding. The essential requirements of a soundly constructed binding are: (1) All sections broken at the back should be mended, and all loose leaves and plates secured to the sections with a guard; (2) the book should be sewn on at least five cords or four tapes, which should project from the backs of the sections; (3) the boards should be firmly attached to the book, all the cords and tapes being interlaced into the board; (4) the leather should be directly attached to the back; and (5) all materials used should be of sound quality, uninjured during manufacture.

With the exception of the cheapest work—cloth binding—there is no reason why all these requirements should not be met; but owing to the demand for a showy exterior at a low price they are not usually considered by the modern binder.

Modern Cheap Binding. Usually, if the sections are broken at the back, the practice is to cut off a piece of the back, thus making the section into single leaves, and to sew these leaves together in the manner shown in **1** A. This is called overcasting, but a section so sewn together will always be liable to break away from the rest of the book and will never open freely.

With sewing, the cords, instead of projecting from the back of the book, are sunk into the sections, saw cuts being made in the back, the level back thus obtained enabling the book to be backed by machinery. But the sewing is not nearly



1. SEWING BOOK SECTIONS

as secure, for instead of the thread passing round the cords as seen in **1** C, it merely passes across them as in **1** B; and if broken, the probability is that the section will come out.

All books that are to be backed by machine should be sewn on tapes. The sewing is secure [**1** D], and the tape does not make sufficient projection to prevent the machine being used.

Too thin a cord is generally used, and often two are cut off, and only the remainder interlaced into the board.

The sinking of the cords prevents the book opening well, and to get over this to some extent, the leather is not attached to the back. A hollow casing made of brown paper is glued on, and the leather attached to this. The leather is attached to the boards, and the boards to the book merely by the cords laced into them; consequently, all the strain of opening and shutting the book is placed on these cords, and they often break away, the book then coming away from its cover. If the leather is stuck directly on the back, it assists the cords in attaching the cover to the book [**16**]. The cords have been sunk into the book, but as the public have been accustomed to see the projections on the back made by the cords, false ones are stuck on.

Good Inexpensive Binding. For the best binding the book should be sewn on cords, and meet all the requirements we have mentioned. If the question of expense has to be considered, the decoration should first be discarded. After that, leather being needed principally on the back and corners, only these portions need be covered with leather, and the remainder with a

Standing press A. Sewing-key 15. Press, with plough and pin 16. Correct and ordinary binding 17. Finishing press

less expensive material. This is what is called "half binding." For a further reduction the book should be sewn on tapes, and by this means an inexpensive and durable binding can be obtained.

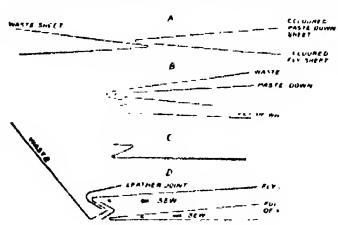
Following is a list of tools and appliances necessary: Standing press; sewing press [**14**]; sewing keys [**14** A]; bloodstone burnisher [**11**]; agate burnisher [**10**]; square; band stick; tenon saw; trindles [**5**]; bodkin [**9**]; pressing boards; cutting boards; backing boards; nickel pressing plates; set of letters, dots, rings, punches, leaves, flowers, gouges, straight lines, and other ornaments [**12**]; press with plough and pin [**15**]; paring stone; paring knife [**2**]; hammer; folders [**3**]; glue pot; compasses; band nippers [**6**]; knocking-down iron [**4**]; gold cushion and knife; pressing tins; millboard shears; finishing press [**17**]; finishing stove; fillet [**7**]; polishing iron [**8**].

If the book is received in sheets, these sheets have to be folded. We will suppose they are to be folded three times, making an 8vo volume. The sheets are lettered alphabetically in one of the corners [**13**]; these are called *signatures*. Usually, J, V, and W are omitted. The sheets are placed in alphabetical order with the signatures in the right-hand bottom corner. The first sheet is turned over, so that the signature comes face downwards on the left-hand bottom corner, and is folded in half from right to left, care being taken that the printing corresponds. A folder [**3**] is used to crease the fold. Pages 2 and 3 will now face. The top right-hand corner is then folded, and pages 12 and 13 will face. Folding in half, so that 8 and 9 face, completes the folding of the first section. The remainder are folded in a similar manner

Washing Stained Sheets. Any stained sheets are washed in the following manner: An ounce of permanganate of potash is dissolved in a quart of slightly warmed water. The stained sheets are put into this solution for about an hour, causing them to turn a dark brown colour; they are then taken out and washed in clean water. One ounce of sulphurous acid is put into a pint of water, and the sheets washed in this until all the stains have disappeared. They are again washed in clean water, and hung up on lines to dry. When dry, they are sized by dipping them into a solution of one ounce of isinglass dissolved in a quart of water, applying heat and again hanging up to dry. If the sheets are too white when taken out of the acid, the size is slightly tinted with tea, coffee, or any other staining fluid.

Making Endpapers. When all the sections have been made sound and the plates guarded on, endpapers are made. They are attached in the following way. Two folded sheets of white paper, similar in tone to that on which the book is printed, and a folded sheet of coloured paper, are required. The coloured sheet is pasted on to one of the white sheets as shown in **18** A. When dry, the white leaf marked "waste sheet" is folded over one coloured leaf, and the other white leaf folded back over the remaining coloured one, as in **18** B. The other folded sheet of white is then inserted where marked, and the end paper is sewn on to the book through this. The waste sheet is for the purpose of protecting the end papers during the binding, and is torn out when the endpapers are finally pasted down.

If a leather joint is used, the endpapers would be made up in the following manner. A white sheet is folded as in **18** C, and the coloured fly-leaf, leather joint, and waste sheet, are pasted on to this as in **18** D. A folded sheet of white is inserted, thus completing the endpaper, which is sewn on in the two places marked in **18** D. The endpapers are placed in their positions



18. ENDPAPERS

at either end of the book and then tins covered with paper are placed between every three or four sections and the book placed in the standing press for about twelve hours.

The positions of the cords or tapes on which the book is to be sewn are then *marked up* on the back. The book is knocked up square at the head and held in the lying press between a pair of pressing boards and the back is divided into six divisions. Five of these are made equal and the tail one slightly longer. On the five points thick pencil lines are drawn across the back. If tapes are used for sewing four are usually sufficient and two lines are marked for each tape. A slight saw cut is then made at the head and tail about half an inch away from the edge, and the book is ready for sewing.

Sewing the Sections Together. The book is sewn on five cords; the number sometimes varies with the size of the book, but five is the most usual; the thickness of the cords also varies according to the size of the volume. Five loops are made of ordinary string over the crossbar of the press; these are called *lay cords*, and are used repeatedly. To these loops are attached the cords on which the book is to be sewn, which are then passed down through the slit in the bed of the frame and fastened by means of keys [**14**].

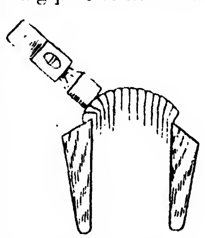
The book is laid down on the bed of the press with the back against the cords, which are moved into position so that they correspond with the lines marked on the back of the book. The cords are then tightened by screwing up the crossbar.

The endpaper is first sewn, the needle with thread or silk being passed into the section at the head and round each cord in turn and brought out at the tail [**1 C**]. The first sheet is then sewn from tail to head in the same way, and the silk is tied to the loose end hanging from the endpaper. Another section is sewn on and the needle is inserted between the previous sections and catches up the silk that joins them: this is called a *kettle stitch*. The remaining sections and endpaper are sewn on in the same way, the silk being fastened off at the last kettle stitch with a double knot. The cords are loosened, by lowering the crossbar, and are cut off about 3 in. from the book; the loose ends are then frayed out with a bodkin.

If the book is to be sewn on tapes, the tapes are set up on the sewing frame as with cords. The sewing is done as described above, with the exception that, owing to the width of the tape, the thread passes out and back into the section again at different points instead of passing out and in at the same point as with cord sewing [**1 D**].

Gluing Up, Rounding and Backing. The book is placed in the press with a piece of millboard on each side, and the back is glued. When the glue has set the book is laid down on its side and half of the back is rounded over with a hammer, it is then turned over and the other half rounded.

Backing is sharply emphasising part of the swelling caused by the thread used in sewing, by compressing the book near the back and beating the back of the sections, one over the other, making a sharp ridge against which the cover will lie. Placed between a pair of backing boards with the back projecting slightly above the boards, the book is lowered into the lying press. With a hammer the



19. BACKING

sections are then beaten one over the other, starting from the centre and going over equally on either side. The two outside sections are well beaten over the backing boards, for this makes a sharp groove for the boards to fit [**19**].

Preparing and Attaching the Boards. The best material for the boards is millboard owing to its toughness and thin substance. Two pieces are cut with the millboard shears about a quarter of an inch larger all round than the book. The edges that are to go to the back of the book are then cut smooth in the lying press with the plough. The boards are screwed up in the press with the amount that has to be cut off projecting above the bed of the press. The knife in the plough travels backwards and forwards level with the bed of the press, and whatever projects is cut off.

The boards are then each lined on one side with a piece of white paper pasted on. Two other pieces of paper, double the size, are pasted and the boards covered with these on both sides. The extra lining of paper on one side will cause the board to warp that way, and this side will be placed against the book to counteract the pull of the leather which will ultimately be pasted on the other side of the cover.

The boards when dry are cut to the size required, with the press and plough, and are then attached to the book. One board is laid in position on the book and a line is drawn on the board from tail to head about half an inch from the back. Lines are then drawn from the cords to this line. On these cross lines small V-shaped pieces are cut out of the boards to allow the cords to sink in level when laced, and holes are punched with a bodkin at the points where the lines meet. The boards are then turned over and holes are punched about half an inch from the previous ones. To attach the boards the slips are pasted and passed through the holes first made and then back through the other holes. They are then drawn tight, tapped with the hammer to fix them, and the ends cut off level with the boards.

If the book is sewn on tapes the selvedge of the tape is cut off and the tape can then be frayed out and interlaced, like a cord. When both boards are attached the book is put in the lying press, with the back projecting slightly; it is then pasted to moisten the glue on the surface, which is scraped off with a folder. The cords are nipped up and straightened with the band-nippers, tins are put on both sides of the boards, well up to the groove, and the book is left in the standing press, tightly screwed up, for about twelve hours. The knocking-down iron is then screwed up in the press, and the slips hammered down until they are impressed level with the board.

To cut the top edge the book is screwed up in the lying press with the back to the worker, the front board being lowered just the distance required for the "square," and the edge is cut with the plough [**15**]. The tail is next cut in the same manner.

For cutting the fore-edge the edge has first to be made flat by inserting trindles [**5**] between the book and the boards across the back. A cutting board is placed on each side and held in place while the trindles are removed. The book is then lowered, with the boards hanging down, into the press and the edge cut with the plough.

Gilding Edges. The back is knocked flat, and a cutting board placed on either side of the leaves, level with the fore-edge, and the book is placed in the press. The edge is scraped and finely sandpapered. A paste, made of powdered red chalk and water, is applied to the edge with a sponge and polished with a hard brush. The edge is then painted with a preparation of the white of an egg,

beaten up and diluted with water, called *glaire*. The gold leaf is cut into strips the width of the edge and applied to the edge with a soft flat brush. The book is left to dry and the edge finally burnished with a flat bloodstone burnisher. The other edges are gilt in a similar manner. The edges can also be stained. Water stains answer the purpose, and are applied to the edge with a soft brush, the edges being afterwards burnished with an agate burnisher.

Headbanding. Headbanding is the stitching on the head and tail of a strip of vellum, gut, or cord, to make a similar projection from the back as is made by the boards projecting beyond the edges of the book. As a book is usually pulled out of the bookshelf by the headband, it is important that this should be firmly attached to the book, and one that is made on the book is far preferable to one bought ready-made and stuck on.

The boards are lowered level with the edge of the book held in the lying press or plough, and a needle, threaded with silk, is passed into the edge and out at the back below the kettle stitch. Half the silk is drawn through, and then the needle is again inserted and drawn out. The silk now has made a loop into which a strip of vellum, slightly narrower than the "squares," and a little longer than the width of the book, is placed. The silk is drawn tight and a pin inserted in the edge at the left-hand side, behind the vellum, to keep it in position. The needle end of the silk is brought over the vellum and the other end crosses it and goes behind. This end is then brought over and is crossed by the needle end. The headbanding is continued in the same manner, being fastened down to the book about every quarter-inch. To do this when the needle end is at the back, it is brought over the vellum and inserted into the book and out at the back, and the headband is then proceeded with as above. To finish it off, the needle end is inserted into the book twice, and the other end then pressed behind, and both are cut off, leaving short ends, which are frayed out and pasted down to the back. The ends of the vellum are then cut off.

This kind of headband would be too expensive for the cheaper bindings. In their place the leather at head and tail can be turned over a piece of string when covering.

Leather for Bindings. Various kinds of skins are used in bookbinding, chief among them being those of sheep, oxen, calves, goats, and pigs. *Sheep skins* are cheap, and, when not subjected to hard wear, last well. Those classes of skins tanned in India, and known as "Persians," both sheep and goat, have little durability. *Calf skin*, although capable of receiving a beautiful finish, does not wear well. *Ox hide* has to be reduced so much in substance to be fit for binding books that the greater part of its strength is lost. *Goat skins* furnish "Morocco" leather of several kinds. Of these, the finest is that of the Cape of Good Hope, known when finished as "Levant Cape Goat"; it has a bold, natural grain, and is perhaps the most beautiful leather for bookbinding. *Pig skin* is very durable, and is best adapted for large work. A leather which has great beauty and strength is made from the Greenland seal, but much depends on its preparation.

In cutting out the leather a piece of paper is first cut to the size of the leather required, and the leather is then cut to the size of the paper. The leather requires thinning (termed *paring*) in several places: (1) where it is turned in, to enable it to turn neatly over the edges of the boards; (2) where it will go over the back, to allow the cords to be sharply emphasised; and (3) where it will go in the joints, to enable the boards to open freely.

As there is a double thickness of leather where it is turned in on the back, it is pared especially thin there. The cover is marked in pencil to show where the paring is required, and is laid on a smooth stone and pared with a knife to the necessary degree of thinness.

Covering the Book. Before covering, the edges of the book are "capped up" to prevent damage from the paste used in the process. Two pieces of thin celluloid are placed on either side of the book itself, which is then completely covered up with paper. Small pieces are next cut from the back corners of the boards to allow for the leather being turned in there.

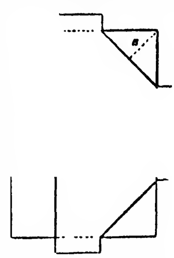
The leather is well pasted, the book, closed, is laid down in the place marked for it, and the remainder of the cover is drawn over the back and the other side. The book is then stood on its fore-edge, and the leather pressed from the back towards the fore-edge. The leather is slightly damped on the back with water, and the bands are nipped up with band-nippers. The cover is next smoothed on the sides and the leather is turned in over the fore-edges of the boards and smoothed down with the folder; finally, the cover is turned in at the head and tail.

At the corners the leather meets at an angle of 45°, and the surplus is cut off with scissors just above the board, and one edge of the leather is lapped over the other. A piece of thread is now tied tightly along the joints passing across the head and tail, and pressing the leather in where the back corners of the board have been cut away.

The bands are again nipped up, and the leather between the bands well rubbed down with a band stick. Finally, the cover is sponged over with water to remove any paste that may have got on the book, and, with a piece of paper on each side, the book is placed between a pair of pressing boards and left for at least twelve hours. When the leather is set, though not actually dry, it is trimmed on the inside of each board.

Half Binding. If the book is to be half bound, the processes are just the same up to covering, and then only the back, about one-third of the sides, and the corners are covered with leather.

The proportion between the back, corners, and the remainder of the sides can be seen in 20. The dotted lines A and B should be of the same length. When dry, the leather is trimmed straight at the back and corners, and the material for the side is cut out. This is usually either paper, cloth, or buckram. It is cut to the shape shown in 20, and then glued on, the edges being turned in over the edge of the boards. With the cheaper bindings, the corners are sometimes omitted, and it is then called a quarter binding.



20. HALF BINDING

Pasting Down Endpapers. The waste sheet is torn out and any pieces that remain in the joint are removed with a knife. The inside edge of the board is then sandpapered or scraped with a knife to remove any glue or paste that may have adhered. The width of the margin of the leather is then taken with a pair of dividers, the pasting-down paper drawn over the board, and the measurement marked off all round on the paper. A tin is then placed on the book and the paper laid down on this, cut round with a knife, and pasted down on the

board. It is rubbed down through a piece of waste paper, particular attention being paid to the joint.

Finishing and Decorating. *Tooling* is the usual method adopted for the decoration of leather bindings. It is divided into two classes —"gold tooling" and "blind tooling." Finishing tools are made in either brass or steel, and have surfaces cut in the forms of lines, dots, or engraved with pattern [12]. For long lines a fillet is used. This is a wheel with an edge cut to the thickness of the line required [7].

If an elaborate pattern is required, a thin, tough paper is used for a working pattern, slightly pasted at the corners, and placed in position on the cover. Then all the tools of which the pattern is made up are heated and stamped in through the paper. A pad of wet cotton-wool is kept close by, and the tools are used when they just cease to hiss on the wool. They are held in the right hand, and when striking, the tool is guided into its place with the thumbnail of the left hand.

If the pattern is to be in blind tooling, the leather is damped and the tools again stamped in. The heated tool coming in contact with the damp leather makes a rich, dark impression.

If the pattern is to be in gold, the leather is washed with vinegar, and when dry, the impressions are painted with glaire, very slightly diluted with vinegar. When the glaire is dry, the gold leaf is cut into pieces of a convenient size to lay on, the leather is slightly greased with a piece of cotton-wool and vaseline, and the gold is picked up with another piece of wool and laid on the pattern and firmly pressed down. The pattern should be clearly seen through the gold, and the tools are now stamped in again. When all the pattern has been impressed, the surplus gold is rubbed off, leaving just the gilded impressions of the tools.

The book is then placed in the press, with tins on the inside of the boards, and nickel plates on the outside, and slight pressure is applied; this causes the boards to close properly, and completes the binding of the book.

PUBLISHING

The publishing of books is admittedly one of the most attractive trades to which a young man can turn his attention. Even old men are tempted to set up as publishers by the general notion that it is about the most lucrative business in which one may engage. This latter is, now, a mistaken idea, whatever reason there may have been for it in the past, and certainly a review of the fortunes made in publishing would go far to support the proposition that it is a paying business. The shrewd Scotsman who founded the house of Murray in the year 1768 had been in the Navy, and was induced to turn publisher because he observed "many blockheads" were then "making fortunes" in that very pleasant occupation. Modern competition has long since made it impossible for any but the most resourceful of men to succeed in the world of publishing, and only a few businesses, which exist very largely on their old reputations, can be conducted on the easy methods of half a century ago. There is undoubtedly no room for blockheads today. In point of fact, after newspaper publishing, there are few businesses in which one can more speedily get rid of a considerable fortune than in book-publishing. To secure any substantial success, a large capital investment is absolutely essential, and this none the less when it is associated with brains and intimate knowledge of the trade.

Value of an "All-round" Experience. There is, of course, a "royal road" to publishing as to most other trades, although our moralisers may deny this. But few of us are in the position to follow the royal road, and have, instead, to take the toilsome way which, in the end, is likely to be more solidly successful, and may, on the whole, by honest endeavour, be made as pleasant. If we cannot, by paying a substantial fee to some publisher for the privilege of receiving an insight into all his departments—as so many Germans do nowadays in London—we must needs begin at the bottom of the ladder. Naturally, the earlier one enters the trade the better. We know one of the most successful of the younger publishers who practically went through every department, beginning as a shop-lad in a large wholesale firm of distributors, with his mind constantly set on becoming a book-publisher. As he had realised his ambition before he was thirty, it will be seen that, given sufficient pertinacity and resource, even the humble shop-lad may look forward to seeing his name as the imprint of thousands of books some day.

In all the leading provincial cities there are large firms of wholesale dealers in any one of which invaluable experience may be obtained, provided always that one enters their service early enough—say, from fourteen to sixteen years of age. By passing through the various departments in a large wholesale house, the Town Department, the Country, the Postal, the Stock, and other departments, a thorough knowledge of a most important side of the publishing business may be obtained. One might come somewhat later to the wholesale trade, if one had previously secured some experience in a retail booksellers' [see BOOKSELLING, page 1096], and, indeed, this would be a wise course to pursue.

The Producing of Books. But after everything has been learned, both in the wholesale and retail, there would still remain the most important knowledge of all to be acquired—namely, the manufacture of books. The bookseller and the wholesaler only come in after the publisher has done his work. It is by no means usual that one man should have experience in every detail of the trade from the producing to the selling of books, and in every publishing house in the country there are many employees who have served for years, and are content to serve, in some particular department without acquiring a general knowledge of the trade. Indeed, such men necessarily form a majority of those engaged in the business, but it is not from such that successful publishers are made, and nothing is more fatal to promotion than remaining too long in any one department.

Before turning to the consideration of the actual business of a publisher, we should point out that most valuable experience can be obtained by engaging as traveller with a wholesale house Of course, every publishing firm of any standing employs a number of travellers from whose ranks many of our most successful publishers have risen. We have preferred to mention the great wholesale houses first, as these are not confined to London, whereas, excepting a few notable firms in Edinburgh and Glasgow, there are practically no important publishing houses outside of London. The provincial youth has thus to turn his attention—in the first place, at least—to the wholesale distributors and the large booksellers, who very often do a small amount of original publishing.

London is essentially the Mecca of publishing, and the young man who is ambitious of becoming a

publisher will do well if he can secure an engagement with a London publisher when he is about twenty years of age.
